From the previous research results, there are many methods for measuring soil water content (SWC), but most of the SWC measurement methods are destructive methods for soil structure. Moreover, it takes a lot of time and manpower. In recent years, the method of estimating SWC from digital images of unmanned aerial vehicle (UAV) is a novel and rapid for measuring SWC non-destructive. While estimating SWC in the field using digital images, the effects are produced sunlight and climates and setting of the camera white balance. While estimating the SWC by digital images, these influences will let these methods have a bias between the hue value of digital images and the color of actual soil. So, the purpose of this study is to add a color calibration method while the process of estimating to remove the influences of sunlight, climates and white balance of camera, to improve the accuracy of estimating SWC by digital images.

At first, this study collected the surface soil samples from 0 to 5 cm below the ground surface at the study site which is the sampling range of in-situ planning. A standard color card (ColorChecker) is placed at the study site as a basis for image color calibration. After that, this study used UAV to take a photo-shooting at 30 meters above the ground, and obtain the digital images of the study site. After the sampling is completed, the surface soil sample is obtained its gravimetric water content by thermogravimetry in the laboratory. Next, the digital images taken by the UAV is used to cut the study area and image color calibration using the image processing software.

Then, using Matlab 2018b software to calculates the hue value of RGB color space (Red (R), Green (G), and Blue (B)) of the digital images before and after the color calibration separately, and transforms them into other six color spaces (normalized RGB, HIS, I1I2I3, Lab, YCbCr, and Lch). At last, this study used multiple linear regression to establish the SWC estimation models separately, and then compare the influences which before and after color calibration.

The results of this study show the influences of sunlight, climates and white balance of camera make a significant bias when estimating SWC using the digital images before color calibration. However, this study which added color calibration improves the accuracy in the estimation of SWC by digital images. Finally, the achievements of this study can apply in reducing the number of water resources of the agriculture irrigation widely.

# Characterizing Geotechnical Properties of Drinking Water Sludge Blended with Graded Crushed Clay Brick for Road Subgrade: Effects of Gradation and Mixing Proportion of Crushed Clay Brick on CBR and Water Permeability

*Muhammad Rashid Iqbal[1], Akihiro Matsuno[1], Ken Kawamoto[1]

1. Graduate School of Science and Engineering, Saitama University

Effective uses of construction and demolition waste, sludge, and industrial by-products for engineering purposes are highly demanded in developing countries. Currently, these materials are used for other construction works such as ground levelling and backfilling without any quality control of materials and/or directly dumped at the landfill site. In this research, an attempt was made to use drinking water sludge (DWS) by blending with crushed clay bricks (CCB) to propose their utilization for constructing road subgrade. DWS with less than 2-mm was blended with CCB with three different particles range; (a) finer fraction having particle size 2-10mm, (b) Coarser fraction 10-30mm, and (c) graded fraction 2-30mm. The mixing proportion has been controlled from 0 to 100% on the dry mass basis. Geotechnical properties such as California bearing ratio (CBR) and water permeability were investigated in the laboratory. Experimental results showed that addition of a finer fraction of CCB from 0 to 100% with DWS improved CBR values from 45% to 88% which was almost double than the DWS itself and captured a well linear relationship. Up to 60% addition of a coarser and graded fraction of CCB increased CBR value from 45% to 110% which was 2.44 times higher than the DWS itself. However, at 80% addition of CCB, graded fraction enhanced the CBR value more as compared to coarser fraction which was due to the well packing and reduction of the voids. On the other hand, at 100% blend of CCB coarser fraction showed quite higher values which could be due to the breakage of the bigger particles and filling the voids effectively. The water permeabilities of all these blended samples showed a very well relationship with Hazen model as compared to Kozeny-Carman model. It can be concluded that graded and coarser fraction 60% blend had an equal or superiority effect than the 100% of the finer fraction blends. All the tested sample fulfilled the improved subgrade requirement to utilize for the road subgrade.

# Investigation and Evaluation of the Multiple-liquefaction Site at the Southern Taiwan

*Chih-Sheng KU[1]

1. I-Shou University

Southern Taiwan experienced several large earthquakes on 5 December 1946 ($M_w$=6.3), 4 March 2010 ($M_w$=6.4) and 6 February 2016 ($M_w$=6.6), respectively. Liquefaction phenomenon evidences was observed at Hsinhwa district, Tainan city, Taiwan during the 1964, 2010, and 2016 earthquake. Re-liquefaction at this site was confirmed by GPS surveying at the sand boiling locations after last two earthquakes. Seismic cone penetration test (SCPT) and boring were conducted at this site after 2010, and 2016 earthquake. The recurrence of liquefaction, availability of pre-earthquake logging, and high fine content in the liquefied soil stratum make this case valuable for detail study. This paper presents the results of the investigation and evaluates the liquefaction potential of the reliquefied site by different period exploration data. The comparison of the SCPT strength profile before and after the last earthquakes seems to indicate that no significant variation has occurred in this multiple liquefied site, making the area vulnerable to liquefaction induced sand boiling in future large-scale earthquakes. Liquefaction analyses with in situ test data show that this site is still highly susceptible to liquefaction.

Discussion

# Investigating the Reproducibility of Hydraulic Tomography Estimates with Time-Variable Boundary Conditions

*Jian-Dao Li[1], Jyun-Lin Chen[1], Hong-Ru Lin[1], Shao-Yang Huang [1], Tian-Chyi Jim Yeh[2], Jet-Chau Wen[1]

1. National Yunlin University of Science and Technology, 2. The University of Arizona

In recent years, the hydraulic tomography (HT) is a popular method for the delineation of the spatial distributions of hydraulic properties in the groundwater aquifer. Previous researches investigated the spatial distributions of hydraulic properties by the HT survey using the constant head boundary condition. However, the constant head is not the real condition in the boundary condition at the field. The study purpose is the case studies of two years at the same site using the time-variable boundary conditions to delineate the reproducibility of hydraulic properties.

The study area is located in National Yunlin University of Science and Technology (NYSUT) campus in Taiwan. The sequential pumping test is carried in 2010 and 2012 were used for the inverse modeling effort to estimate the hydraulic properties. The boundary condition is applied to the HT method using the sensitivity equation method (SEM) to calibrate the time-variable heads. Then, the reproducibility of estimates and prediction were analyzed in two different years. The results show that the more heterogeneity of hydraulic properties. The HT method can be improved using the time-variable boundary conditions.

# Applying river pollution index and QUAL2K model for water quality assessment and management in Ke-Ya river, Taiwan

*Hong-Syuan Li[1], Yu-Chih Lin[1]

1. Department of Environmental Engineering & Health, Yuanpei University of Medical Technology

Waste water from hundreds of factories in Hsiang-Shan industrial park, Hsinchu Science Park, animal husbandry, metal surface electroplating industries, and domestic sewage are discharged into Keiya River HshinChu, Taiwan. In this study, monitoring data of the Keya River was collected, the river pollution index (RPI) and QUAL2K models were utilized for analysis and assessment of water quality. The divide of pollution collection area and evaluation of the assimilative capacity were also discussed.
The results indicated that the main pollutant in the water quality of Keiya River was ammonia nitrogen, which was contained in wastewater discharged from residential areas and Hsinchu Science Park etc., the second was biochemical oxygen demand (BOD). In order to improve the problem of ammonia nitrogen in the rivers, the Taiwan Environmental Protection Agency has tightened the emission limits of ammonia and nitrogen concentrations in wastewater discharges from 2012. The ammonia nitrogen wastewater treatment modules were also installed in the Hsinchu Science Park to reduce ammonia nitrogen emissions into rivers. In addition, the Hsinchu City Environmental Protection Bureau has strengthened the control of the copper standard for discharge water upto 1.5mg/L from 2017, so that the copper concentration in the current river water was maintained at <0.001-0.03mg/L, which was compliance with the environmental standards related to human health protection.

# Environmental assessment at CDW disposal sites in Vietnam: Case study in Thanh Tri landfill, Hanoi

*Thanh Ha Ngo[1], Akihiro Matsuno[1], Ken Kawamoto[1]

1. Graduate School of Science and Engineering, Saitama University

In the last recent decade, Vietnam has become one of most developing countries within South East Asia. Due to a rapid increasing of economic and industrial, the amount of construction and demolition waste (CDW) in Vietnam also increasing fast and becoming one of the biggest issue for the surrounding environment. According to MONRE, in 2015, Vietnam produced 1.9 million tons of CDW, while the recycling rate was only accounted for 1 −2%. In particularly, 30% of total solid waste generated in Hanoi was reported as CDW during the period of 2010 −2014. Currently, most of generated CDW from construction and demolition sites is reused on-/off sites without any quality control of materials and dumped at disposal sites along with collected waste from town cleaning (e.g., sludge and soil). At CDW disposal site, there is a potential risk of accepting hazardous and scheduled waste together with non-hazardous waste due to lack of management and control of waste acceptance. Therefore, in order to have environmental risk assessment of CDW disposal sites in Vietnam, it is important to identify the current environmental status of CDW dumping sites according to an appropriate monitoring program. In this study, we assessed qualities of water, gas, and fine residues (soil and fines of dumped CDW) inside the disposal site and its surrounding at Thanh Tri Landfill CDW disposal site in Hanoi as a case study. The final goal of study is to develop a standard monitoring/operating procedure for environmental assessment of CDW disposal sites in Vietnam. The field monitoring of surface gas emission and the sampling of internal gas, water, and fine residues, and investigation of dumped scheduled waste at the site were carried out on December 2018. The internal gas samples were collected at six different points from 0.5 - 1m depth and a flux chamber method applied to determine surface gas emission. The groundwater sample was taken from a well inside the disposal site. Results showed very low concentration of methane (CH4) and Carbon Dioxide (CO2). In the meantime, groundwater quality showed that the amount of Ferrous and Arsenic became higher than Vietnam technical regulation on drinking water (QCVN 01:2009/BYT) and Vietnam technical regulation on domestic water (QCVN 02:2009/BYT).

# Modeling Study on the Impacts of Groundwater Pumping to Regional Hydroclimatology in 37 World Major Aquifers

*Pat J.-F. Yeh[1]

1. Monash University Malaysia

Groundwater pumping (GWP) introduces dormant fossil waters into the active hydrologic cycle and alters the mand and atmosphere water budgets, but its effects are poorly understood due to the lack of large-scale GWP information and hydrometeorological data to estimate these changes. In this study, two sets of global-scale model simulations by a fully-coupled climate-hydrologic model, one with GWP and the other one without, are conducted for the 1900-1999 period. The effects of GWP in affecting the land and atmospheric water budgets are investigated over the selected 37 major aquifers worldwide by analyzing the output data from both sets of simulations. The entire set of the internally-consistent water budget components, includ precipitation (P), evaporation (E), runoff (R), atmospheric vapor convergence (C), and changes in land, ocean and atmosphere water storages, are analyzed, and their differences between tow simulations are considered the effects due to GWP. The contribution of GWP to global sea level rise (GSLR) as a result of the changes in the land and atmospheric water budgets is also estimated via (1) the direct R contribution from land to ocean and (2) the indirect C contribution via atmospheric interactions.

# CHRATERIZING BURIED WASTE COMPOSITION AT CONSTRUCTION AND DEMOLITION WASTE (CDW) DISPOSAL SITE IN VIETNAM: A CASE STUDY IN THANH TRI LANDFILL IN HANOI

*Tselmeg Aldarjav[1], Akira Kato[1], Akihiro Matsuno[1], Ken Kawamoto[1,2]

1. Graduate School of Science and Engineering, Saitama University, Japan , 2. International Institute for Resilient Society, Saitama University, Japan

In recent years building and construction work has been growing rapidly in Vietnam, as construction sector expanded simultaneously the waste generated have increased as well. Due to increasing cost and handling availability of CDW disposal the landfilling approach is the most common and cost-efficient way of disposal in developing countries, including Vietnam. On the other hand, due to lack of technical and management abilities, it is very difficult to collect the data on amount and composition of CDW dumped to the landfilling site. The data on amount and composition of dumped CDW is necessary to evaluate the remaining lifetime of present CDW landfills and to examine the possible recycling strategy and method of CDW fills in future. Besides, the waste composition data contributes to classify the type of CDW landfills. The data on the ratio of each amount is currently not available. In this study, a field survey including pit sampling of buried waste, size grading, weighting of graded fractions, and categorization of waste has been done at Thanh Tri landfill site located on the south-eastern side of Hanoi, Vietnam. The final goals of study are 1) to develop a technical manual to investigate buried CDW at disposal sites, and 2) to characterize waste composition, physical and chemical characteristics of dumped waste in Vietnam. The overall procedure of the manual includes 5 parts: 1. Preliminary survey work, 2. Design of CDW composition survey, 3. Set-up of CDW composition survey, 4. Excursion of CDW composition survey, and 5. data analysis. The proposed manual enables not only to measure the waste composition but also to characterize particle size distribution of buried waste.

# The role of anthropogenic activities in spring discharge cessation: Jinci Springs China

Yaru Guo[1], *Yonghong Hao[1], Chun Zhao[1], Huan Lian[1]

1. Tianjin Normal University

Most of the karst spring discharge in northern China has been declining since 1950s. Jinci Springs, as one of the typical karst springs in northern China, has dried up in May 1994. In this study, we proposed grey relational analysis with time lag to calculate the delay between spring discharge and precipitation, and set up GM (1, N) model to simulate the spring discharge. The methods were applied to investigate the drying-up of Jinci Springs. Based on its characteristics of the Jinci Springs discharge, we divided the spring discharge into two stages: in the first stage (1954-1960), the spring discharge only affected by climate variations, and in the second stage (1961-1994), the spring discharge impacted by both climate variations and anthropogenic activities. In the first stage, the Jinci Springs discharge had large grey relational degrees with precipitation ahead of one year and three years. Then the GM (1, 3) model with time lag of one year and three years was set up to simulate the spring discharge of the second stage under sole effect of climate variations. Subtracted the observed spring discharge from the simulated spring discharge, we obtained the contribution of human activities to Jinci Springs cessation. Results showed that the contribution of human activities to the cessation of Jinci Springs was 1.456$m^3$/s, accounting for 70%. The contribution of climate variations was 0.624$m^3$/s, accounting for 30%. The impact of human activities on the spring cessation surpassed climate variations and became the major factor. The contribution of the groundwater exploitation increment was 0.97$m^3$/s, the dewatering from coal mining increment was 0.60$m^3$/s, and the leakage reduction of Fenhe River was 0.19$m^3$/s. The total amount was 1.76$m^3$/s. After the Jinci Springs dried up, human further overexploited groundwater about 0.304$m^3$/s.

# Groundwater response to tidal fluctuations in a leaky confined coastal aquifer with finite length

*Zhi-Xue Zhao[1], Tongke Wang[1], Jun Li[1]

1. Tianjin Normal University, Tianjin, China

We derive an analytical solution to calculate the groundwater response to tidal fluctuations in a horizontally-finite, leaky, coastal aquifer system. Our solution represents a generalized formulation that encompasses previous results as special cases. Based on the solution, we investigate the joint effects of the leakage and inland aquifer length on the behavior of the groundwater level fluctuation. We show that neglecting the finite-length effect may lead to significant errors in parameter estimations. Moreover, the range where the finite-length effect dominates is quantitatively determined by a characteristic dimensionless parameter. Finally, we demonstrate the usage of the proposed solution in calculating hydraulic properties through an application to a field experiment conducted at the Seine River estuary, France.

Keywords: Coastal aquifer, Analytical solution, Leakage, Tidal effect

# Relationship between "source and sink"landscape patterns and river nutrient discharge in a peri-urban watershed

*Chongwei Li[1]

1. Tianjin Normal University

Better understanding of landscape pattern affects water quality in the peri-urban watershed are essential for sustainable development and utilization of water resources.A peri-urban watershed refers to a watershed located in the transition or interaction zone, landscape features aresubject to rapid modifications induced by human activities.Humans alter land uses and the landscape patterns both temporally and spatially.Land uses in a watershed can be functionally grouped into “source” or “sink” landscapes based on their contribution to the formation of nonpoint-source pollution in the watershed.As a result, the surface runoff and nutrient loading from a watershed are affected not only by the proportion of “source” and “sink” landscapes but also by their spatial arrangement and distribution.The assessment of non-point source pollution in peri-urban and urban watersheds is challenging but crucial for bothwater resource managers and urban planners.
The Yuqiao Watershed located in northern Tianjin City and southern part of Hebei Province, China ,which was chosen as an example of a peri-urban watershed. Based on the "source-sink" landscape characteristic index of the river basin and combined with the water quality data of 33 sub-basins in the river basin of the bridge reservoir in recent years, The relationship between landscape pattern and water quality was analyzed by spatial analysis, correlation analysis and redundancy analysis (RDA) using landscape use and landscape index as explanatory variables and nitrogen and phosphorus load as dependent variables.Results show that Under the influence of urbanization, From 1984 to 2013, the percentage of "sink" landscape (forest and grassland) decreased from 46.5% to 31.9%, entirely the result of the sharp reduction in forested area from 37.5% to 18.9%. In contrast, the percentage of "source" landscape (urban, orchard, and cultivated land) increased from 49.6% to 62.5%. Among them, the urban land increased from 11.6% to 18.1%. The global Moran's I value of landscape spatial load comparison index (LWLI) is 0.637, $P < 0.01$, and tends to cluster in space.LWLI was significantly correlated with the spatial distribution of nitrogen and phosphorus in the basin. The complex correlation coefficient $R^2$ of TN and LWLI in peacetime was 0.811, and that of LWLI and TP in wet season was 0.741.The axial angles among patch density (PD) , Shannon Diversity index (SHID) and TN,TP were smaller,indicating that PD and SHID had more influence on the nitrogen and phosphorus in the catchment.Compared with other landscape characteristics indexes, LWLI has the largest impact on nitrogen and phosphorus in rivers, and urban residential land is an important contributor to water pollution in watershed. The results could potentially provide a thoretical support for the optimization of the landscape paterrn in watershed.

# Assessing the Urban Storm-Flood Disaster of Zhengzhou city Based on Fuzzy Methods

*Caihong Hu[1], Xian Du[1], Ying Zhang[1], SHAN E HYDER ALIAS TAHIR[1], Shengqi Jian[1]

1. School of water conservancy and environment, Zhengzhou University, Zhengzhou City, Henan Province, P.R. China, 450001

The frequency of urban waterlogging floods increased year by year with the accelerating process of urbanization in China. It is very important for us to study the urban waterlogging warning and emergency management. Four flood evaluation indexes, which are the 3h cumulative rainfall, submergence and waterlogging disaster degree and comprehensive management efficiency, are selected as the accessing indexes based on the DPSIR (Driving forces, Pressure, State, Impact and Responses model) model. Fuzzy comprehensive evaluation method is applied to evaluate the urban disaster degree based on the index weight determined by the analytic hierarchy process (AHP). Zhengzhou city, which located in the middle of China, is taken as an example for our study. Based on the SWMM model, this paper divides the urban area of Zhengzhou into 2200 unit areas. Four grades were divided for disaster degrees. The results show that Zhengzhou city will encounter different grades of waterlogging disasters with different precipitation. 469, 708, 1006 and 1057 units area of the city will encounter the second grades for warning when the rain of half a year, one year, two years and five years return period happen. The results show that the method is scientific and reasonable and can be applied to practical work.

Keywords: waterlogging warning grade, DPSIR model, evaluation index, fuzzy comprehensive evaluation method

# Application of RAMMS Software to Predict the submerged area of Debris Flow: A Case Study of Feng-Chiou torrent in Taiwan

*Hsin-Ying Hsieh[1], Chun-Yi Wu[1]

1. Department of Soil and Water Conservation, National Chung Hsing University

Predicting the submerged area of debris flow hazard events can effectively reduce the extent of catastrophe. In this study, we used three-dimensional debris flow runout model, RAMMS (Rapid mass movements simulation), to simulate the debris flow of Feng-Chiou torrent in Feng-Chiou Village, Xinyi Township, Nantou County, Taiwan. The RAMMS is based on the Voellmy-Salm rheology theory and describes the flow development of debris flow in a depth-averaged equation. The RAMMS can be used to simulate the debris flow phenomenon caused by landslide in the study area. We use the well-documented debris-flow event to calibrate the model parameters by back analysis, so that the simulation results are more realistic. Then we used parameters of the total volume (M), flow height (H), dry-Coulomb type friction (coefficient $\mu$) and viscous-turbulent friction (coefficient $\xi$) of the debris flow event for sensitivity analysis and discussed the effect of each parameter on the simulation results. Further, we used the rational formula to estimate the discharges corresponding to the rainfall intensities of different recurrence intervals. We used simply hydrograph method as the initial condition to predict the possible submerged area of debris flow events caused by different recurrence intervals.

Keywords: RAMMS, debris flow, Feng-Chiou torrent, landslide

# Applications of the Cholesteric Liquid Crystal (CLC) Sensor to Rapidly Measure the Volatile Organic Compounds in the Atmosphere Environment

Ruey-Fang YU[1], *GUAN-BO CHAO[1], Jian-cheng XU[1], KUANG-PENG HSIEH[1]

1. Department of Safety, Health and Environmental Engineering, National United University, Taiwan, R. O. C.

The Volatile Organic Compounds (VOCs) are one of the most important air pollutants emitted from industries. Some of the emitted Volatile Organic Compounds are carcinogenic which are harmful the health of both the human and environments. Typically, the concentrations of the VOCs in the atmosphere environment were measured by a Gas Chromatography (GC). However, these methods are expensive, complex, and difficult to be used for on-line application. According to the literatures, there is a lack of simple and economy detection methods for rapidly measure the VOCs in the atmosphere environment. The purpose of this study was to develop a Cholesterol Liquid Crystal (GLC) sensor for rapidly measure the concentrations of volatile organic compounds (VOCs) in the atmosphere environment.

According to the experimental results of this study, the physical directions of the GLC molecules will be changed when the prepared CLC sensor contact with the VOCs, and resulting the color on the surface of the CLC sensor changed from a Green or Red color to colorless, therefore, the target VOCs can be identified. By using a UV-VIS spectrophotometer or digital image analysis, the color can be identified. Moreover, it was also found that the color change from Green to colorless is rapid when contact with higher concentrations of VOCs. The durations of color change from Green to colorless was also found presented a liner relationship with the concentrations of VOCs, therefore, the concentrations of VOCs in the atmosphere environment can be identified. The CLC sensor was arranged to contact the VOCs by the controlled of different temperatures of 22±0.3$^0$C, 24± 0.3$^0$C, 27 ±0.3$^0$C and 30± 0.3$^0$C, respectively. The concentrations of VOCs can be measured from 19,955 ppm to 36,585 ppm with a linear relationship of $R^2$ =0.97 at 22±0.3$^0$C, the concentrations of VOCs from 9,978 ppm to 26,607 ppm ($R^2$=0.97) can be measured the GLC sensor at 24±0.3$^0$C, the concentrations of VOCs from 26,607 ppm to 43,237 ppm ($R^2$ =0.90) by the GLC sensor at 27±0.3$^0$C, as well as the concentrations of VOCs from 8,315 ppm to 19,955 ppm ($R^2$=0.90) by the GLC sensor at 30±0.3$^0$C. As a result, the VOCs concentrations can be easy and rapid identified by the prepared CLC sensor using the analysis data from both UV-VIS and image analysis.

# Solar Ag/P3HT@$TiO_2$ Photocatalysis of Phenol Wastewater by a Pilot-Scale Fresnel Lens Assisted IPCC Reactor

*An-Chi Chen[1], Ting-Yu Zeng [1], Wen-Shiuh Kuo[1]

1. National United University,Department of Safety, Health and Environmental Engineering

One of advanced oxidation processes (AOPs) - solar photocatalysis with novel Ag/P3HT@$TiO_2$ as catalyst was used to treat phenol wastewater (10 mg/L) in this study. Moreover, a pilot-scale Fresnel lens mounted inclined plate curvature channel (IPCC) reactor was well design, established and evaluated for the treatment of phenol wastewater. 5 Fresnel lens which were made of PMMA with a thickness of 2 mm, a pitch of 0.5 mm, a facet depth of 0.2 mm, and Fresnel circles of 395 were used and mounted on IPCC. Results showed that the degradation efficiency of phenol wastewater could reach 98.35% with a dosage of 0.5 g/L Ag/P3HT@$TiO_2$ and a reaction time of 3 h under solar light irradiation (average $UV_{a+b}$ : 42.90 $W/m^2$). In addition, the intensity of solar light was found to be focused with an increase of 1.86 to 3.91 times and the temperature of wastewater could be raised for 3 to 5˚C with the assistance of Fresnel lens, leading to that the degradation rate of phenol molecule in Ag/P3HT@$TiO_2$ photocatalytic process increases 1.66 times as compared to without Fresnel lens system. The molecules of phenol were more efficiently decomposed into low-molecular-weight organic acids which were further mineralized into $CO_2$ and $H_2O$. Accordingly, the Fresnel lens enhanced IPCC reactor showed a synergistic effect on the solar photocatalytic process not only in effectively dealing with a large amount of industrial organic wastewater, but also in the sector of energy conservation in terms of effective utilization of solar energy.

# Using fluorescence quenching effect to investigate the electrical neutralization ability for different aromatic organic compounds

*Yu-Ting Chen[1], Wen-Po Cheng[1]

1. National United University,Department of Safety, Health and Environmental Engineering

The sources of organic matter in water include natural organic matter and synthetic organic matter. Most part of natural organic matter in water is humic acid which molecular weight is counted for hundreds to hundreds of thousands. The existence of humic acid not only affects the color and smell of water, but also produces toxic disinfection by-products. In addition, in synthetic organic matter, dye is used in the textile industry and the issue of process that produced waste water has been aware of increasingly. Therefore, effectively removing organic matter from water through the chemical coagulation process continues to be considered as a fairly important index of water purification efficiency.When the organic matter contains an aromatic heterocyclic structure and is excited by absorbing a specific radiation, it will eventually release the absorbed energy to the lower electronic energy level. Normally, the energy is released in the form of fluorescence. On the other hand, if the organic matter and metal ions are bonded to each other, the fluorescence intensity will be reduced. This phenomenon is known as the fluorescence quenching effect. In this study, the Stern-Volmer formula $F0F=1+K_q[M]$ will be used to evaluate the ability of the $Al^{3+}$ coagulant complex with organic matter. Where $F_0$ is the fluorescence intensity in the absence of $Al^{3+}$ quencher and F is the fluorescence intensity in the presence of $Al^{3+}$quencher, [M] is the concentration of the quencher, and $K_q$ is the equilibrium constant or quenching constant. Furthermore, the value of $K_q$ also represents the electrical neutralization capacity of coagulant under different conditions such as pH, molecular weight, hydrophilicity, functional groups of organic compound and coagulant dosage etc.The results in this study show that (1) under conditions of solution pH=6, the order of Kq values with different aluminum chloride dosage are Humic acid > Quinic acid > Salicylic Acid. Indicating that the molecular weight of organic matter is an important factor causing the degree of electrical neutralization ability; (2) under different solution pH, Reactive Blue 49 obtains the maximum Kq values than Direct Red 28 and Disperse Red 60 those often used in textile industry demonstrating the more number of sulfonic groups in the dye molecule, the more intensify electrical neutralization ability. (3) The Kq value of hydrophilic molecule (Direct Red 28) is higher than hydrophobic molecule (Disperse Red 60). These results indicate that the hydrophilicity of organic matter has a certain influence on the electrical neutralization by aluminum ions.All of results in this study show that the Stern-Volmer formula is a viable and simple method in operation to find the influencing factor of electrical neutralization ability between organic matter and aluminum coagulant and find the optimum coagulation conditions.

# Sustainable recovery of sugarcane biowastes to prepare biochar-derived electrodes for recycling of brackish water

*Shou-Heng Liu[1]

1. National Cheng Kung University

Membrane capacitive deionization (MCDI) is an emerging technology for the energy-efficient and cost-effective removal of ions from salt water by electrosorption. To further enhance the capacitive deionization performance, sugarcane bagasse biowastes are used as raw materials to synthesize biochars by microwave-assisted carbonization and activation with potassium hydroxide in the flows of carbon dioxide, which has the advantages of reducing preparation time and saving energy. Experimentally, the effect of microwave power (500-800 W) has been studied on the morphology, the ratios of mesoporosity in the biochars and their corresponding desalination performance of MCDI. Accordingly, the biochars which are activated at 700 W of microwave irradiation under carbon dioxide atmosphere (denoted as SB-$CO_2$-700) possess the ratios of mesopores to total pore volume ratio ($V_{meso}/V_{total}$) of ca. 64.1% with surface areas of 764 $m^2$ $g^{-1}$. By using cyclic voltammetry, the specific capacitance of SB-$CO_2$-700 is calculated to be ca. 123 F $g^{-1}$ at 5 mV $s^{-1}$. From the desalination tests at 1.2 V, the electrosorption capacity of SB-$CO_2$-700 samples is estimated to be 15.8 mg $g^{-1}$ in 5 mM of NaCl solution. The enhancement in the desalination performance of SB-$CO_2$-700 is possibly due to the greater $V_{meso}/V_{total}$ ratio, reasonable surface area and hierarchically porous structure.

# The National Survey of POPs in Soil: A study of polybrominated diethyl ethers (PBDEs) in Soil in Taiwan

*Shyh-Wei Chen[1], Ming-Yang Syue[2], I HSIN LEE[3], Chia Hsin Li[3], Yihsin Lai[3], Bo-Wei Power Liang[3]

1. Chung Yuan Christian Univ. Taiwan, 2. Soil and Groundwater Pollution Remediation Fund Management Board, EPA, Taiwan, 3. Sinotech Engineering Service LTD., Taiwan

The United Nations Environment Programme (UNEP) elaborates the Stockholm Convention on Persistent Organic Pollutants (Stockholm Convention) to protect human health and the environment through a range of measures aimed at reducing and eliminating the production and use of POPs. In order to understand the distribution of POPs in soil, a national soil quality survey has been carried out by Taiwan Environmental Protection Administration (EPA). The survey result can serve as the basis for promoting the management measures and evaluation of management effectiveness. In Taiwan, decabromodiphenyl ether (decaBDE) is still being used as flame retardants that are mostly used in electronic and electrical products. This study discusses the survey result of PBDEs in soil as one of the achievements of soil quality survey.

The strategy of soil quality survey involved investigation for potential pollution sources areas and baseline soil quality areas (Figure 1). Industries handled with a large quantity of decaBDE, large waste treatment facilities for waste electrical and electronic equipments and industrial parks were identified as potential pollution sources which were selected and soils sampled were collected at their surrounding areas. The baseline soil quality survey were undertaken to understand the environmental soil quality without the effect of potential pollution sources. Sixty composite soil samples were collected at surrounding areas of potential pollution sources and 60 composite soil samples were collected at baseline survey areas. Soil samples were analyzed for 24 PBDE congeners by gas chromatography /high resolution mass spectrometer (GC/HRMS).

The survey result shows that PBDEs concentration of all soil samples, collected from surrounding areas of the potential pollution sources and baseline survey areas, are ranged from 0.189 μg/kg to 656 μg/kg (the mean concentration is 39.6 μg/kg) and 0.268 μg/kg to 41.9 μg/kg (the mean concentration is 6.25 μg/kg), respectively (Table 1 and Figure 2). The levels of PBDEs in all soil samples are far lower than U.S. EPA's Regional Screening Levels. The study also performed hypothesis test and the result shows that the concentration at surrounding areas of potential pollution sources is significant higher than that at baseline survey areas. It means that the industrials with high polluting potential may have impact on their surrounding environment. In addition, this study compares the spatial distribution of soil surrounding potential pollution sources and baseline survey areas. The higher PBDEs concentrations are detected in soil at surrounding areas of the industrials using decaBDE. It is speculated that decaBDE which is an additive type flame retardant is affected their surrounding soil by emissions during the use of the addition process. The soil concentrations at the surrounding areas of waste treatment facilities for waste electrical and electronic appliances are on an equal level with baseline areas. Furthermore, the PBDE congener pattern is analyzed. The BDE congener pattern is dominated by BDE-209 and account for more than 80% of the total PBDEs concentration. It is speculated that it may be related to the use of decaBDE in recent years in Taiwan and accumulate easier than other BDEs with low bromine number in soil due to their solubility.
To monitoring the condition of the soil quality, assessing the effect of the potential pollution sources on soil quality, a systematic survey and monitoring plan for POPs in the Stockholm Convention was

©2019. Japan Geoscience Union. All Right Reserved. 

established by Taiwan EPA. The survey and monitoring works will be conducted in accordance with latest chemical lists of Stockholm Convention. The achievement of soil quality monitoring will help to tracking the influence of potential pollution sources and changes on environmental quality. It also can provide information to assess the effectiveness of control measures, strengthen the soil quality management and ensure the sustainable use of land resources.

# Remediation of Total Peteoleum Hydrocarbons in Soils by Combining Cyclodextrin and Microbubble Ozonation

*Kuan-Yi Kuo[1], Meng-hau Sung[1], Fu-yin Xie[1]

1. Department of Environmental Science and Engineering,Tunghai University,Taiwan

In recent years, there have been many studies to increase the solubility of ozone by ozone-binding microbubbles or cyclodextrins, so that ozone has a better treatment effect. At present, no research has been conducted on the treatment of ozone in combination with microbubbles and cyclodextrins. Therefore, this study hopes to use ozone combined with microbubbles and cyclodextrin to treat the total petroleum hydrocarbons (TPH) in soil, and hopes to have better treatment effect than using microbubbles or cyclodextrin alone. This method is also a green remediation method that does not cause secondary pollution to the environment. In this study, ozone was first produced by an ozone generator and passed into a microbubble generator. Micron bubble ozone was then introduced into a water sample containing cyclodextrin, and finally the water sample was passed through a soil contaminated with TPH. In this study, different forms and concentrations of cyclodextrin were tested to examine their pertinent effects, so that the overall treatment efficiency of this method can be optimized. The instruments used in this study include spectrophotometer for the detection of ozone, LC with RID for the detection of cyclodextrin, and GC for the detection of TPH. It is expected that using microbubbles together with cyclodextrins simultaneously will improve the green remediation process.

# Treatment of organic pollutants in wastewater by ozone microbubbles and cyclodextrins

*Fu-Yin XIE[1], Meng-hau Sung[1]

1. Department of Environmental Science and Engineering,Tunghai University,Taichung City,Taiwan

The hydroxyl radicals generated during ozonation can be used to oxidize organic pollutants in water. However, ozone gas is only slightly soluble in water. To increase the treatment efficiency, ozone microbubbles and cyclodextrins can be applied to increase the solubility. Microbubbles have high surface area and long residence time in aqueous solution. If they are combined with ozone gas to form ozone microbubbles, the solubility and half-life of gaseous ozone in water can be significantly improved. In definition, microbubbles refers to bubbles with a diameter between 1 micrometer and 1 millimeter. In addition to oxidative hydroxyl radicals generated, at the moment when the microbubble bursts, the pressure will be released, resulting in a high-speed microjet and ultra-high temperature locally. Under this condition, organic pollutants can also be degraded by pyrolysis. Cyclodextrins are often used in foods and are not harmful to humans. Adding cyclodextrin to the ozone microbubble system can increase the residence time of ozone in water and increase the half-life of ozone in water. Consequently, the combination of microbubbles and cyclodextrins appears to be a promising method for effective degradation of organic pollutants in water. Pesticides are common organic pollutants in water. After application, it may enter the environment via surface runoff, which may directly or indirectly enters water resources such as lakes or reservoirs. It has a certain impact on the environment and ecology, and may enter the groundwater system, which may affect the drinking water quality. The objective of this study is to establish an ozone microbubble system with cyclodextrin to treat organic pollutants in water. A variety of tests are conducted to examine its performance. Parameters considered in the experiments are pH and dosages of ozone microbubbles and cyclodextrin. The best condition for efficient degradation will be determined.

# Applying GIS Site Suitability Analysis to Optimize Landfill Selection in Mozambique

*Chelsea Adelina Langa[1]

1. Tohoku University, Graduate School of Environmental Studies

Proper selection of landfills is a complex task. However, with the application of GIS technology, it is possible to aid in the selection of an optimal site, one that ensures environmental and social standards for potential landfills. In Maputo city, site selection of landfills is difficult due to land restrictions resulting from the land conflicts and groundwater presence. However, in the need of improving waste disposal conditions, a new landfill site has been selected. The goal of this study was to identify potential areas for landfill and evaluate the suitability of the new landfill. Environmental and social criteria were combined to firstly identifying potential disposal sites. By making a cross-reference of criteria map, three types of areas were selected, unsuitable, subjected to special evaluation and suitable areas. It was possible to estimate how the current landfill is in terms of environmental and social safety, based on the AHP ranking process. GIS and its aided tools were proved to be efficient in this process and of great value for the improvement of the municipal solid waste management in Maputo, however, due to the characteristics of the area, on-site studies are still necessary in order to validate landfills.

# Effectiveness of Solidification/Stabilization of a Heavy Metal-Contaminated Soil Using a Sustainable Binder

*Yasong Feng[1,2,3], Weiyi Xia[1], Shiji Zhou[1], Ming Zhang[2], Yanjun Du[1]

1. Southeast Univ., 2. AIST, 3. Tohoku Univ.

Cement and lime are currently extensively used in solidifying/stabilizing heavy metals contaminated soils. However, cement and lime production is associated with intensive consumption of energy and nonrenewable resources. Under the drive of environmental friendliness, some by-products-based binders such as ground granulated blast furnace slag, pulverized fuel ash, and cement kiln dust have been successfully used in the remediation of contaminated soil. The authors have recently developed a sustainable binder, basic oxygen furnace slag (BOFS) activated by calcium carbide residue (CCR) and phosphogypsum (PG). The binder has almost no negative environmental impacts, and it can be used as an excellent substitute for cement.

This study presents a preliminary evaluation of the effectiveness of the BOF-based binder to stabilize mixed nickel (Ni) and zinc (Zn) contaminated soil collected from a vacant lot of an electroplating plant. The effects of binder dosage and curing time on soil pH, leachability and strength properties of the stabilized soils were examined. In addition, modified European Communities Bureau of Reference (BCR) sequential extraction procedure (SEP) and mercury intrusion porosimetry (MIP) analyses were performed to investigate the mechanisms that control the variations in heavy metal speciation and soil structure.

The results showed that soil pH and unconfined compressive strength (UCS) increased with increasing binder dosage and curing time. After 90 days of curing, the UCS of stabilized soils was approximately 2.9 - 6.6 times higher compared with those of untreated soil. Leaching concentrations of Ni and Zn were significantly reduced with increases in binder dosage and curing time. With 8% of binder addition and 28 days of curing, the leaching concentrations of both Ni and Zn were well below their corresponding remediation goals. The SEP results indicated that the binder addition significantly reduced the acid-soluble fractions of heavy metals while increased their residual fractions. The MIP test results showed that the soil pore volume reduced notably and soil structure changed remarkably after stabilization, inducing higher UCS compared with the untreated soil.

# Determining diffusive parameters using out-diffusion experiment with consideration of sampling effect

*Ranran Song[1], Chihiro Inoue[1], Ming Zhang[2]

1. Tohoku University, 2. Geological Survey of Japan, AIST

To know the details of diffusive properties of geo-materials is vital in geological disposal engineering projects. Out-diffusion experiment involves the process of heavy metal when diffuses out of geometries. It has simple structure and easy-operational experiment procedure. A theoretical solution considering the adsorption effect and sampling effect was developed. By applying theoretical analyses, we can estimate and decrease the errors induced by sampling. Sensitive analyses were also conducted to estimate a reasonable sampling time range and frequency. With the assist of theoretical analyses, a proper experiment can be designed. In this study, we assumed that heavy metal is linearly adsorpted on the surface of geo-material and linearly desorpted into the porous solution. We tested clay samples to get the effective diffusion-coefficient and capacity factor and examined the effect of sampling. As the linearly adsorption assumption may not be sufficient, especially to describe heavy-metals which easily adsorpted, we also try to discuss the effect of the heavy metal adoption effect to the diffusive process in these experiments.

# Exploring the removal characteristics of heavy metals employing Nanofiltration (NF) technique

*Jagdeesh Kumar[1], Himanshu Joshi[1]

1. INDIAN INSTITUTE OF TECHNOLOGY ROORKEE

Heavy metals are serious environmental concern in recent industrial era, release from different industrial process. These are non-degradable, persistent, highly toxic and tendency of bioaccumulation into body tissues of organism, which causes several health consequences. Various technologies have been reported to develop so far in the removal of these contaminants which primarily include adsorption, chemical precipitation, and phytoremediation. These are conventional techniques of treatment process, which have several disadvantages such as high treatment cost, generation of sludge in bulk and requirement of large amount of adsorbent. From last few decades, usage of nanofiltration membrane (NF) during treatment process has gained significant attention in chemical processing, biotechnology and desalination industries. Recently, nanofiltration technique has been reported to be employed for the treatment of heavy metals in electroplating industries, due to its high efficiency, less energy consumption and minimum generation of toxic sludge. Therefore, a synergistic approach has been explored for the removal of concerned metals in combination with the electrocoagulation technique.

In present study, synthetic waste water was formulated containing different concentration of Zn, Cu and Ni metal ions for the treatment process. A central composite design was explored to study the effect of variable such as pH, concentration, pressure temperature ranges from the value of 4.5-9.5, 10-20 bar, 10-25 ppm and 15-35-degree C, respectively. A set of 30 experimental runs was examined for the removal. Further, the Response Surface Methodology (RSM) was adopted to optimize the removal percentage (maximize) by minimizing the pressure and maximizing the concentration. The experiments were also performed at the optimize conditions which have shown significant co-relation with the predicted values.

The removal percentage (%) of 99.96, 99.82 and 99.93 was observed at temperature of 15 -degree C for Cu, Ni and Zn metal ions, respectively. At low pH, high copper removal was observed as compared to those nickel and zinc ions. The high removal of copper occurred due to the formation of its precipitates at lower pH. The results show that the value of pH and metal concentration are not significantly affected the flux while pressure and temperature increase flux increase. This can be attributed to the fact that increased temperature decreased the viscosity and increase in the diffusion rate of solute through the membrane. The effect of pH and concentration on removal efficiency shows that the removal efficiency increases as pH increases while it decreases with the increased concentration. At desirability 0.993, the maximum removal of Zn, Ni, Cu were observed to be 101.53, 97.81 and 102.48, respectively. The maximum flux 225.88 was achieved at ambient temperature of 25-degree C. A good correlation of 0.9823 was observed for the experimental outcomes among the optimised experimental runs and predicted values.

# Potential of Potash Recovery Employing Electrodialysis(ED) Technique from Distillery Effluent

*SUNIL YADAV[1], HIMANSHU JOSHI[1]

1. INDIAN INSTITUTE OF TECHNOLOGY ROORKEE

Sugarcane is one of the major cash crop of north-western and central part of India. Distillery industry coupled with sugar industry provides an economic and social infrastructure to the rural economy. The byproduct of sugar industry known as Molasses, utilized as raw material for the production of ethanol. The ethanol is a major source of beverages, biofuels and organic solvent production. It generates a large volume (approx. 8-10 L/L) complex, highly colored and concentrated organic stream alongwith high concentration of total dissolved solids as spent wash, which is a great concern as for treatment and disposal. Waste management and resource recovery has become a major task for large volume effluent generating industry to achieve long term sustainable economic development.

The characterization of spent wash shows a high concentration of potassium up to 8-10 g/L. High level of potassium concentration in the spent wash provide a way for economic utilization of the effluent. Several conventional technologies have been reported so far in recovering the potash from spent wash using incineration, ion exchange and chemical precipitation. These are having several disadvantageous in respect to high energy consumption, economically nonviable and less environmental significant. Presently, most of the industries depend on membrane processes alongwith anaerobic digestion techniques for the treatment of spent wash. However, the effluent is rich in potassium which can be recovered in the form of potash for its usage in agriculture production, as fertilizer.

In the present study, desalination experiments were carried out for nanofiltration membrane (NF) treated effluent, containing the concentration of potassium upto 6,000 mg $L^{-1}$ and electrical conductivity (EC) upto 28 mS $cm^{-1}$. The reject stream after the Nano filtration treatment was passed as feed through the Electrodialysis (ED). The main objective of the study is to separate the feed stream into dilute and concentrate stream with the aim of generating a highly saline effluent. A laboratory scale electrodialysis stack (mega EDR-Z) containing eleven cation exchange membranes and ten anion-exchange membranes of 64 $cm^2$ effective area was investigated for potassium removal. Two stream generated during the process one is the concentrated brine and the second one is the deionized effluent. The influence of applied voltage (10, 15, and 18 V) on removal efficiency was also examined. From these analyses, the potassium removal up to 92, 96 and 97 % has been observed at operating time of 120, 90 and 75 min, respectively. Similarly, the salinity removal upto 83, 95 and 97 % were observed. A desalinated effluent i.e. the dilute stream with conductivity less than 1mS $cm^{-1}$ and potassium level less than 150mg/l was generated. It is concluded that the increases in the voltage led to salt and potassium separation. This is due to the increase in current induces migration movement of all the dissolved ions in the process solutions. So, with the addition of an ED system with NF, a highly concentrated brine stream can be generated that can be further subjected to advance electrochemical process for potassium separation and crystallization.

# CHARACTERIZATION OF WATER RETENTION AND MASS TRANSPORT PROPERTIES FOR RECYCLED ROADBED MATERIALS BLENDED WITH AAC FINES

*Ryohei ITO[1], Akira KATO[1], Akihiro MATSUNO[1], Ken KAWAMOTO[1,2]

1. Graduate School of Science and Engineering, Saitama University, 2. National University of Civil Engineering, Vietnam

Permeable pavement systems (PPS) contribute to reduce surface runoff during heavy rainfall and to mitigate urban heat island effect.

The purpose of this study is to improve water retention capacity for recycled road-base materials utilizing fines (typically under 2 mm) from industrial by-products. Especially, the effects of mixing of fine grains made from autoclave aerated concrete (AAC; 0.106-2 mm) with graded recycled concrete (RC; 0.075-31.5 mm) and steel slag for roadbed construction (SS; 0.075-31.5 mm) were examined. Besides, mass transport parameters such as gas diffusion coefficient, air permeability, thermal conductivity, and heat capacity were measured for tested samples to characterize gas and heat exchange properties and pore structural properties of gas flow. After compacting the samples by Proctor D method, water retention curves were obtained through the drying process from water saturation. The gas and heat transport parameters were also measured at each suction stage and air-dried condition.

As a result, the mixing of AAC fines contributed highly to increase water retention capacities for both graded RC and SS. The mixing of AAC fine grains, on the other hand, did not affect the pore structural properties such as equivalent diameter and tortuosity for gas flow, suggesting the retained water in AAC fine grains would not impede the gas flow in graded roadbed materials mixed with AAC fine grains.

# Characterizing Geotechnical Properties of Drinking Water Sludge Blended with Graded Crushed Clay Brick for Road Subgrade: Effects of Gradation and Mixing Proportion of Crushed Clay Brick on Compaction Property

*Tserenlkham Ikhagvasuren[1], Muhammad Rashid Iqbal[1], Ken Kawamoto[1]

1. Graduate school of science and engineering Saitama University, Japan

With rapid construction and renovation works, a huge amount of construction and demolition waste (CDW) is generated in urban areas of developing countries. The CDW is mostly dumped at the landfill sites directly and/or reused for construction works such as ground levelling and backfilling without any quality control of materials. Effective use and recycling of CDW is highly required to establish sustainable urban development. In this study, drinking water sludge (DWS) blended with crushed clay brick (CCB) was tested for the possible application to road subgrade. Especially, the effects of gradation/particle size of CCB and its mixing proportion to DWS on compaction properties have been examined using laboratory tests. A series of the modified Proctor compaction test was conducted using testing samples with three different particles of CCB; the finer (2-10 mm), coarser fraction (10-30 mm), and graded fraction (2-30 mm) and with different mixing proportions to DWS; 20, 40, 60, 80 and 100% on the dry mass basis. The tested results showed that particle breakage of all the above-mentioned fraction was almost the same up to 40% addition of CCB to DWS and was independent of particle size as well. A coarser fraction of CB showed the highest value of particle breakage (45.7%) which was almost double than that of finer (26.9%) and graded fraction breakage (22.8%) respectively. Measured compaction curves of all the mixed samples showed a linear relationship between maximum dry density and mixing proportion of the blended samples. The CCB mixing proportions more than 40% did not show any peak in the compaction curve probably due to a higher quantity of the cohesionless material (i.e., CCB).

# CHARACTERIZING PHYSICAL AND CHEMICAL PROPERTIES OF RESIDUES GENERATED FROM CONSTRUCTION AND DEMOLITION WASTE

*NINGNING HAO[1], Ken Kawamoto[1], Akihiro Matsuno[1]

1. Saitama University

Due to rapid urbanization and population increase, the generation of Construction and Demolition Waste (CDW) is increasing in urban areas and industrial zones in developing countries. In order to promote sustainable development, it is important to have sound CDW management and recycling. Among of generated and dumped CDW, general masonry such as concrete and clay brick can be recycled for road construction and backfilling materials after suitable treatments like crushing and sieving. On the other hand, the reuse of fine residues (typically < 10 mm) faces some difficulties with regards to quality control and potential risk of hazardous materials. Based on the background, this study aims to characterize chemical and physical properties of CDW fines (especially for mortar samples). The testing samples were taken from 3 different demolition sites in Hanoi and Haiphong and a CDW dumping site in Hanoi. For the testing samples, two different fractions, one is bigger than 2mm and the other is grounded and sieved less than 2mm, were used for SEM-EDS analysis. Results showed that the samples with less than 2mm observed by 100 magnification of SEM became more stable (less spatial variability and following normal distribution). The measured Ca/Si values varied widely from 1.36 to 2.60 and became lower than that from a control mortar sample except for one sample from Hanoi demolition site. Further studies are planned to determine the mixing per cents of mortar and clay brick in CDW fines for characterizing the chemical composition and for promoting effective and safe use of recycled fines from CDW.

# CHARACTERIZATION OF PORE-STRUCTURE PARAMETERS FOR UNDISTURBED AND REPACKED SAMPLES AT FIELD WATER CONTENTS

*Arjun Baniya[1], Akihiro Matsuno[1], Ken Kawamoto[1]

1. Saitama University , Graduate school of Science and Engineering

Mass transport in soils occurs through the soil pore network, which is highly influence by pore structure parameters (i.e. pore size distribution, porosity, pore tortuosity and pore coordination number). Micro-focus X-ray computed tomography (CT) has emerged as a powerful non-destructive tool for the direct visualization and better understand soil pore geometry. However, there have been few studies on visualization and quantification of soil pore network and soil pore networks linked to indirect pore parameters for gas flow based on measured gas diffusion coefficient and air permeability. In this study we visualized soil-pore networks for different soils, a sandy loam from Saitama, Japan and silty clay loam from Hawke’ s Bay, New Zealand. The study aimed to identify pore structure parameters using a microfocus X-ray computed tomography (MFXCT) system and compare indirect pore parameters such as tortuosity-connectivity parameter and equivalent pore diameter for gas flow. Undisturbed and repacked samples were used for characterizing soil pore networking and structure. For repacked soil samples, particle size (d<2mm) with field water content were used with different dry bulk densities by hand compaction. Soil samples were scanned by MFXCT system with different scanning resolutions of 12,30 and 50 μm/voxels. Then, 3-dimensional models were reconstructed with different regions of interest (ROI) of 50, 100, 200 and 300 voxels. Finally, soil pore-structural parameters such as effective pore radius, coordination number, and tortuosity in z direction were analyzed. With increasing ROI, the pore structure parameters of undisturbed and repacked samples showed less variation. The pore connectivity-tortuosity factors derived from MFXCT were well correlated with the indirect connectivity tortuosities from measured soil gas diffusion. However, it was observed that there were some variations between effective pore diameters from MFXCT and equivalent pore diameters for gas flow estimated by gas transport parameters depending on scanning resolutions (ranging from 1:1 to 1:3 for SR =12 μm/voxels and 1:1 to 4:1 for SR = 30 μm/voxels).

# CHECK SHEET SURVEY FOR ESTIMATING CDW GENERATION AND CASH FLOW AT BUILDING DEMOLISHING SITES IN HANOI, VIETNAM

*Cuong Viet Tran[1], Kawamoto Ken[1]

1. Graduate School of Science and Engineering, Saitama University

## Abstract

A number of studies on reuse and recycling of construction demolition waste (CDW) for construction works as well as the properties of building materials using recycled aggregates have been carried out in many developed countries. However, in Vietnam, there are many difficulties to classify and recycle the CDW after demolition construction at site. Because the generation of CDW is increasing in Vietnam due to rapid urbanization and economic growth and CDW was dumped without any quality control of material at disposal site. It is highly demanded to promote the recycling of CDW in a sustainable manner.

In this study, in order to identify the CDW generation and cash flow at actual demolition sites in Vietnam. Firstly, we proposed a check sheet survey to discuss suitable CDW separation and treatment methods. The survey sheet enables to collect data on demolition period, number of labors and equipment, volume of CDW, number of trucks which brought the generated waste from the site, total floor areas, total cost for the demolition work, and so on. Then, using the survey sheet, actual survey works carried out at 3 different building demolishing sites in Hanoi. Finally, utilizing the collected data, we determined waste components and waste generation rates of typical materials such as concrete, brick, valuables (e.g., steel).

Results showed that most CDW generated from demolishing sites was sold to other contractors/buyers for the purpose of construction works (e.g., ground leveling). The generation rates of CDW including valuables varied widely from 0.29 to 1.22 tons/ ($m^2$ of total ground floor) depending on the building type and scale, and smaller building demolition gave a higher generation rate. As a result of cash flow, the estimated cost for selling valuables and CDW masonry to buyers became much higher than those for the contract cost of demolition work from land owner/client.

# APPLICATION OF CRUSHED GRAINS OF LATERITE AND AUTOCLAVED AERATED CONCRETE FOR HEAVY METAL REMOVAL FROM WASTEWATER

*Buddhika Priyadarshani Bandara Arachchillage[1], Yuki Yoshida[1], Pradeep Kumara Gajanayake Mudalige[1], Akihiro Matsuno[1], Ken Kawamoto[1]

1. Graduate School of Science and Engineering, Saitama University

Adverse effects on the environment and human health is highly influence by heavy metal contamination in water is a global significance problem. Among conventional treatment technologies for treating wastewater, a particular attention is given to adsorption process, considering as low-cost and easy technical applicability. In this study, in order to examine the applicability of locally available geo-materials and industrial by-products as cost-effective adsorbents in the treatment technology of heavy metal-contaminated water, laterite made from Vietnam and autoclaved aerated concrete were tested for the removal of arsenic and chromium in wastewater. Zeolite made from Japan was also used as a reference material. The testing samples were first grounded and sieved to be 0.105-2 mm grain size. The standard batch adsorption method by Organization of Economic Cooperation and Development (OECD 2000) was applied to determine adsorption isotherms. The isotherm experiments were evaluated for 1:10 solid liquid ratio at natural pH and 20 $^{0}$C temperature for solutions with initial concentrations ranging from 100 –2000 mg/L for both metals. The results indicated that Langmuir isotherm described the experimental data the best. Laterite removed arsenic and chromium in solutions up to 8.21 and 1.33 mg/g respectively. It revealed that laterite had higher adsorption capacity for arsenic than autoclaved aerated concrete. The measured removal percentages decreased with increasing in initial ion concentrations. Future, the adsorption mechanism will be suggested by correlating both laterite and autoclaved aerated concrete for heavy metal removal from wastewater.

# Effects of Silicic Acid on Environmental Stability of Spent Calcium-based Arsenic Adsorbents

*Hajime Sugita[1], Terumi Oguma[1], Ming Zhang[1], Junko Hara[1], Yoshishige Kawabe[1]

1. National Institute of Advanced Industrial Science and Technology

In some areas of developing countries, health effects caused by arsenic contained in groundwater used as drinking water have been a serious problem. Calcium compounds show promise for arsenic removal as effective and inexpensive adsorbents. However, the spent adsorbent would contain a great amount of arsenic. When the spent adsorbent is not properly recovered and is discarded near residences, secondary environmental pollution due to arsenic leaching from the spent adsorbent may occur. In our previous studies (leaching tests with soils), it was suggested silicic acid which leached from soils greatly affects leaching behavior of arsenic from the spent adsorbents. In this study, in order to examine the influence of silicic acid on the environmental stability of spent adsorbents in detail, leaching tests with silicic acid solution and 2 kinds of spent calcium-based adsorbent (CaO and $Ca(OH)_2$) were carried out. This study revealed that when the initial silicic acid concentration in solution is high, the leaching rate of arsenic decreases. This was inferred that when the silicic acid component in the solution reacted with the calcium component eluted from the spent adsorbents to form the calcium silicate species, the arsenate component leached from the spent adsorbents was taken into the products.

# The Fate of Chloroethene in Geo-environment

*Ming Zhang[1], Miho Yoshikawa[1]

1. Institute for Geo-Resources and Environment, Geological Survey of Japan, AIST

Chloroethene, also has the names of chloroethylene, ethylene monochloride, vinyl chloride monomer (VCM) or vinyl chloride (VC), is an important chemical substance widely used to produce polymer polyvinyl chloride (PVC) in plastic industry. Due to its high volatility, the pollution induced by the use of chloroethene itself is principally limited to air pollution. In geo-environment, such as soils and groundwater, the occurrence of chloroethene is mainly from biodegradation of its parent compound, like *cis*- Dichloroethene (*cis*-DCE), *trans*-DCE or 1,1-DCE, an intermediate product of biodegradation of trichloroethylene (TCE) and/or tetrachloroethylene (PCE). Either TCE or PCE has been widely used as an industrial solvent both in developed and developing countries.

To understand the fate of chloroethene in geo-environment, this presentation overviews the pathways, microorganisms, and degrading rates associated with biodegradation of chloroethene, the pollutant newly specified by the Japanese Soil Contamination Countermeasures Act. In natural environment, biodegradation of chloroethene is very slow and distribution of chloroethene around or downstream a source of pollution is dominantly affected by advection and dispersion. An advection-dispersion equation and sensitive analysis were, therefore, used to examine possible distances of chloroethene which may spread downstream of a source point over long time period. The control of groundwater flow can be an effective countermeasure against further spreading of pollutant plume.

## [A-CG34] Satellite Earth Environment Observation

convener:Riko Oki(Japan Aerospace Exploration Agency), Yoshiaki HONDA(Center for Environmental Remote Sensing, Chiba University), Yukari Takayabu(Atmosphere and Ocean Research Institute, the University of Tokyo), Tsuneo Matsunaga(Center for Global Environmental Research and Satellite Observation Center, National Institute for Environmental Studies), Chairperson:Kentaroh Suzuki

In recent years, we cannot avoid facing issues on global environmental changes that occur in various spatiotemporal scales. The earth environmental observation data by satellites became the necessary basic data to tackle and solve those issues. Due to the recent advancement in the observation sensor technique and the data processing technique, the satellite observation has been showing rapid progress, and the time is changing from examining the accuracy of the observation sensor data to the advancement of the data application, leading to broaden potential users. In these days application became synergetic, so we comprehensively pick<br/>up this topic in the Atmospheric and Hydrospheric Sciences Session of this Union Meeting that enables to comprise the atmospheric, oceanic and land sciences; by combining the intelligence and the knowledge of the party, we propose a session that aims to prompt further studies towards the issues on earth environmental change, the advancement in the data application and future plans of Earth Observation missions.

# GCOM-C “Shikisai” FIRST YEAR OBSERVATIONS

*Hiroshi Murakami[1], Masahiro Hori[1], Risa Miyazaki[1], Toshiyuki Kobayashi[1], Takashi M. Nagao[1], Kazunori Ogata[1], Rigen Shimada[1], Junichi Takaku[2]

1. Earth Observation Research Center, Japan Aerospace Exploration Agency, 2. Remote Sensing Technology Center of Japan

One-year observation results of Global Change Observation Mission-Climate (GCOM-C) called “SHIKISAI” are introduced.

JAXA polar-orbit satellite, GCOM-C, which carries Second-generation Global Imager (SGLI), has been launched on 23 Dec. 2017, and operated in orbit during 2018. The key characteristics of the SGLI are (1) 250-m spatial resolution with 1150 km or 1400 km swath, and (2) nineteen bands in 0.38-12 um including two polarimetry bands (at 672 nm and 866 nm) with +/- 45 degree along-track tilt.

The SGLI radiometric gain was evaluated by the on-board calibration functions (solar, lamp, lunar, and electric calibrations) and vicarious calibration over the land, ocean and ice sheet. The radiometric gain was stable during the first year except for slight degradation (<2 %/year) in 380-565 nm bands. The geometric correction accuracy was evaluated by the Ground Control Point (GCP) matching. The deviation from the GCPs was stable and kept less than about 0.3 pixels.

The SGLI 250-m bands could capture seasonal change of the vegetation and the snow cover, the large-scale red tide, and the fine structures of land-surface temperature and coastal sea-surface temperature. Especially, unique functions of SGLI, the 380-nm band and polarimetry revealed the fine-mode aerosol distribution around wild fires (e.g., California, Africa, and Siberia) and Asian city areas (e.g., North India, and East China). The polarimetry seemed to improve estimation of the aerosols emitted densely from the fires. Difference of the 250-m land-surface temperature between the day and nighttime may give us information about the heat budget in the various land covers including city and crop areas. The GCOM-C standard products have been evaluated and open to public freely through JAXA data portal, G-portal, since Dec. 2018. The re-process of the 2018 data will be completed in the early summer 2019. The accumulating GCOM-C data products are expected to be used in the wide areas of the earth environment researches.

# Algorithm improvement for GCOM-C/SGLI Above Ground Biomass Standard product.

*KAJIWARA Koji[1], Yoshiaki HONDA[1]

1. Chiba University

On 23rd Dec., 2017, Japan Aerospace Exploration Agency (JAXA) has launched new Earth observation satellite GCOM-C . GCOM-C equips Second-generation Global Land Imager (SGLI) as core sensor. Since SGLI can observe nadir and off-nadir angle with along-track direction simultaneously, it is expected to retrieve forest Above Ground Biomass (AGB) using bi-directional spectral data.

For the estimation of forest AGB, difference of bi-directional reflectance of each observation angle caused by forest canopy structure will be key information.

Authors have been developed basic AGB estimation algorithm for SGLI AGB standard product. This algorithm is based on the empirical model related to the relationship between reflectance shift on the Red-NIR plane for different viewing angle and AGB. The algorithm requires optimum approximation coefficients directly related AGB amount in observed area for each forest type. In 1st stage product algorithm, we have decided these coefficients using AGB in-situ dataset collected from literature survey which work has been conducted by JAMSTEC. While the AGB estimation results using SGLI reflectance data achieved success criteria for initial stage, it is required for getting better accuracy to achieve the full success criteria.
In this paper, development of algorithm for aimed at improving accuracy was discussed. The improved algorithm which adopting the rasterized AGB existed data base and change the zoning method, has been tested. The result of the trial, the accuracy of estimation has been confirmed.

# Common retrieval of Atmospheric Aerosol Properties for geostationary and polar-orbital Satellite Imaging Sensors: Himawari8/AHI and GCOM-C/SGLI results

*Yoshida Mayumi[1], Maki Kikuchi[1], Takashi M. Nagao[1], Hiroshi Murakami[1], Keiya Yumimoto[2]

1. Japan Aerospace Exploration Agency, 2. Kyusyu University

Aerosols influence the energy budget of the earth’ s climate system through scattering and absorbing solar radiation. The Intergovernmental Panel on Climate Change Fifth Assessment Report (IPCC, 2014) reported that the radiative forcing of the total aerosol effect in the atmosphere, which includes cloud adjustments due to aerosols, is −0.9 W $m^{-2}$ and results from a negative forcing from most aerosols with a positive contribution from black carbon absorption of solar radiation. However, the range of the uncertainties remains large (−1.9 W $m^{-2}$ to −0.1 W $m^{-2}$).

For a more precise estimation of the impact of aerosols on climate systems, investigation of the behavior of aerosols on a global scale is essential but challenging because aerosol amounts and characteristics vary over space and time.

Aerosol remote sensing studies have been carried out using polar-orbital Earth observation satellites. JAXA has launched Global Change Observation Mission-Climate (GCOM-C)/Second-generation GLobal Imager (SGLI) at the end of 2017, and Greenhouse gases Observing SATellite- 2 (GOSAT-2)/Cloud and Aerosol Imager 2 (CAI-2) in 2018. In several years, Earth Clouds Aerosols and Radiation Explorer (EarthCARE)/ Multi-Spectral Imager (MSI) will be launched.

In addition, the next-generation geostationary satellite of the Japan Meteorology Agency (JMA), Himawari-8, was launched on October 7, 2014. It carries the Advanced Himawari Imager (AHI), which has six bands from visible to near-infrared wavelengths. It is significantly different from the previous Himawari-6/7 having only one channel in the wavelengths, which made the estimation of aerosol difficult because the assumption of aerosol type is necessary. Himawari-8/AHI observes the top of atmosphere (TOA) visible and near-infrared radiance at a resolution of 0.5–2.0 km over Asia and Oceania at every 10 min, which enables frequent aerosol estimation over the same ground targets.

The synergistic uses of these various imaging sensors on both geostationary and polar-orbital satellites are helpful to understand a complete picture of aerosol distribution in the global scale. For this purpose, we developed the common retrieval algorithm of the atmospheric aerosol properties for various satellite sensors and over both land and ocean.

The algorithm is based on the method developed by Higurashi and Nakajima (1998) and Fukuda et al. (2013). The three main features in the concept of this algorithm are as follows: (1) automatic selection of the optimum channels for aerosol retrieval by introducing a weight for each channel to the object function, (2) setting common candidate aerosol models over land and ocean, and (3) preparation of lookup tables for every 1 nm in the range of 300 to 2500 nm of wavelength and weighting the radiance using the response function for each sensor.

The method was applied to Himawari-8/AHI and GCOM-C/SGLI. The validation study indicated that

©2019. Japan Geoscience Union. All Right Reserved. 

aerosol optical thickness estimated from our algorithm was generally consistent with the products from Moderate Resolution Imaging Spectro-radiometer (MODIS) and Aerosol Robotic Network, and SKYNET.

In addition, the utilization of the aerosol properties forecasted by a global aerosol transport model for the retrieval are discussed.

# Cloud optical properties from various ground and satellite instruments evaluated during an intensive campaign

*Alessandro Damiani[1], Hitoshi Irie[1], Takashi Horio[1], Tamio Takamura[1], Rei Kudo[2], Pradeep Khatri[3], Hironobu Iwabuchi[3], Ryosuke Masuda[3], Takashi M. Nagao[4]

1. CEReS, Chiba University, 2. Meteorological Research Institute, Japan Meteorological Agency, 3. Graduate School of Science, Tohoku University, 4. Earth Observation Research Center, JAXA

An intensive campaign to monitor the atmospheric environment (i.e., aerosols, clouds, and gases) has been carried out at the SKYNET station of Chiba University in November 2018. The station is equipped with a broad range of meteorological instruments as well as sky radiometers and is part of various international research networks. Due to their challenging estimation from ground observations and the typical discrepancy between satellite and surface-based estimates, here we focus on cloud optical properties taking a particular interest in cloud optical depth (COD). First, we conducted a careful evaluation of four COD datasets retrieved from surface observations of i) zenith radiance recorded by a sky-radiometer (based on two independent algorithms), ii) solar radiation taken by a pyranometer and iii) spatial distribution of radiance recorded by a camera system equipped with fisheyes lens. Then, we assessed satellite-based estimations of COD retrieved from AHI/Himawari-8 and SGLI/GCOM-C observations trying to explain the differences between satellite and ground data in term of atmospheric conditions, acquisition geometry and COD spatial distribution. Preliminary results achieved from this activity will be presented.

# Issues in aerosol-cloud-climate interaction: Needs for future satellite mission

*Kentaroh Suzuki[1]

1. Atmosphere and Ocean Research Institute, University of Tokyo

The aerosol forcing is the largest source of uncertainty in determining climate forcing that drives global climate change. The aerosol forcing consists of the so-called direct (aerosol-radiation interaction) and indirect (aerosol-cloud interaction) effects, both of which are subject to significant uncertainty. This uncertainty arises from our lack of understanding on key processes that govern interactions between aerosol, cloud and climate. Precipitation, among those processes, is central to the aerosol-cloud-climate interaction through its effect of depleting both clouds and aerosols. The aerosol-induced precipitation change influences the cloud lifetime and amount, whereas the precipitation change also modulates the wet removal of aerosols. This underscores a fundamental role of precipitation in shaping the aerosol-cloud-climate interaction. Recent advance in satellite observations by multiple sensors and platforms enabled us to observationally diagnose the precipitation processes on the global scale particularly, which also offers a process-level constraint on model representation of the processes. Such a “bottom-up” model constraint, however, turned out to be inconsistent with “top-down” energy balance requirement on model performance, exposing error compensations in state-of-the-art climate models at a fundamental level. This proposes that there is still a gap in our understanding of the aerosol-cloud-climate processes that hampers their reliable modeling. This presentation discusses what is required to observe in future satellite missions for filling the gap in understanding and modeling the aerosol-cloud-climate interaction. In particular, observational needs for aerosol, cloud and precipitation will be argued to better quantify aerosol-induced climate forcing in the context of recent Aerosol-Cloud-Convection-Precipitation (A-CCP) discussion emerging from the US Decadal Survey and multiple community efforts for process-oriented model diagnostics in an attempt to advance climate modeling.

# Impact of aerosol vertical profile and optical parameters on the accuracy of satellite AOD retrieval

*Jing Li[1], Chong Li[1]

1. Peking University

Satellite sensors are widely used to monitor large scale aerosol variability from space. However, current aerosol retrieval algorithm used by passive sensors still suffers from uncertainties in a series of assumptions, with two important ones being aerosol vertical distribution and scattering/absorbing parameters. In this study, we investigate the effect of these two assumptions on the accuracy of retrieved aerosol optical depth (AOD) using both sensitivity experiments and actual retrieval practices. Using the 6S and Modtran radiative transfer model, we find that the retrieved AOD is very sensitive to the height of absorbing aerosols, and the effect increases with surface albedo. In extreme cases, the error can be as large as 80%. The retrieval results are also quite sensitive to aerosol single scattering albedo, compared to other parameters such as asymmetry parameter and effective radius. Using the aerosol profiles and optical parameters measured by lidar and sunphotometer at the PKU site, we find that the retrieval accuracy can be greatly improved by ~50%. Our results highlight the necessity to refined aerosol profile and optical parameters in the passive retrieval algorithms, possibly through space born lidars and ground based observations.

Thu. May 30, 2019 10:45 AM - 12:15 PM JST | Thu. May 30, 2019 1:45 AM - 3:15 AM UTC | 302 3F

## [A-CG34] Satellite Earth Environment Observation

convener:Riko Oki(Japan Aerospace Exploration Agency), Yoshiaki HONDA(Center for Environmental Remote Sensing, Chiba University), Yukari Takayabu(Atmosphere and Ocean Research Institute, the University of Tokyo), Tsuneo Matsunaga(Center for Global Environmental Research and Satellite Observation Center, National Institute for Environmental Studies), Chairperson:Nobuhiro Takahashi(Institute for Space-Earth Environmental Research, Nagoya University)

In recent years, we cannot avoid facing issues on global environmental changes that occur in various spatiotemporal scales. The earth environmental observation data by satellites became the necessary basic data to tackle and solve those issues. Due to the recent advancement in the observation sensor technique and the data processing technique, the satellite observation has been showing rapid progress, and the time is changing from examining the accuracy of the observation sensor data to the advancement of the data application, leading to broaden potential users. In these days application became synergetic, so we comprehensively pick<br/>up this topic in the Atmospheric and Hydrospheric Sciences Session of this Union Meeting that enables to comprise the atmospheric, oceanic and land sciences; by combining the intelligence and the knowledge of the party, we propose a session that aims to prompt further studies towards the issues on earth environmental change, the advancement in the data application and future plans of Earth Observation missions.

# Statistical validation of drop size distribution estimated by GPM/DPR

*Nobuhiro Takahashi[1]

1. Institute for Space-Earth Environmental Research, Nagoya University

The dual-frequency precipitation radar (DPR) onboard Global Precipitation Measurement (GPM) core satellite provides the information of the model parameter of the drop size distribution (DSD) assuming the Gamma type DSD model by using Ku-band (KuPR) and Ka-band (KaPR) radar observations. In the current DPR algorithm introduces $\varepsilon$ (epsilon) as a DSD parameter that is constant in the vertical profile. The $\varepsilon$ is defined as a control parameter in k-Z relationship as $k=\varepsilon \alpha Z^{\wedge}\beta$, where k is specific attenuation in (dB/km) and, $\alpha$ and $\beta$ is constant value, respectively. Therefore, once $\varepsilon$ and Z are determined, DSD (and then R) and Z(Ku) - Z (Ka) relationship are determined.

The purpose of this study is to evaluate $\varepsilon$ estimated from DPR algorithm by statistical approach. In this study, two methods are implemented: 1) Histogram matching between Z from KuPR and KaPR, and 2) Estimation of $\varepsilon$ from PIA-zeta relationship that can be calculated both KuPR and KaPR individually (single frequency method).

Data used in this study are DPR level-2 (Matched swath) in 2015, 2016 and 2017. Before applying the methods, backscattering database for Ku, Ka and W band using Mie theory and Z(Ku)-Z(Ka), Z(Ku)-Z(W) table for various $\varepsilon$ ranging from 0.3 to 2.0 with 0.05 intervals, are prepared.

The histogram method compares histograms of Z (Ku) and Z (Ka). In this analysis, the average $\varepsilon$ at a certain area (e.g. 10 x 10 degrees box in latitude and longitude) represent the typical value of the area. Since the difference in the histograms of Z both from the KuPR and KaPR reflects the difference in Mie effect between KuPR and KaPR and therefore $\varepsilon$ represents the corresponding DSD model. In other words, if we know the $\varepsilon$, we can reproduce the KaPR histogram from KuPR histogram. In this analysis, starting from KuPR histogram, the most appropriate KaPR histogram is tried to find by changing the $\varepsilon$. The advantage of this approach is that $\varepsilon$ can be estimated various height (e.g. 1 km, 2 km) if the both KuPR and KaPR data exist. This method, however, is not independent estimation of $\varepsilon$ from the standard algorithm of DPR because this method uses the attenuation corrected Z by the standard algorithm that implicitly include the $\varepsilon$. For the calculation of $\varepsilon$, exceedance probability of Z histogram is used. This method can be utilized for different orbital sensors such as the comparison between CloudSat and TRMM/PR.

The next method is to utilize the path integrated attenuation (PIA)- zeta($\zeta$) relationship (regression method). According to Iguchi et al. (2000),
$1-10^{\wedge}(-PIA\beta/10)=\varepsilon\zeta$, where $\zeta$ is the integral of specific attenuation using the observed Z(Zm) instead of attenuation corrected Z multiplied by $0.2\ln(10)\beta$. PIA is estimated by the observation of the surface echo (surface reference method). By making a scatter plot of $1-10^{\wedge}(-PIA\beta/10)$ and $\zeta$, $\varepsilon$ corresponds to the slope of this plot. The slope in Ku-band corresponds to the $\varepsilon$ in this study. Ka-band epsilon is calculated using the same k-Z relationship with Ku-band.

The $\varepsilon$ estimated by these two methods are compared with the average value of $\varepsilon$ from standard algorithm. Basically $\varepsilon$ from both methods correlate well with the $\varepsilon$ from the standard algorithm. Note that the variance $\varepsilon$ from the regression method is twice large as the standard algorithm. This result may be

©2019. Japan Geoscience Union. All Right Reserved. 

caused by that the standard algorithm not to determine the $\varepsilon$ under less attenuated situation. The regression method can be utilized to assess the k-Z relationship between Ku and Ka and the histogram method of various height indicates the constant $\varepsilon$ of the throughout the profile may not be valid.

# Impact study of DPR SLH nudging method for data assimilation in the JMA Local NWP system

*Yasutaka Ikuta[1]

1. Japan Meteorological Agency

GPM DPR Spectral Latent Heating (GPM-SLH) profile is a very valuable product with three-dimensional latent heating information of precipitation system. The data assimilation of this GPM-SLH is expected to improve the precipitation prediction in numerical weather prediction. The impact of SLH data assimilation is investigated in the Local NWP system which includes the high-resolution numerical prediction model called Local Forecast Model (LFM) of Japan Meteorological Agency.

The purpose of the operation of LFM is to provide information on very-short range precipitation forecast and aviation weather forecasting. The initial condition for the LFM is created by hourly data assimilation in the Local NWP system because the forecast immediacy is important for the achievement of the LFM's aims. Thus the forecast of LFM from the initial condition has latest information of real atmosphere by the hourly assimilation. However, this data assimilation system consists of simple 3D-VAR combined with prediction which is capable of performing speedy calculation for rapidly updating the forecast.

GPM-SLH nudging method corrects the latent heating in cloud microphysics scheme while the numerical prediction model is running in the assimilation window. It is a very efficient method that can input SLH information into the model with keeping immediacy of forecast. In the Local NWP system, the nudging method was implemented and impact studies of SLH assimilation were conducted in typical cases of mid-latitude precipitation system. In this presentation, I will show the result of impact study of GPM-SLH assimilation and the problems to be addressed.

# Precipitation Extremes Monitoring using Global Satellite Mapping of Precipitation (GSMaP) Product

*Takuji Kubota[1], Tashima Tomoko[1], Riko Oki[1], Tomoaki Mega[2], Tomoo Ushio[2]

1. Earth Observation Research Center,Japan Aerospace Exploration Agency, 2. Department of Aerospace Engineering, Tokyo Metropolitan University

Natural hazards caused by weather and climate tend to increase in recent years, and it is recognized that there is a need to better utilize and improve the monitoring of extreme weather and climate events from space. Recently, satellite-based precipitation datasets have been developed to achieve higher spatial and temporal resolutions using combined data from passive microwave (PMW) sensors in low Earth orbit and infrared (IR) radiometers in geostationary Earth orbit. Global Satellite Mapping of Precipitation (GSMaP) is a blended PMW–IR precipitation product and has been developed in Japan for the Global Precipitation Measurement (GPM) mission. In this study, detections of drought and heavy precipitation events are examined using standardised precipitation index (SPI) and a statistical value, to demonstrate a capability of the GSMaP. Such efforts will contribute to precipitation extremes monitoring activities using satellite data, such as the World Meteorological Organization (WMO) Space-based Weather and Climate Extremes Monitoring Demonstration Project (SEMDP) with focus on monitoring drought and heavy precipitation in countries of the South-East Asia and the Pacific.

In this study, GSMaP Near-real-time Gauge-adjusted Rainfall Product (GSMaP_Gauge_NRT) for algorithm version 6 is used. This product is adjusted using an optimization model with parameters calculated from data during the past 30 days. As for weather and climate extremes, here it is defined as an extreme precipitation, when a mean rainfall for a specified period is higher than a threshold based on the percentiles (ex. 95th, 99th percentile). Whereas, drought is diagnosed based on SPI over 1, 2 and 3 months. Percentiles and SPI are calculated in 0.1x0.1 grid at lat/lon resolution from the dataset during 18 years from April 2000 to March 2018. To demonstrate feasibilities of GSMaP_Gauge_NRT (v6) for climate extremes monitoring, we evaluated past cases of drought and heavy rainfall.

The first case is drought in south-eastern Australia during July-September 2007. A drought area where 3-month SPI is less than -1.2 spreads widely around the south of Australia. The detected drought area is roughly consistent with an area above 9$^{th}$ decile (Very Much Below Average) shown by the Bureau of Meteorology (BoM) in Australia. However, because there are few rain gauges in Western Australia’s eastern part, distributions between both are different. The second case is heavy rainfall events in western and eastern Australia in December 2010. Monthly mean precipitation exceeds 95$^{th}$ percentile in western and eastern Australia. These detected heavy rainfall area roughly corresponds to an area below 2$^{nd}$ decile (Very Much Above Average) shown by the BoM. The last case is heavy rainfall events in Malay Peninsula in December 2014, which extreme rainfall caused widespread flooding over Thailand and the east coast of Peninsular Malaysia. Time-fluctuation of GSMaP_Gauge_NRT (v6) daily precipitation averaged over these areas is roughly in good agreement with that of CPC Gauge Analysis. A series of heavy rainfall events beginning on 14 December 2014 can be confirmed from space-based observations. Especially, pentad precipitation for 22-26 December 2014, is higher than 99$^{th}$ percentile over large portion of Peninsular Malaysia. Actually, floods caused by heavy rain hit in this area.

# Estimation of cloud water content over land using satellite-based passive microwave observations with a coupled land and atmosphere assimilation method

*Rie Seto[1], Shinjiro Kanae[1]

1. Tokyo Institute of Technology

We proposed a method to estimate the cloud water content (CWC) over land at multiple-kilometer resolutions and to concurrently assimilate the estimated CWC into the model by using multi-frequency satellite-based passive microwave brightness temperatures (TBs) and coupled land and atmosphere assimilation.
The need for a better understanding and more accurate representation of clouds in atmospheric models has been apparent for decades. However, a lack of sufficient observations and reanalysis products is a major obstacle. The use of TBs is an effective way to retrieve CWC of extensive and heterogeneous cloud systems all at once, but it is challenging to estimate CWC over land due to complexities of cloud processes and uncertainties in strong and heterogeneous land emissions. Our method overcomes the difficulty of retrieving clouds over land from TBs and representing them in models by simultaneously optimizing land emissions and CWC over land, and assimilating the estimations into models.
The estimated CWC was in good accordance with vertical two-dimensional products of CloudSat in terms of cloud water path and the vertical distribution of CWC. In addition, we examined the uncertainties of this method by sensitivity analysis of CWC estimates of TBs and cloud top height. The results suggested that the error in TBs is not large, and that cloud top height affects the estimated CWC more sensitively than TBs. The addition of cloud top height information from other satellite observations as a constraint of optimization allows further improvement of the vertical distributions of CWC.
This study revealed that the proposed method has great potential to provide unprecedented data for CWC with adequate accuracy, which are continuously distributed over land and ocean.

# Ensemble-Based Data Assimilation of GPM/DPR Reflectivity into the Nonhydrostatic Icosahedral Atmospheric Model NICAM

*Shunji Kotsuki[1], Koji Terasaki[1], Takemasa Miyoshi[1]

1. RIKEN Center for Computational Science

This study aims to improve the precipitation forecasts from numerical weather prediction models through effective assimilation of satellite-observed precipitation data. The assimilation of precipitation data is known to be difficult mainly due to highly non-Gaussian statistics of precipitation-related variables. We have been developing a global atmospheric data assimilation system NICAM-LETKF, which comprises the Nonhydrostatic ICosahedral Atmospheric Model (NICAM) and Local Ensemble Transform Kalman Filter (LETKF). Using the NICAM-LETKF system, Kotsuki et al. (2017, JGR) successfully improved the weather forecasts by assimilating the Japan Aerospace eXploration Agency (JAXA)' s Global Satellite Mapping of Precipitation (GSMaP) data into the NICAM at 112-km horizontal resolution. However, assimilating space-borne precipitation radar data remains to be a challenging issue.

This study pioneers to assimilate radar reflectivity measured by the Dual-frequency Precipitation Radar (DPR) onboard the Global Precipitation Measurement (GPM) core satellite into the NICAM. We conduct the NICAM-LETKF experiments at 28-km horizontal resolution with explicit cloud microphysics of a single-moment 6-class bulk microphysics scheme. To simulate GPM/DPR reflectivity from NICAM model outputs, the joint-simulator (Hashino et al. 2013; JGR) is used. Our initial tests showed a better match with the observed reflectivity by assimilating GPM/DPR reflectivity into NICAM forecasts. However, the results from a 1-month data assimilation cycle experiment showed general degradation by assimilating GPM/DPR reflectivity. For better use of GPM/DPR reflectivity data, we are exploring to estimate model cloud physics parameters by assimilating them. This presentation will include the most recent progress up to the time of the meeting.

# An ecohydrological land reanalysis by integrating simulation and satellite observations

*Yohei Sawada[1], Tosiyuki Nakaegawa[1], Kozo Okamoto[1], Takeshi Iriguchi[1], Hideyuki Fujii[2]

1. Meteorological Research Institute, 2. Japan Aerospace Exploration Agency

Monitoring terrestrial water, energy, and ecosystem is crucially important to understand global environmental changes. Land reanalysis, in which a land surface model (LSM) is driven by bias-corrected atmospheric forcing based on an atmospheric reanalysis dataset, has greatly contributed to generating the long-term and spatiotemporally homogeneous dataset of terrestrial environmental condition. Here we propose a new land reanalysis called ECoHydrological Land reAnalysis (ECHLA). Compared with the other existing land reanalyses, the characteristics of ECHLA are: (1) ECHLA can simulate not only water and energy, but also vegetation dynamics; (2) ECHLA is generated by sequential data assimilation of satellite microwave observation, which is sensitive to soil moisture and vegetation water content, into a LSM; (3) ECHLA can quantify the uncertainty in its simulated variables by an ensemble method. In this presentation, we will show the concept of ECHLA and the preliminary results of the validation of the ECHLA’ s prototype and its application to drought quantification.

# Impact of usage of multiple-satellite sensors on accuracy of daily-mean sea surface wind data

*Ayumi Koizumi[1], Masahisa Kubota[2], Kunio Kutsuwada[3], Hiroyuki Tomita[4], Tsutomu Hihara[5]

1. Tokai University, 2. Tokai University, Institute of Ocean Research and Development, 3. School of Marine Science and Technology, Tokai University, 4. Institute for Space-Earth Environmental, Nagoya University, 5. Japan Agency for Marine-Erth Science and Technology

Most satellites observing sea surface winds have sun-synchronous orbits and provide observation data at the same place two times per a day. We can expect that daily-mean values estimated from these data have some errors when diurnal changes in wind field cannot be neglected. For this problem, use of multiple satellites is helpful. Since the number of sensors used to construct daily-mean data is different among the years, it is expected that the accuracy of a daily-mean value changes from year to year.

The purpose of this study is to describe time variation of accuracy in daily-mean wind data in the Japanese Ocean Flux Data Sets with Use of Remote Sensing Observation (J-OFURO)-3 and to investigate its causes by comparing with in-situ measurement data by moored buoys and calculating three statistical values.

Results reveal that the statistical values are improved with year. To examine the relationship between the yearly statistics and the yearly number of satellite sensors, we plotted a scatter diagram between the number of satellites and three statistical values in each year. We found that the correlations between them are very high. We also focused on a time interval of the satellite wind observation, namely maximum missing time within a day. The result showed that the correlation between three statistical values and maximum missing time intervals is high. Since the relation between these two factors is not independent, we analyzed by considering both factors together. First, we chose five buoys with various standard deviations for a daily-mean value. Next, we picked up data from buoy's hourly data using random numbers, and calculated the daily mean value using the random data, and then determined the number of observations and the maximum missing time interval each day. Assuming the daily mean value calculated from 24 hourly data as a true value, the RMSE between this true value and the daily mean created from random data was calculated. From the result of this analysis, it was found that the value of Root Mean Square Error(RMSE) depends on the maximum missing time interval rather than the number of observations. Furthermore, when RMSE was normalized by standard deviation, the same figures were obtained for all buoys. This result implies that the RMSE of the daily mean value of the buoy station can be estimated if the magnitude of diurnal variation is known by giving the number of satellites used for observation and the maximum missing time interval, Moreover, by applying this result, we think that it is possible to show the optimal number of sensors and observation time for target accuracy. This result gives very breakthrough information to the design of the satellite observation system for sea surface wind.

# Temperature and Size Variability of Warm Pools in the Global Oceans

*ChunYi Lin[1]

1. National Museum of Marine Science & Technology

Using advance satellite-derived Sea surface height anomaly, sea surface temperature (SST) data, and heat flux data, we investigate the thermal variability, temperature and size variability of warm pools in the global oceans, the Pacific, the Atlantic, and the Indian Ocean, respectively. Because of the high density and specific heat of seawater, water can store and transport large amounts of heat. High SST has particular influence on global climate system. Furthermore previous studies focused on the global warming or area warming, in this investigation we present results of warm pool SST binned into 1 ˚C interval. Detecting temperature and size variability of warm pools in the global oceans, it suggests that the high SST area (SST ≧ 28˚C) has faster increasing rate than surrounding area (SST 20˚C - 27˚C) in the global oceans, the Pacific, the Atlantic, and the Indian Ocean, respectively. To understand the role of surface heat flux in the tropical SST fluctuation, we analyze the mixed layer heat balance equation. Upper ocean heat budget between the heat advection and heat diffusion term are compared and heat diffusion processes may be a mechanism for transporting excessive amount of heat that the warm pool through enhancing the SST gradient around the edge of the warm pool. In order to find out dominant period components and the relationship of energy-frequency distribution without influenced induced by nonlinear and nonstationary signals, the Hilbert-Huang Transform applied by ensemble empirical mode decomposition is employed. The ensemble empirical mode decomposition analysis indicates that the interannual component has strong influence on the variability of the warm core pool in the Pacific, presumably because of the presence of El Niño phenomenon, while the annual cycle dominates the variability in the Indian and the Atlantic Ocean.

# Sea surface temperature from SGLI aboard the GCOM-C satellite of JAXA

*Yukio Kurihara[1], Kazunori Ogata[2], Hiroshi Murakami[2], Misako Kachi[2]

1. Tripli-I Co., Ltd., 2. JAXA EORC

The Global Change Observation Mission-Climate (GCOM-C) satellite, which is one of two satellites for the GCOM mission of the Japan Aerospace and Exploration Agency (JAXA), was launched on 23 December 2017. The Second Generation Global Imager (SGLI) is the optical sensor aboard GCOM-C which consists of two components: the Visible and Near-infrared Radiometer (VNR) and the Infrared Scanner (IRS). SGLI has switchable spatial resolution from 250 m x 250 m to 1 km x 1 km. The resolution of 250 m x 250 m is expected to reveal complicated structure of geophysical parameters. Sea surface temperature (SST), which is one of the important parameters in the geophysical field, is also determinable by using split window data of SGLI. SGLI SST is retrieved by utilization of newly developed cloud masking method and a modified SST method originally developed for Himawari-8. Considering combined utilization of satellite SSTs, the methods developed for SGLI SST will be applied back to Himawari-8 data as well as the data from the Visible Infrared Imaging Radiometer Suite (VIIRS) aboard the Suomi National Polar-orbiting Partnership (Suomi NPP) satellite. SGLI SST is validated by comparison with buoy data. The comparison result shows RMSD of ~0.4 K, good agreement between SGLI SSTs and buoy data. Triple comparison with Himawari-8 and VIIRS SSTs is being started. Operational retrieval of SGLI SST started at the end of 2018. The products are available at the G-Portal site of JAXA and the JAXA Satellite Monitoring and Environmental Studies (JASMES) site of the Earth Observation Center (EORC) of JAXA.

# Concept of small satellite UV/visible imaging spectrometer optimized for tropospheric $NO_2$ measurements in air quality monitoring

*Tamaki Fujinawa[1,5], Katsuyuki Noguchi[2], Akihiko Kuze[3], Andreas Richter[4], John P. Burrows[4], Andreas C. Meier[4], Tomohiro Sato[1], Takeshi Kuroda[1], Naohiro Yoshida[5], YASUKO KASAI[1,5]

1. National Institute of Information and Communications Technology, 2. Nara Women's University, 3. Japan Aerospace Exploration Agency, 4. University of Bremen, 5. Tokyo Institute of Technology

Satellite observations at nadir can potentially facilitate a better understanding of the emissions and distribution of tropospheric nitrogen dioxide, $NO_2$. The identification of emissions requires adequate spatiotemporal resolution measurements of the total column amounts of $NO_2$. The spatial resolution of previous and current observations is insufficient for the identification of $NO_2$ hot-spots. Switching to a spatial resolution of ~1 km x ~1 km can improve the identification of local sources of $NO_2$ and their emissions. To investigate the feasibility of observations with such a high spatial resolution, we simulated radiance spectra for different cases under varying parameters, such as area, season, satellite altitude, and surface reflectance by using the radiative transfer model SCIATRAN. We subsequently retrieved $NO_2$ slant column densities (SCDs) using the differential optical absorption spectroscopy (DOAS) technique with several fit windows. For test cases associated with polluted conditions, we found that the conceptual nadir-observing instrument on a satellite at an altitude of ~300 km involved the lowest retrieval errors for signal-to-noise ratios of around 1000 with accuracy better than the required 5% for tropospheric $NO_2$ SCD and that the fit window of 425--497 nm met the scientific requirements for both surface reflectance cases.

# Analysis of the Surface Echo Characteristics Derived from GPM/DPR Wide Swath Observation Experiment

*Kosuke Yamamoto[1], Kinji Furukawa[1], Nobuhiro Takahashi[2], Takuji Kubota[1]

1. Japan Aerospace Exploration Agency, 2. Nagoya University

The observation from spaceborne precipitation radar has been contributed to better understanding of earth climate system. Global Precipitation Measurement (GPM) core satellite Dual-frequency Precipitation Radar (DPR) provides us 3-dimentional information of precipitation by the scan width of about 250 km, but there have been arguments that to bring systematic impact on the weather monitoring through global rainfall map such as GSMaP, wider swath observation by precipitation radar is necessary.

Based on those requirements, the scan pattern of GPM/DPR was experimentally changed for 1 day from 13UTC on September 26th. In this experiment, the scan angle was changed to observe from nadir to about +34˚ assuming future spaceborne precipitation radar with wider swath width, while in the normal observation DPR scans ±17˚. The height and strength of the mainlobe clutter with larger incident angle were assessed statistically to examine the possibility of the rainfall retrieval with wide swath observation by DPR.

In order to examine mainlobe clutter height, it is inevitable to reduce sidelobe and grating lobe effect. In this study, clutter-free observation data is extracted based on following procedures; 1) extract bins above mainlobe clutter; 2) extract bins under non-precipitation condition from 1); 3) extract bins that satisfy |received power −averaged noise power| < 2 sigma of the noise power from 2). Note that this procedure was applied only for KuPR observation since sidelobe and grating lobe clutter is not prominent in KaPR.

The result for KuPR observation shows that the mainlobe clutter top height at the larger incident angle over ocean is somehow suppressed at around 4 km while over land it increases almost linearly up to around 5 km due to the strong surface scattering. The same tendency is found on the KaPR observation, but it has lower clutter top height of around 2.5 km and 3.5 km, over ocean and land respectively. Suppression is clearer over ocean thanks to the specular reflection. The results also indicate that relatively intense rainfall can be retrieved while shallow rainfall with weak echo power may not be acceptable for retrieval because it should be masked by the surface clutter.

# The Recent Results from the Global Precipitation Measurement (GPM) mission in Japan

*Riko Oki[1], Takuji Kubota[1], Kinji Furukawa[1], Yuki Kaneko[1], Moeka Yamaji[1], Kosuke Yamamoto[1], Toshio Iguchi[2], Yukari Takayabu[3]

1. Japan Aerospace Exploration Agency, 2. NICT, 3. the University of Tokyo

The Global Precipitation Measurement (GPM) mission is an international cooperate satellite project to achieve highly accurate and highly frequent global precipitation observations. The GPM mission consists of the GPM Core satellite jointly developed by the U.S. and Japan and Constellation Satellites that carry microwave radiometers and provided by the GPM partner agencies. The GPM Core satellite carries the Dual-frequency Precipitation Radar (DPR) by the Japan Aerospace Exploration Agency (JAXA) and the National Institute of Information and Communications Technology (NICT) and the GPM Microwave Imager (GMI) provided by National Aeronautics and Space Administration (NASA). The GPM Core satellite was launched in February 2014 and achieved its prime mission period planned for 3 years in 2017.

It has been continuing its observation as the extended mission phase after that.

JAXA develops the DPR Level 1 algorithm and the NASA-JAXA Joint Algorithm Team develops the DPR Level 2 and DPR-GMI combined Level 2 algorithms. The DPR, the DPR-GMI combined algorithms and the latent heating algorithm were updated, and those products were released in October 2018 as Version 0.6. Using dual frequency information of DPR, the latest Level 2 products include information such as precipitation phase at surface, heavy ice precipitation and so on. Also, the calibration factors of TRMM/PR were re-examined to have consistency between DPR/Ku. The same GPM Ku-band radar L2 algorithm now applies to the TRMM/PR, so that the long radar precipitation data exceeding more than 20 years are now available. From May 2018 in the extended mission period, the scan pattern of the Ka-band radar has been changed to realize matched beam observation in full swath. The new algorithm applying to the changed scan pattern is now under development.

JAXA also develops the Global Satellite Mapping of Precipitation (GSMaP), that is hourly and 0.1-degree horizontal resolution global rainfall map. It is available through the “JAXA Global Rainfall Watch” website (https://sharaku.eorc.jaxa.jp/GSMaP/index.htm). GSMaP product family includes different data latency products and rain gauge calibrated products and so on. The GSMaP near-real-time version (GSMaP_NRT) product provides global rainfall map in 4-hour after observation, and an improved version of GSMaP near-real-time gauge-adjusted (GSMaP_Gauge_NRT) product has been released since Dec. 2018.

The GSMaP real-time product called GSMaP_NOW now product is providing data at the earliest timing. It has been realized using the geostationary satellite Himawari-8 operated by the Japan Meteorological Agency (JMA) since November 2015. Since Nov. 2018 the domain of GSMaP_NOW has been extended to the region of the geostationary satellite Meteosat operated by the European Organization for the Exploitation of Meteorological Satellites (EUMETSAT) in November 2018. JAXA is further developing the GSMaP_NOW to provide global real-time rainfall product.

# Verification of Global Satellite Mapping of precipitation (GSMaP) for providing its error information

*Moeka Yamaji[1], Takuji Kubota[1]

1. Earth Observation Research Center, Japan Aerospace Exploration Agency

Precipitation is one of the most essential parameters in the Earth system. Due to address water issues like water shortage or floods, JAXA has developed and provided Global Satellite Mapping of Precipitation (GSMaP), which is hourly global precipitation dataset. It is under the Global Precipitation Measurement (GPM) mission and contributes.
GSMaP allows us to capture the hourly horizontal distribution of precipitation with good latency after observation. The spatial resolution is 0.1 x 0.1 degrees latitude/longitude. It has been used for various kinds of utilization purposes.
In terms of accuracy, GSMaP algorithms were updated in several times, and GSMaP has been getting more accurate day by day, however, it is known that the inhomogeneous of accuracy is existed depending on algorithm characteristics. It has been needed to provide information about the uncertainty and accuracy of GSMaP by users.
In this study, verification result of GSMaP near-realtime product version 6 (GSMaP_NRT) is reported. The radar/raingauge analysed precipitation data by Japan Meteorological Agency, which is an hourly rainfall analysis generated from ground-based precipitation radars corrected by automated rain gauges, are used as the reference data. Since the purpose of this study is for providing generalized error information, root mean square errors (RMSE) is statistically calculated for each precipitation level and each reliability flag during May-June-July-August-September-October in 2015-2018. Some initial results showed that the RMSE qualitatively represented the error for each precipitation level and reliability flag. The RMSE ratio to the average precipitation rate got larger as the precipitation rate became smaller while it became stable around 60 –80 % when precipitation rate was more than 10 mm/h. We report the validation results in detail, such as land/ocean difference or sampling dependence, and focus on the effectiveness of it.

# Detection of the mixed phase top using the measured dual-frequency ratio of reflectivity with GPM/DPR

*Yuki Kaneko[1], Toshio Iguchi[2]

1. Japan Aerospace Exploration Agency, 2. National Institute of Information and Communications Technology

The core observatory of the Global Precipitation Measurement (GPM) mission was launched in 2014 and has been observing rain and snow between 65˚S and 65˚N by the Dual Frequency Precipitation Radar (DPR) and the GPM Microwave Imager (GMI). The DPR provides three-dimensional structure of storms derived from reflected energy from precipitation particles. Precipitation echoes at the two frequencies of the DPR, Ka-band (25GHz) and Ku-band (14GHz), make it possible to infer the mean size and physical property of precipitation particles. The swath width of Ka-band scanning was 125 kilometers centered at nadir and was nested within the Ku-band’ s wider scan width of 254 kilometers. On May 21 2018, the Ka-band scan pattern was changed to match with the Ku-band’ s. Dual frequency radar reflectivity factors are available for full swath of 254 kilometers now.

The classification (CSF) module in the standard DPR level2 algorithm detects a bright band (BB) and classifies precipitation into three types, stratiform, convective, and other. Rain types affect the retrievals of rain amount and latent heating in the DPR algorithm. Accurate classification is also important in the Global Satellite Mapping of Precipitation (GSMaP) algorithm because it affects the rain profile database used in the rain retrieval with microwave radiometers. The BB detectability by the standard CSF algorithm is lower at and near the swath edges than near nadir because only Ku-band data was available in the outer swath before and because slant incidence of radar beams smears the vertical profiles.

As the Ka-band scan pattern has changed to cover the full swath, we can apply a dual-frequency method to detect a BB now. We have developed a method that uses the dual frequency ratio (DFR) to detect the mixed phase top. It looks at the slope of DFR as a function of range to identify the transition height from ice to water. DFR itself is estimated from measured DFR (DFRm) with attenuation correction. Preliminary experiments show that the developed method can detect the BB in stratiform rain over the swath almost uniformly. This method also has a potential to identify the transition height even in some convective cases. In this research we evaluate the performance of the algorithm by comparing the altitude of BB and the transition height with those estimated by using X-band multi-parameter radar (XRAIN) data.

# Comparison between high frequency satellite rainfall estimation and APHRODITE-2 ground rain gauge observation

*Hitoshi Hirose[1], Koichi Toyoshima[1], Atsushi Higuchi[1], Akiyo Yatagai[2], Natsuko Yasutomi[3]

1. Center for Environmental Remote Sensing, Chiba University, 2. Hirosaki University, 3. Disaster Prevention Research Institute, Kyoto University

APHRODITE project collects daily precipitation observation data from ground rain gauges in each country, and then performs appropriate quality control and converts it into gridded data. APHRODITE holds long-term data from the 1960s to the present and focuses on analyzes such as changes in characteristics of extreme rainfall due to long-term climate change. However, ground-based daily rain observations has a problem which end of the day (EOD) in each country is different from each other. To estimate the EOD in each country, we developed a Rain Potential Map (RPM) which is a product that can estimate global rain probability using geostationary meteorological satellites (GEO) (Hirose et al., 2016, JMSJ). In this study, we used the RPM, GSMaP and CMORPH which are global satellite rain estimation data based on microwave satellite and GEO observations.

Since the above satellite rainfall observation data can estimate global precipitation every hour, it is possible to create daily average data in which the average section is shifted by one hour. By correlating the satellite daily precipitation observation time series with the APHRODITE daily precipitation observation time series, the EOD value in each country was estimated from the time when the correlation coefficient is largest. We confirmed that the reliability of this method is high by a verification analysis in the field where true value of EOD is already known. Moreover, we made pseudo hourly rain time series of APHRODITE by inserting APHDOITE daily rain time series to satellite hourly rain time series. By this method, we will try to make a new APHRODITE data that is corrected for the EOD difference between each country.

# Development of the high resolution GSMaP by the Himawari-8

*Tomoaki Mega[1], Tomoo Ushio[1]

1. Tokyo Metropolitan University

There is a new generation infrared (IR) imager on new-generation gestationary weather-satellite such as the Himawari-8 and the Geostationary Operational Environmental Satellite-R series. The imagers observe multi-channel passive imaging radiometer. The imagers observe wave a full disk with several km in about ten minutes. In Near-future, the IR imager observation should cover the globe.

Global precipitation information is an important tool for water management or earth science. Spaceborne sensors is one of the most convenient tools of global observation. The sensors cover global and provide uniform quality data. Precipitation estimation use microwave radiometer in low earth orbit (LOE). A microwave radiometer has high spatial resolution. However, one drawback of the microwave radiometer in LOE is narrow observation area. Whole earth observation by a microwave radiometer on a LOE satellite need some days. Therefore, global precipitation map is made from combined satellite data. However, combined data of microwave radiometer on LOE don’ t cover global in one hour. One of the global precipitation map is the Global satellite mapping of Precipitation (GSMaP). Precipitation estimation of the GSMaP made from microwave radiometer data. The GSMaP Moving Vector with Kalmanfilter (MVK) and Near real time compensate precipitation of no observation area by IR information. Spatial and temporal resolution of the GSMaP MVK achives 0.1 degree and one hour. This study shows downscale technique for GSMaP precipitation map by High-spatial and temporal resolution IR data of the Himawari-8. IR datasets of Himawari-8 are available every 2.5 minutes in the Japan region. In the presentation, we will also show validation the high resolution GSMaP and ground-radar network in Japan.

# Preliminary results of on-orbit estimation for polarization sensitivity of GCOM-C/SGLI

*Risa Miyazaki[1], Hiroshi Murakami[1], Masahiro Hori[1]

1. Japan Aerospace Exploration Agency

The GCOM-C has been launched successfully on 23th Dec. 2017 from the Tanegashima Space Center by H-IIA vehicle No.37. After the initial calibration/validation phase of one year after launch, all SGLI standard products have been released from JAXA’s data providing service (G-Portal) from Dec. 20, 2018.

In generally, the radiance reflected by the sea surface and the atmosphere is strongly polarized. When observing a large polarized light, the output radiance vary from the actual radiance because of the polarization sensitivity characteristic of the optical sensor. Especially for ocean color products, it is important to evaluate the effect of polarization sensitivity because it is necessary to extract the weak water-leaving reflectance (<10% of the whole) by the accurate atmospheric correction.
The polarization sensitivity of GCOM-C/SGLI of each NP (Non-Polarization) band has been measured in the pre-launch ground test. The ground test results of polarization sensitivity were shown to be <3.5% on average in the pixel direction in all bands. In this study, we evaluate whether the polarization sensitivity estimated from on-orbit observation data is consistent with the pre-launch test results. In this work, we report on the RED bands (VN07, VN08) and the NIR bands (VN10, VN11) of SGLI.
Polarization sensitivity on-orbit was evaluated based on Gordon and Zhang (1997) and Meister et al. (2005). We use the observation data by SGLI/PL (Polarization) band to estimate the real stokes vector components at the top of atmosphere (TOA). In order to obtain the polarization sensitivity with respect to directly observed radiance at TOA, L1B before inter-pixel sensitivity correction and before inter-telescope sensitivity correction was self-made from L1A data.
We analyzed the observation data of 12 path that PL band is observed nadir direction. The characteristics of the instrument for polarization sensitivity (polarization factor) were estimated by the least squares method. On the east side of the observation image, the error is large because of Sun-Glint. Although the variation in the pixel direction was still large, the estimated polarization factors (3 to 5 %) were consisted with the prelaunch ground test (~ 3.5%). However, sensitivity patterns in the pixel direction could not be identified, so we will continue to improve the evaluation in the future.

# Analysis of SGLI validation datas based on the effects of the growth and ground types for the AGB development

*Ryota Ishibashi[1], Koji KAJIWARA[1], Yoshiaki HONDA[1]

1. Center for environmental remote sensing, Chiba University

The effects of the earth of the time variant system should be difficult to detect the influence of the growth types and also the effects of the growth field’s variations. The research may occur the SGLI’s RSRF datas of the calculated AGB data accuracy analysis that observed between every kinds of the growth and also the ground types. The significance area of the SGLI observed, each of detected datas accuracy have to be considered. We show observation ways for the ground truth of the reflectance, LAI and fAPAR. The first case we use is a case of vegetation at the grassland. And then, based of reflectance values, we compare the other type as the Mixed coniferous forest example. The influence of an effect of the type of growth may occur the reflectance of the distributed area. We will detect these effects of the growth type. The influence at the observed area be necessarily to be verified.

The research topic includes the ground truth observation for the accuracy verification of a SGLI data obtained. For development of ground truth, the way to obtain datas were important. This paper explains how to examine growth (such as a second growth forest and other) and the slope factor of the second growth forest area and also the reflectance of each forest types. Then, this paper make ground truth observation scheme for the high accuracy AGB referenced data development at ground cover area. We explain the method of examine the error detection way including observation devices and also the problem of the research topic to be examined. Results may occur an example case of such kinds of the sloped forest and the kinds of the plane. The results shows a typical difference between the sloped and the plane, and then the results may occur the possibility that comparison of standard deviation may be an effective way to detect the volume of the forest type between every ground truth.

The case of we use as the sloped fields, reflectance of each wavelength were low and then the near 400 to 700 nm area will be higher than other wavelength (ANOVA values of results: $p < 0.001$). And then, we can see the effects of slope should be detected at total values of the reflectance. The reflectance of a wavelength were obtained that aimed to detect the verification of the slope and the growth type’s reflectance. When the mixed coniferous forest, static observation develop same reflectance values but the effect of the sloped factor occur the high value of the standard deviations. Then, our method applied to the method of the SGLI’s data calculation scheme, and then the growth factor of the area be affects the influence of the from 400 to 700 nm wavelength and also the factor of slope region be affects the wavelength of reflectance. SGLI data analysis, the factor of these parameters were used to remake the size of RSRF data from 250 m to 1000 m resolution. The future, we investigate more and then, the mask area of high value difference around the nearest 16 pixels be considered. Datas were significant at some pixels, such as a steep sloped, growth types, or error detected area. Data development of RSRF, the reflectance of each cells are detected as the values of the every ground types by the standard deviation.

# Remote sensing of aerosol optical properties and water-leaving radiance based on the optimal estimation approach

*Chong Shi[1], Teruyuki Nakajima[1], Makiko Hashimoto[1], Hideaki Takenaka[1]

1. Japan Aerospace Exploration Agency

A flexible inversion algorithm is proposed for jointly retrieving aerosol optical properties and water-leaving radiance from multispectral instrument over the ocean. A combined multi-wavelength and multi-pixel constraint approach is used to estimate aerosol and hydrosol over clear and turbid waters, based on the forward simulation from a coupled atmospher-ocean radiative transfer model. This sort of simultaneous inversion helps to correct the biases induced by the neglect of water-leaving radiance in the traditional aerosol retrieval algorithms, in addition, it can provide more aerosol information than the standard ocean color approach. To investigate the availability of current scheme, we conduct the retrieval in the process of MODIS, GOSAT/CAI and GCOM-C/SGLI instruments.

# Aerosol retrieval and PM2.5 from space using GOSAT/TANSO-CAI

*Makiko Hashimoto[1], Hideaki Takenaka[1], Teruyuki Nakajima[1], Akiko Higurashi[2]

1. Japan Aerospace Explortion Agency, 2. NIES

Aerosol in the atmosphere has a great impact not only for the Earth’ s radiation budget and changing the Earth’ s climate, but also on human health. Especially, the fine particle, which is often called PM2.5, has drawn attention as a cause of health damage.

The urban area is a source of anthropogenic aerosol, which is mostly composed of small particles, and the particles are transported to other regions. Satellite remote sensing provides effective means to monitor the atmospheric aerosols in wide area including urban areas.

Accurate retrieval of fine mode aerosol optical thickness (AOT) is necessary to calculate an equivalent value of PM2.5 from space. Therefore, an aerosol retrieval algorithm for satellite remote sensing of urban areas to improve the retrieval accuracy of aerosol properties, which is called MWPM (Multiple wavelengths and pixels method) (Hashimoto and Nakajima, 2017), was developed. The method simultaneously retrieves fine and coarse mode AOT and single scattering albedo by using several wavelengths and spatial difference of surface reflectance. The method is useful for aerosol retrieval over spatially inhomogeneous surface like an urban area.

The algorithm was applied to GOSAT (Greenhouse Gases Observing Satellite) / TANSO-CAI (Cloud and Aerosol Imager, CAI) data. The GOSAT launched ten years ago (on January 23th, 2009) is a satellite to monitor greenhouse gases (GHG) such as carbon dioxide and methane with TANSO-FTS (Fourier Transform Spectrometer, FTS). The CAI is a supplementarysensor of the FTS, detecting cloud and deriving aerosol optical properties.

PM2.5 using retrieved fine mode AOT by MWPM in East Asian region from 2009 was calculated. The poster presents a retrieval result of PM2.5 over the East Asian region from space in several years and discusses the seasonal and annual variations.
Monitoring of aerosol properties such as AOT, PM2.5 and soot mixing ratio over land is added to the mission of GOSAT-2 that was launched on Otober 29th 2018. As a near-future plan, the algorithm will be applied to GOSAT-2/TANSO-CAI-2 data to generate standard PM2.5 data products.

# Establishing a high resolution road fugitive dust emission inventory in Kaifeng City, China

*Yiming Xu[1], Shili Liu[1], Xinyue Cao[1], Xianbao Shen[1], Zhiliang Yao[1]

1. Department of Environmental Science and Engineering, Beijing Technology and Business University

Due to the rapid urbanization and industrialization in many Chinese cities, ambient particulate matter pollution such as road fugitive dust pollution becomes a serious environmental problem. However, the emission of road fugitive dust is relatively difficult to quantify as it is of high uncertainty and spatial heterogeneity. The research aims to build a high resolution road fugitive dust emission inventory which is transferrable and applicable to other cities in China. High spatial resolution images were utilized to digitalize whole road network of Kaifeng City, Henan Province, China. Vehicle flows of the whole road network were estimated by incorporating the whole road network, field measured data and GPS data on an hourly, daily, weekly, monthly and yearly basis at city level. By fusing the road network information, vehicle flow, road dust load, average vehicle weight, a high resolution road fugitive dust emission inventory was established. The results showed that the total emissions of $PM_{10}$, $PM_{2.5}$ and Total Suspended Particulate from road fugitive dust at commuter time and downtown were much higher compared with other time and location in Kaifeng City. The framework of this road fugitive dust emission inventory can be applied to other cities, and it can provide data support and guide fugitive dust management in China.

# A Relationship between Diurnal Change Patterns of Land Surface Temperature and Spatial Configuration of the Osaka Metropolitan Area Captured by Himawari-8

*Yuhei Yamamoto[1], Hirohiko Ishikawa[1]

1. Disaster Prevention Research Institute, Kyoto University

Land surface temperature (LST) is a physical quantity that greatly contributes to the formation of an urban thermal environment. Therefore, understanding the spatiotemporal characteristics of LST is necessary for constructing a sustainable urban environment. The spatial distribution relationship between the instantaneous LST and urban land use has been investigated using polar-orbiting satellite/airborne sensors. This study explored how the urban spatial configuration and meteorological field affect the temporal changes of LST by using Japanese geostationary satellite (Himawari-8) sensor.
The study area is the Osaka metropolitan area in Japan and target days are three days that were clear-sky throughout the day in summer (August 12, 2016, July 19, 2018, and August 4, 2018). We used 100 m-mesh urban land use data and ground-based meteorological observation data to examine the urban spatial configuration and meteorological fields, respectively. The temporal changes of LST are the amplitude and phase mainly forming the diurnal change of LST. These two temporal changes were extracted by applying principal component analysis to the diurnal changes of LST represented by the 10-minute LST dataset retrieved from Himawari-8 data.
Our results showed that the spatial variations in the amplitude and phase corresponded to the penetration time and duration of the sea breeze and the thermal inertia of surface materials. Besides, it was found that the LST change during daytime was larger in the high-density low-building areas than in the low-density low-building areas. This result suggests that the increase in building density increases the LST change during the daytime. These findings lead to a deeper understanding of an urban hot environment and are helpful for urban planning to mitigate the deterioration of a hot environment.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-CG Complex & General

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_12

## [A-CG34] Satellite Earth Environment Observation

convener:Riko Oki(Japan Aerospace Exploration Agency), Yoshiaki HONDA(Center for Environmental Remote Sensing, Chiba University), Yukari Takayabu(Atmosphere and Ocean Research Institute, the University of Tokyo), Tsuneo Matsunaga(Center for Global Environmental Research and Satellite Observation Center, National Institute for Environmental Studies)

In recent years, we cannot avoid facing issues on global environmental changes that occur in various spatiotemporal scales. The earth environmental observation data by satellites became the necessary basic data to tackle and solve those issues. Due to the recent advancement in the observation sensor technique and the data processing technique, the satellite observation has been showing rapid progress, and the time is changing from examining the accuracy of the observation sensor data to the advancement of the data application, leading to broaden potential users. In these days application became synergetic, so we comprehensively pick<br/>up this topic in the Atmospheric and Hydrospheric Sciences Session of this Union Meeting that enables to comprise the atmospheric, oceanic and land sciences; by combining the intelligence and the knowledge of the party, we propose a session that aims to prompt further studies towards the issues on earth environmental change, the advancement in the data application and future plans of Earth Observation missions.

# Impact of usage of multiple-satellite sensors on accuracy of daily-mean sea surface wind data

*Ayumi Koizumi[1], Masahisa Kubota[2], Kunio Kutsuwada[3], Hiroyuki Tomita[4], Tsutomu Hihara[5]

1. Tokai University, 2. Tokai University, Institute of Ocean Research and Development, 3. School of Marine Science and Technology, Tokai University, 4. Institute for Space-Earth Environmental, Nagoya University, 5. Japan Agency for Marine-Erth Science and Technology

Most satellites observing sea surface winds have sun-synchronous orbits and provide observation data at the same place two times per a day. We can expect that daily-mean values estimated from these data have some errors when diurnal changes in wind field cannot be neglected. For this problem, use of multiple satellites is helpful. Since the number of sensors used to construct daily-mean data is different among the years, it is expected that the accuracy of a daily-mean value changes from year to year.

The purpose of this study is to describe time variation of accuracy in daily-mean wind data in the Japanese Ocean Flux Data Sets with Use of Remote Sensing Observation (J-OFURO)-3 and to investigate its causes by comparing with in-situ measurement data by moored buoys and calculating three statistical values.

Results reveal that the statistical values are improved with year. To examine the relationship between the yearly statistics and the yearly number of satellite sensors, we plotted a scatter diagram between the number of satellites and three statistical values in each year. We found that the correlations between them are very high. We also focused on a time interval of the satellite wind observation, namely maximum missing time within a day. The result showed that the correlation between three statistical values and maximum missing time intervals is high. Since the relation between these two factors is not independent, we analyzed by considering both factors together. First, we chose five buoys with various standard deviations for a daily-mean value. Next, we picked up data from buoy's hourly data using random numbers, and calculated the daily mean value using the random data, and then determined the number of observations and the maximum missing time interval each day. Assuming the daily mean value calculated from 24 hourly data as a true value, the RMSE between this true value and the daily mean created from random data was calculated. From the result of this analysis, it was found that the value of Root Mean Square Error(RMSE) depends on the maximum missing time interval rather than the number of observations. Furthermore, when RMSE was normalized by standard deviation, the same figures were obtained for all buoys. This result implies that the RMSE of the daily mean value of the buoy station can be estimated if the magnitude of diurnal variation is known by giving the number of satellites used for observation and the maximum missing time interval, Moreover, by applying this result, we think that it is possible to show the optimal number of sensors and observation time for target accuracy. This result gives very breakthrough information to the design of the satellite observation system for sea surface wind.

# Temperature and Size Variability of Warm Pools in the Global Oceans

*ChunYi Lin[1]

1. National Museum of Marine Science & Technology

Using advance satellite-derived Sea surface height anomaly, sea surface temperature (SST) data, and heat flux data, we investigate the thermal variability, temperature and size variability of warm pools in the global oceans, the Pacific, the Atlantic, and the Indian Ocean, respectively. Because of the high density and specific heat of seawater, water can store and transport large amounts of heat. High SST has particular influence on global climate system. Furthermore previous studies focused on the global warming or area warming, in this investigation we present results of warm pool SST binned into 1 ˚C interval. Detecting temperature and size variability of warm pools in the global oceans, it suggests that the high SST area (SST ≧ 28˚C) has faster increasing rate than surrounding area (SST 20˚C - 27˚C) in the global oceans, the Pacific, the Atlantic, and the Indian Ocean, respectively. To understand the role of surface heat flux in the tropical SST fluctuation, we analyze the mixed layer heat balance equation. Upper ocean heat budget between the heat advection and heat diffusion term are compared and heat diffusion processes may be a mechanism for transporting excessive amount of heat that the warm pool through enhancing the SST gradient around the edge of the warm pool. In order to find out dominant period components and the relationship of energy-frequency distribution without influenced induced by nonlinear and nonstationary signals, the Hilbert-Huang Transform applied by ensemble empirical mode decomposition is employed. The ensemble empirical mode decomposition analysis indicates that the interannual component has strong influence on the variability of the warm core pool in the Pacific, presumably because of the presence of El Niño phenomenon, while the annual cycle dominates the variability in the Indian and the Atlantic Ocean.

# Sea surface temperature from SGLI aboard the GCOM-C satellite of JAXA

*Yukio Kurihara[1], Kazunori Ogata[2], Hiroshi Murakami[2], Misako Kachi[2]

1. Tripli-I Co., Ltd., 2. JAXA EORC

The Global Change Observation Mission-Climate (GCOM-C) satellite, which is one of two satellites for the GCOM mission of the Japan Aerospace and Exploration Agency (JAXA), was launched on 23 December 2017. The Second Generation Global Imager (SGLI) is the optical sensor aboard GCOM-C which consists of two components: the Visible and Near-infrared Radiometer (VNR) and the Infrared Scanner (IRS). SGLI has switchable spatial resolution from 250 m x 250 m to 1 km x 1 km. The resolution of 250 m x 250 m is expected to reveal complicated structure of geophysical parameters. Sea surface temperature (SST), which is one of the important parameters in the geophysical field, is also determinable by using split window data of SGLI. SGLI SST is retrieved by utilization of newly developed cloud masking method and a modified SST method originally developed for Himawari-8. Considering combined utilization of satellite SSTs, the methods developed for SGLI SST will be applied back to Himawari-8 data as well as the data from the Visible Infrared Imaging Radiometer Suite (VIIRS) aboard the Suomi National Polar-orbiting Partnership (Suomi NPP) satellite. SGLI SST is validated by comparison with buoy data. The comparison result shows RMSD of ~0.4 K, good agreement between SGLI SSTs and buoy data. Triple comparison with Himawari-8 and VIIRS SSTs is being started. Operational retrieval of SGLI SST started at the end of 2018. The products are available at the G-Portal site of JAXA and the JAXA Satellite Monitoring and Environmental Studies (JASMES) site of the Earth Observation Center (EORC) of JAXA.

# Concept of small satellite UV/visible imaging spectrometer optimized for tropospheric $NO_2$ measurements in air quality monitoring

*Tamaki Fujinawa[1,5], Katsuyuki Noguchi[2], Akihiko Kuze[3], Andreas Richter[4], John P. Burrows[4], Andreas C. Meier[4], Tomohiro Sato[1], Takeshi Kuroda[1], Naohiro Yoshida[5], YASUKO KASAI[1,5]

1. National Institute of Information and Communications Technology, 2. Nara Women's University, 3. Japan Aerospace Exploration Agency, 4. University of Bremen, 5. Tokyo Institute of Technology

Satellite observations at nadir can potentially facilitate a better understanding of the emissions and distribution of tropospheric nitrogen dioxide, $NO_2$. The identification of emissions requires adequate spatiotemporal resolution measurements of the total column amounts of $NO_2$. The spatial resolution of previous and current observations is insufficient for the identification of $NO_2$ hot-spots. Switching to a spatial resolution of ~1 km x ~1 km can improve the identification of local sources of $NO_2$ and their emissions. To investigate the feasibility of observations with such a high spatial resolution, we simulated radiance spectra for different cases under varying parameters, such as area, season, satellite altitude, and surface reflectance by using the radiative transfer model SCIATRAN. We subsequently retrieved $NO_2$ slant column densities (SCDs) using the differential optical absorption spectroscopy (DOAS) technique with several fit windows. For test cases associated with polluted conditions, we found that the conceptual nadir-observing instrument on a satellite at an altitude of ~300 km involved the lowest retrieval errors for signal-to-noise ratios of around 1000 with accuracy better than the required 5% for tropospheric $NO_2$ SCD and that the fit window of 425--497 nm met the scientific requirements for both surface reflectance cases.

# Analysis of the Surface Echo Characteristics Derived from GPM/DPR Wide Swath Observation Experiment

*Kosuke Yamamoto[1], Kinji Furukawa[1], Nobuhiro Takahashi[2], Takuji Kubota[1]

1. Japan Aerospace Exploration Agency, 2. Nagoya University

The observation from spaceborne precipitation radar has been contributed to better understanding of earth climate system. Global Precipitation Measurement (GPM) core satellite Dual-frequency Precipitation Radar (DPR) provides us 3-dimentional information of precipitation by the scan width of about 250 km, but there have been arguments that to bring systematic impact on the weather monitoring through global rainfall map such as GSMaP, wider swath observation by precipitation radar is necessary.

Based on those requirements, the scan pattern of GPM/DPR was experimentally changed for 1 day from 13UTC on September 26th. In this experiment, the scan angle was changed to observe from nadir to about +34˚ assuming future spaceborne precipitation radar with wider swath width, while in the normal observation DPR scans ±17˚. The height and strength of the mainlobe clutter with larger incident angle were assessed statistically to examine the possibility of the rainfall retrieval with wide swath observation by DPR.

In order to examine mainlobe clutter height, it is inevitable to reduce sidelobe and grating lobe effect. In this study, clutter-free observation data is extracted based on following procedures; 1) extract bins above mainlobe clutter; 2) extract bins under non-precipitation condition from 1); 3) extract bins that satisfy |received power −averaged noise power| < 2 sigma of the noise power from 2). Note that this procedure was applied only for KuPR observation since sidelobe and grating lobe clutter is not prominent in KaPR.

The result for KuPR observation shows that the mainlobe clutter top height at the larger incident angle over ocean is somehow suppressed at around 4 km while over land it increases almost linearly up to around 5 km due to the strong surface scattering. The same tendency is found on the KaPR observation, but it has lower clutter top height of around 2.5 km and 3.5 km, over ocean and land respectively. Suppression is clearer over ocean thanks to the specular reflection. The results also indicate that relatively intense rainfall can be retrieved while shallow rainfall with weak echo power may not be acceptable for retrieval because it should be masked by the surface clutter.

# The Recent Results from the Global Precipitation Measurement (GPM) mission in Japan

*Riko Oki[1], Takuji Kubota[1], Kinji Furukawa[1], Yuki Kaneko[1], Moeka Yamaji[1], Kosuke Yamamoto[1], Toshio Iguchi[2], Yukari Takayabu[3]

1. Japan Aerospace Exploration Agency, 2. NICT, 3. the University of Tokyo

The Global Precipitation Measurement (GPM) mission is an international cooperate satellite project to achieve highly accurate and highly frequent global precipitation observations. The GPM mission consists of the GPM Core satellite jointly developed by the U.S. and Japan and Constellation Satellites that carry microwave radiometers and provided by the GPM partner agencies. The GPM Core satellite carries the Dual-frequency Precipitation Radar (DPR) by the Japan Aerospace Exploration Agency (JAXA) and the National Institute of Information and Communications Technology (NICT) and the GPM Microwave Imager (GMI) provided by National Aeronautics and Space Administration (NASA). The GPM Core satellite was launched in February 2014 and achieved its prime mission period planned for 3 years in 2017.

It has been continuing its observation as the extended mission phase after that.

JAXA develops the DPR Level 1 algorithm and the NASA-JAXA Joint Algorithm Team develops the DPR Level 2 and DPR-GMI combined Level 2 algorithms. The DPR, the DPR-GMI combined algorithms and the latent heating algorithm were updated, and those products were released in October 2018 as Version 0.6. Using dual frequency information of DPR, the latest Level 2 products include information such as precipitation phase at surface, heavy ice precipitation and so on. Also, the calibration factors of TRMM/PR were re-examined to have consistency between DPR/Ku. The same GPM Ku-band radar L2 algorithm now applies to the TRMM/PR, so that the long radar precipitation data exceeding more than 20 years are now available. From May 2018 in the extended mission period, the scan pattern of the Ka-band radar has been changed to realize matched beam observation in full swath. The new algorithm applying to the changed scan pattern is now under development.

JAXA also develops the Global Satellite Mapping of Precipitation (GSMaP), that is hourly and 0.1-degree horizontal resolution global rainfall map. It is available through the “JAXA Global Rainfall Watch” website (https://sharaku.eorc.jaxa.jp/GSMaP/index.htm). GSMaP product family includes different data latency products and rain gauge calibrated products and so on. The GSMaP near-real-time version (GSMaP_NRT) product provides global rainfall map in 4-hour after observation, and an improved version of GSMaP near-real-time gauge-adjusted (GSMaP_Gauge_NRT) product has been released since Dec. 2018.

The GSMaP real-time product called GSMaP_NOW now product is providing data at the earliest timing. It has been realized using the geostationary satellite Himawari-8 operated by the Japan Meteorological Agency (JMA) since November 2015. Since Nov. 2018 the domain of GSMaP_NOW has been extended to the region of the geostationary satellite Meteosat operated by the European Organization for the Exploitation of Meteorological Satellites (EUMETSAT) in November 2018. JAXA is further developing the GSMaP_NOW to provide global real-time rainfall product.

# Verification of Global Satellite Mapping of precipitation (GSMaP) for providing its error information

*Moeka Yamaji[1], Takuji Kubota[1]

1. Earth Observation Research Center, Japan Aerospace Exploration Agency

Precipitation is one of the most essential parameters in the Earth system. Due to address water issues like water shortage or floods, JAXA has developed and provided Global Satellite Mapping of Precipitation (GSMaP), which is hourly global precipitation dataset. It is under the Global Precipitation Measurement (GPM) mission and contributes.
GSMaP allows us to capture the hourly horizontal distribution of precipitation with good latency after observation. The spatial resolution is 0.1 x 0.1 degrees latitude/longitude. It has been used for various kinds of utilization purposes.
In terms of accuracy, GSMaP algorithms were updated in several times, and GSMaP has been getting more accurate day by day, however, it is known that the inhomogeneous of accuracy is existed depending on algorithm characteristics. It has been needed to provide information about the uncertainty and accuracy of GSMaP by users.
In this study, verification result of GSMaP near-realtime product version 6 (GSMaP_NRT) is reported. The radar/raingauge analysed precipitation data by Japan Meteorological Agency, which is an hourly rainfall analysis generated from ground-based precipitation radars corrected by automated rain gauges, are used as the reference data. Since the purpose of this study is for providing generalized error information, root mean square errors (RMSE) is statistically calculated for each precipitation level and each reliability flag during May-June-July-August-September-October in 2015-2018. Some initial results showed that the RMSE qualitatively represented the error for each precipitation level and reliability flag. The RMSE ratio to the average precipitation rate got larger as the precipitation rate became smaller while it became stable around 60 –80 % when precipitation rate was more than 10 mm/h. We report the validation results in detail, such as land/ocean difference or sampling dependence, and focus on the effectiveness of it.

Keywords: precipitation, GPM, GSMaP, validation

# Detection of the mixed phase top using the measured dual-frequency ratio of reflectivity with GPM/DPR

*Yuki Kaneko[1], Toshio Iguchi[2]

1. Japan Aerospace Exploration Agency, 2. National Institute of Information and Communications Technology

The core observatory of the Global Precipitation Measurement (GPM) mission was launched in 2014 and has been observing rain and snow between 65˚S and 65˚N by the Dual Frequency Precipitation Radar (DPR) and the GPM Microwave Imager (GMI). The DPR provides three-dimensional structure of storms derived from reflected energy from precipitation particles. Precipitation echoes at the two frequencies of the DPR, Ka-band (25GHz) and Ku-band (14GHz), make it possible to infer the mean size and physical property of precipitation particles. The swath width of Ka-band scanning was 125 kilometers centered at nadir and was nested within the Ku-band’ s wider scan width of 254 kilometers. On May 21 2018, the Ka-band scan pattern was changed to match with the Ku-band’ s. Dual frequency radar reflectivity factors are available for full swath of 254 kilometers now.

The classification (CSF) module in the standard DPR level2 algorithm detects a bright band (BB) and classifies precipitation into three types, stratiform, convective, and other. Rain types affect the retrievals of rain amount and latent heating in the DPR algorithm. Accurate classification is also important in the Global Satellite Mapping of Precipitation (GSMaP) algorithm because it affects the rain profile database used in the rain retrieval with microwave radiometers. The BB detectability by the standard CSF algorithm is lower at and near the swath edges than near nadir because only Ku-band data was available in the outer swath before and because slant incidence of radar beams smears the vertical profiles.

As the Ka-band scan pattern has changed to cover the full swath, we can apply a dual-frequency method to detect a BB now. We have developed a method that uses the dual frequency ratio (DFR) to detect the mixed phase top. It looks at the slope of DFR as a function of range to identify the transition height from ice to water. DFR itself is estimated from measured DFR (DFRm) with attenuation correction. Preliminary experiments show that the developed method can detect the BB in stratiform rain over the swath almost uniformly. This method also has a potential to identify the transition height even in some convective cases. In this research we evaluate the performance of the algorithm by comparing the altitude of BB and the transition height with those estimated by using X-band multi-parameter radar (XRAIN) data.

# Comparison between high frequency satellite rainfall estimation and APHRODITE-2 ground rain gauge observation

*Hitoshi Hirose[1], Koichi Toyoshima[1], Atsushi Higuchi[1], Akiyo Yatagai[2], Natsuko Yasutomi[3]

1. Center for Environmental Remote Sensing, Chiba University, 2. Hirosaki University, 3. Disaster Prevention Research Institute, Kyoto University

APHRODITE project collects daily precipitation observation data from ground rain gauges in each country, and then performs appropriate quality control and converts it into gridded data. APHRODITE holds long-term data from the 1960s to the present and focuses on analyzes such as changes in characteristics of extreme rainfall due to long-term climate change. However, ground-based daily rain observations has a problem which end of the day (EOD) in each country is different from each other. To estimate the EOD in each country, we developed a Rain Potential Map (RPM) which is a product that can estimate global rain probability using geostationary meteorological satellites (GEO) (Hirose et al., 2016, JMSJ). In this study, we used the RPM, GSMaP and CMORPH which are global satellite rain estimation data based on microwave satellite and GEO observations.

Since the above satellite rainfall observation data can estimate global precipitation every hour, it is possible to create daily average data in which the average section is shifted by one hour. By correlating the satellite daily precipitation observation time series with the APHRODITE daily precipitation observation time series, the EOD value in each country was estimated from the time when the correlation coefficient is largest. We confirmed that the reliability of this method is high by a verification analysis in the field where true value of EOD is already known. Moreover, we made pseudo hourly rain time series of APHRODITE by inserting APHDOITE daily rain time series to satellite hourly rain time series. By this method, we will try to make a new APHRODITE data that is corrected for the EOD difference between each country.

# Development of the high resolution GSMaP by the Himawari-8

*Tomoaki Mega[1], Tomoo Ushio[1]

1. Tokyo Metropolitan University

There is a new generation infrared (IR) imager on new-generation gestationary weather-satellite such as the Himawari-8 and the Geostationary Operational Environmental Satellite-R series. The imagers observe multi-channel passive imaging radiometer. The imagers observe wave a full disk with several km in about ten minutes. In Near-future, the IR imager observation should cover the globe.

Global precipitation information is an important tool for water management or earth science. Spaceborne sensors is one of the most convenient tools of global observation. The sensors cover global and provide uniform quality data. Precipitation estimation use microwave radiometer in low earth orbit (LOE). A microwave radiometer has high spatial resolution. However, one drawback of the microwave radiometer in LOE is narrow observation area. Whole earth observation by a microwave radiometer on a LOE satellite need some days. Therefore, global precipitation map is made from combined satellite data. However, combined data of microwave radiometer on LOE don’ t cover global in one hour. One of the global precipitation map is the Global satellite mapping of Precipitation (GSMaP). Precipitation estimation of the GSMaP made from microwave radiometer data. The GSMaP Moving Vector with Kalmanfilter (MVK) and Near real time compensate precipitation of no observation area by IR information. Spatial and temporal resolution of the GSMaP MVK achives 0.1 degree and one hour. This study shows downscale technique for GSMaP precipitation map by High-spatial and temporal resolution IR data of the Himawari-8. IR datasets of Himawari-8 are available every 2.5 minutes in the Japan region. In the presentation, we will also show validation the high resolution GSMaP and ground-radar network in Japan.

# Preliminary results of on-orbit estimation for polarization sensitivity of GCOM-C/SGLI

*Risa Miyazaki[1], Hiroshi Murakami[1], Masahiro Hori[1]

1. Japan Aerospace Exploration Agency

The GCOM-C has been launched successfully on 23th Dec. 2017 from the Tanegashima Space Center by H-IIA vehicle No.37. After the initial calibration/validation phase of one year after launch, all SGLI standard products have been released from JAXA’s data providing service (G-Portal) from Dec. 20, 2018.

In generally, the radiance reflected by the sea surface and the atmosphere is strongly polarized. When observing a large polarized light, the output radiance vary from the actual radiance because of the polarization sensitivity characteristic of the optical sensor. Especially for ocean color products, it is important to evaluate the effect of polarization sensitivity because it is necessary to extract the weak water-leaving reflectance (<10% of the whole) by the accurate atmospheric correction.
The polarization sensitivity of GCOM-C/SGLI of each NP (Non-Polarization) band has been measured in the pre-launch ground test. The ground test results of polarization sensitivity were shown to be <3.5% on average in the pixel direction in all bands. In this study, we evaluate whether the polarization sensitivity estimated from on-orbit observation data is consistent with the pre-launch test results. In this work, we report on the RED bands (VN07, VN08) and the NIR bands (VN10, VN11) of SGLI.
Polarization sensitivity on-orbit was evaluated based on Gordon and Zhang (1997) and Meister et al. (2005). We use the observation data by SGLI/PL (Polarization) band to estimate the real stokes vector components at the top of atmosphere (TOA). In order to obtain the polarization sensitivity with respect to directly observed radiance at TOA, L1B before inter-pixel sensitivity correction and before inter-telescope sensitivity correction was self-made from L1A data.
We analyzed the observation data of 12 path that PL band is observed nadir direction. The characteristics of the instrument for polarization sensitivity (polarization factor) were estimated by the least squares method. On the east side of the observation image, the error is large because of Sun-Glint. Although the variation in the pixel direction was still large, the estimated polarization factors (3 to 5 %) were consisted with the prelaunch ground test (~ 3.5%). However, sensitivity patterns in the pixel direction could not be identified, so we will continue to improve the evaluation in the future.

# Analysis of SGLI validation datas based on the effects of the growth and ground types for the AGB development

*Ryota Ishibashi[1], Koji KAJIWARA[1], Yoshiaki HONDA[1]

1. Center for environmental remote sensing, Chiba University

The effects of the earth of the time variant system should be difficult to detect the influence of the growth types and also the effects of the growth field’s variations. The research may occur the SGLI’s RSRF datas of the calculated AGB data accuracy analysis that observed between every kinds of the growth and also the ground types. The significance area of the SGLI observed, each of detected datas accuracy have to be considered. We show observation ways for the ground truth of the reflectance, LAI and fAPAR. The first case we use is a case of vegetation at the grassland. And then, based of reflectance values, we compare the other type as the Mixed coniferous forest example. The influence of an effect of the type of growth may occur the reflectance of the distributed area. We will detect these effects of the growth type. The influence at the observed area be necessarily to be verified.

The research topic includes the ground truth observation for the accuracy verification of a SGLI data obtained. For development of ground truth, the way to obtain datas were important. This paper explains how to examine growth (such as a second growth forest and other) and the slope factor of the second growth forest area and also the reflectance of each forest types. Then, this paper make ground truth observation scheme for the high accuracy AGB referenced data development at ground cover area. We explain the method of examine the error detection way including observation devices and also the problem of the research topic to be examined. Results may occur an example case of such kinds of the sloped forest and the kinds of the plane. The results shows a typical difference between the sloped and the plane, and then the results may occur the possibility that comparison of standard deviation may be an effective way to detect the volume of the forest type between every ground truth.

The case of we use as the sloped fields, reflectance of each wavelength were low and then the near 400 to 700 nm area will be higher than other wavelength (ANOVA values of results: $p < 0.001$). And then, we can see the effects of slope should be detected at total values of the reflectance. The reflectance of a wavelength were obtained that aimed to detect the verification of the slope and the growth type’s reflectance. When the mixed coniferous forest, static observation develop same reflectance values but the effect of the sloped factor occur the high value of the standard deviations. Then, our method applied to the method of the SGLI’s data calculation scheme, and then the growth factor of the area be affects the influence of the from 400 to 700 nm wavelength and also the factor of slope region be affects the wavelength of reflectance. SGLI data analysis, the factor of these parameters were used to remake the size of RSRF data from 250 m to 1000 m resolution. The future, we investigate more and then, the mask area of high value difference around the nearest 16 pixels be considered. Datas were significant at some pixels, such as a steep sloped, growth types, or error detected area. Data development of RSRF, the reflectance of each cells are detected as the values of the every ground types by the standard deviation.

# Remote sensing of aerosol optical properties and water-leaving radiance based on the optimal estimation approach

*Chong Shi[1], Teruyuki Nakajima[1], Makiko Hashimoto[1], Hideaki Takenaka[1]

1. Japan Aerospace Exploration Agency

A flexible inversion algorithm is proposed for jointly retrieving aerosol optical properties and water-leaving radiance from multispectral instrument over the ocean. A combined multi-wavelength and multi-pixel constraint approach is used to estimate aerosol and hydrosol over clear and turbid waters, based on the forward simulation from a coupled atmospher-ocean radiative transfer model. This sort of simultaneous inversion helps to correct the biases induced by the neglect of water-leaving radiance in the traditional aerosol retrieval algorithms, in addition, it can provide more aerosol information than the standard ocean color approach. To investigate the availability of current scheme, we conduct the retrieval in the process of MODIS, GOSAT/CAI and GCOM-C/SGLI instruments.

# Aerosol retrieval and PM2.5 from space using GOSAT/TANSO-CAI

*Makiko Hashimoto[1], Hideaki Takenaka[1], Teruyuki Nakajima[1], Akiko Higurashi[2]

1. Japan Aerospace Explortion Agency, 2. NIES

Aerosol in the atmosphere has a great impact not only for the Earth’ s radiation budget and changing the Earth’ s climate, but also on human health. Especially, the fine particle, which is often called PM2.5, has drawn attention as a cause of health damage.

The urban area is a source of anthropogenic aerosol, which is mostly composed of small particles, and the particles are transported to other regions. Satellite remote sensing provides effective means to monitor the atmospheric aerosols in wide area including urban areas.

Accurate retrieval of fine mode aerosol optical thickness (AOT) is necessary to calculate an equivalent value of PM2.5 from space. Therefore, an aerosol retrieval algorithm for satellite remote sensing of urban areas to improve the retrieval accuracy of aerosol properties, which is called MWPM (Multiple wavelengths and pixels method) (Hashimoto and Nakajima, 2017), was developed. The method simultaneously retrieves fine and coarse mode AOT and single scattering albedo by using several wavelengths and spatial difference of surface reflectance. The method is useful for aerosol retrieval over spatially inhomogeneous surface like an urban area.

The algorithm was applied to GOSAT (Greenhouse Gases Observing Satellite) / TANSO-CAI (Cloud and Aerosol Imager, CAI) data. The GOSAT launched ten years ago (on January 23th, 2009) is a satellite to monitor greenhouse gases (GHG) such as carbon dioxide and methane with TANSO-FTS (Fourier Transform Spectrometer, FTS). The CAI is a supplementarysensor of the FTS, detecting cloud and deriving aerosol optical properties.

PM2.5 using retrieved fine mode AOT by MWPM in East Asian region from 2009 was calculated. The poster presents a retrieval result of PM2.5 over the East Asian region from space in several years and discusses the seasonal and annual variations.
Monitoring of aerosol properties such as AOT, PM2.5 and soot mixing ratio over land is added to the mission of GOSAT-2 that was launched on Otober 29th 2018. As a near-future plan, the algorithm will be applied to GOSAT-2/TANSO-CAI-2 data to generate standard PM2.5 data products.

# Establishing a high resolution road fugitive dust emission inventory in Kaifeng City, China

*Yiming Xu[1], Shili Liu[1], Xinyue Cao[1], Xianbao Shen[1], Zhiliang Yao[1]

1. Department of Environmental Science and Engineering, Beijing Technology and Business University

Due to the rapid urbanization and industrialization in many Chinese cities, ambient particulate matter pollution such as road fugitive dust pollution becomes a serious environmental problem. However, the emission of road fugitive dust is relatively difficult to quantify as it is of high uncertainty and spatial heterogeneity. The research aims to build a high resolution road fugitive dust emission inventory which is transferrable and applicable to other cities in China. High spatial resolution images were utilized to digitalize whole road network of Kaifeng City, Henan Province, China. Vehicle flows of the whole road network were estimated by incorporating the whole road network, field measured data and GPS data on an hourly, daily, weekly, monthly and yearly basis at city level. By fusing the road network information, vehicle flow, road dust load, average vehicle weight, a high resolution road fugitive dust emission inventory was established. The results showed that the total emissions of $PM_{10}$, $PM_{2.5}$ and Total Suspended Particulate from road fugitive dust at commuter time and downtown were much higher compared with other time and location in Kaifeng City. The framework of this road fugitive dust emission inventory can be applied to other cities, and it can provide data support and guide fugitive dust management in China.

# A Relationship between Diurnal Change Patterns of Land Surface Temperature and Spatial Configuration of the Osaka Metropolitan Area Captured by Himawari-8

*Yuhei Yamamoto[1], Hirohiko Ishikawa[1]

1. Disaster Prevention Research Institute, Kyoto University

Land surface temperature (LST) is a physical quantity that greatly contributes to the formation of an urban thermal environment. Therefore, understanding the spatiotemporal characteristics of LST is necessary for constructing a sustainable urban environment. The spatial distribution relationship between the instantaneous LST and urban land use has been investigated using polar-orbiting satellite/airborne sensors. This study explored how the urban spatial configuration and meteorological field affect the temporal changes of LST by using Japanese geostationary satellite (Himawari-8) sensor.
The study area is the Osaka metropolitan area in Japan and target days are three days that were clear-sky throughout the day in summer (August 12, 2016, July 19, 2018, and August 4, 2018). We used 100 m-mesh urban land use data and ground-based meteorological observation data to examine the urban spatial configuration and meteorological fields, respectively. The temporal changes of LST are the amplitude and phase mainly forming the diurnal change of LST. These two temporal changes were extracted by applying principal component analysis to the diurnal changes of LST represented by the 10-minute LST dataset retrieved from Himawari-8 data.
Our results showed that the spatial variations in the amplitude and phase corresponded to the penetration time and duration of the sea breeze and the thermal inertia of surface materials. Besides, it was found that the LST change during daytime was larger in the high-density low-building areas than in the low-density low-building areas. This result suggests that the increase in building density increases the LST change during the daytime. These findings lead to a deeper understanding of an urban hot environment and are helpful for urban planning to mitigate the deterioration of a hot environment.

## [A-CG34] Satellite Earth Environment Observation

convener:Riko Oki(Japan Aerospace Exploration Agency), Yoshiaki HONDA(Center for Environmental Remote Sensing, Chiba University), Yukari Takayabu(Atmosphere and Ocean Research Institute, the University of Tokyo), Tsuneo Matsunaga(Center for Global Environmental Research and Satellite Observation Center, National Institute for Environmental Studies), Chairperson:Tsuneo Matsunaga

In recent years, we cannot avoid facing issues on global environmental changes that occur in various spatiotemporal scales. The earth environmental observation data by satellites became the necessary basic data to tackle and solve those issues. Due to the recent advancement in the observation sensor technique and the data processing technique, the satellite observation has been showing rapid progress, and the time is changing from examining the accuracy of the observation sensor data to the advancement of the data application, leading to broaden potential users. In these days application became synergetic, so we comprehensively pick<br/>up this topic in the Atmospheric and Hydrospheric Sciences Session of this Union Meeting that enables to comprise the atmospheric, oceanic and land sciences; by combining the intelligence and the knowledge of the party, we propose a session that aims to prompt further studies towards the issues on earth environmental change, the advancement in the data application and future plans of Earth Observation missions.

1. Japan Aerospace Exploration Agency, 2. RESTEC

Since 2009 Thermal And Near infrared Sensor for carbon Observation Fourier-Transform Spectrometer (TANSO-FTS) onboard the Greenhouse gases Observing SATellite (GOSAT) TANSO-FTS onboard GOSAT has provided 0.2 cm-1-step radiance spectra from solar reflected light in shortwave infrared (SWIR) to thermal infrared (TIR) light using the FTS multiplex-advantage.
The SWIR light passes from the top of the atmosphere to the Earth’ s surface providing column-averaged dry air mole fractions of carbon dioxide (CO2) and methane (CH4). TIR light is the thermal emission from the Earth’ s atmosphere and surface. By combining these wide spectral data, GOSAT can extract the partial column density of lower troposphere, which shows enhanced density from local anthropogenic emission sources.
For SWIR data analysis, we use robust algorithm of differential optical absorption spectroscopy and optical path modification by thin clouds and aerosol can be calibrated by simultaneously observed oxygen (O2) data. On the other hand, thermal emission measurements need absolute radiometric calibration. Furthermore, the PC-MCT detector for TIR is less linear than the Si and InGaAs detectors for SIWR.
During the 10-year operation in orbit, TANSO-FTS had system-shut-down in May 2014, May 2018, and November 2018 due to satellite anomalies and cryo-cooler shutdown in August 2018. Every time TANSO-FTS restarted, the thermal condition of the TIR detector and optics had changed and parameters for non-linearity corrections had to be updated. We present how we can calibrate SWIR and TIR spectra for 10 years for decade-long uniform quality.

# Estimating regional anthropogenic methane emissions with GOSAT satellite retrievals and ground-based observations

*Shamil Maksyutov[1], Aki Tsuruta[2], Rajesh Janardanan[1], Fenjuan Wang[1], Akihiko Ito[1], Motoki Sasakawa[1], Toshinobu Machida[1], Isamu Morino[1], Yukio Yoshida[1], Johannes Kaiser[3], Greet Janssens-Maenhout[4], Ed Dlugokencky[5], Tsuneo Matsunaga[1]

1. National Institute for Environmental Studies, 2. Finnish Meteorological Institute, 3. Deutscher Wetterdienst, 4. European Commission, Joint Research Centre , 5. National Oceanic and Atmospheric Administration, Global Monitoring Division

GOSAT satellite observations of methane are being used for regional and national methane emission estimates in a number of studies using either high resolution regional inverse models or global medium resolution models. We perform global high-resolution methane flux inversion to estimate global methane emissions using atmospheric methane data collected at global in-situ network, which is archived at WDCGG and NIES, and GOSAT satellite retrievals. High resolution tracer transport is implemented by coupling Lagrangian model FLEXPART to a global atmospheric tracer transport model (NIES-TM) and its adjoint. Prior fluxes at 0.1˚ resolution were prepared for anthropogenic emissions (EDGAR 4.3.2), biomass burning (GFAS), and wetlands (VISIT). The inverse model based on NIES-TM-FLEXPART applies variational optimization to two categories of fluxes: anthropogenic and natural (wetlands). Bi-weekly emissions are estimated for years 2009 to 2017. To reduce GOSAT retrieval biases, the monthly mean difference between GOSAT data and the inversion-optimized forward simulation is estimated for each 5˚ latitude band and it is subtracted from GOSAT retrievals (NIES Level 2 retrievals, v. 02.72) before including them in the inversion. The bias correction is designed to remove large scale biases in GOSAT retrievals, while retaining local scale variability that contains most information on anthropogenic emissions from intense sources such as megacities. Estimated anthropogenic emissions over large regions (US, China, India) are compared to GCP-CH4 top-down estimates. The sensitivity of the estimated emissions to prior fluxes is tested by adjusting the prior fluxes to match UNFCCC reports for selected large countries.

# The Status and the Future Plan of GOSAT-2 Level 2 and 4 Products

*Tsuneo Matsunaga[1], Isamu Morino[1], Yukio Yoshida[1], Makoto Saito[1], Hibiki M Noda[1], Hirofumi Ohyama[1], Akihide Kamei[1], Fumie Kawazoe[1], Ryoichi Imasu[2], Teruyuki Nakajima[4], Takashi Nakajima[5], Naoko Saitoh[3], Makiko Hashimoto[4]

1. Center for Global Environmental Research and Satellite Observation Center, National Institute for Environmental Studies, 2. The University of Tokyo, 3. Chiba University, 4. Japan Aerospace Exploration Agency, 5. Tokai University

GOSAT-2 (Greenhouse Gases Observing Satellite 2), launched in October, 2018, is the second Japanese Earth observation satellite for greenhouse gas observation from space. It is a joint mission promoted by Ministry of the Environment, JAXA (Japan Aerospace Exploration Agency), and NIES (National Institute for Environmental Studies) as similar to the first satellite, GOSAT, launched in and operated since 2009. Both satellites are designed to measure atmospheric concentrations of carbon dioxide ($CO_2$) and methane ($CH_4$) using Fourier transform spectrometers, FTS and FTS-2, with a help of moderate resolution imagers, CAI and CAI-2, for aerosol and cloud observation. The design lifetime of GOSAT-2 is five years and the 15-year record of atmospheric $CO_2$and $CH_4$is now expected from these two satellites.

NIES is responsible for the generation of GOSAT-2's Level 2 and Level 4 standard products which are

1) GOSAT-2 TANSO-CAI-2 L2 Cloud Discrimination Product
2) GOSAT-2 TANSO-CAI-2 L2 Aerosol Property Product
3) GOSAT-2 TANSO-FTS-2 SWIR L2 Chlorophyll Fluorescence and Proxy-method Product
4) GOSAT-2 TANSO-FTS-2 SWIR L2 Column-averaged Dry-air Mole Fraction Product
5) GOSAT-2 TANSO-FTS-2 TIR L2 Cloud and Aerosol Property Product
6) GOSAT-2 TANSO-FTS-2 TIR L2 Temperature and Gas Profile Product
7) GOSAT-2 L4A Global CO2 Flux Product
8) GOSAT-2 L4A Global CH4 Flux Product
9) GOSAT-2 L4B Global CO2 Distribution Product
10) GOSAT-2 L4B Global CH4 Distribution Product

The public release of GOSAT-2 Level 2 and Level 4 products will start by the end of October 2019 and 2020, respectively.

In this presentation, the latest status and the future plan of these products will be introduced.

# A preliminary initial check of the cloud discrimination products by CAI-2 onboard GOSAT-2

*Yoshiaki Ishihara[1], Yu Oishi[2], Haruma Ishida[3], Takashi Nakajima[4]

1. NIES, 2. NARO, 3. JMA, 4. Tokai Univ.

GOSAT-2, which is a successor of Japanese GOSAT (Greenhouse Gases Observing Satellite) which was launched in January 2009 and has been operated for about ten years, is successfully launched on Oct. 29, 2018. Both satellites are jointly developed and operated by Ministry of the Environment, Japan Aerospace Exploration Agency, and National Institute for Environmental Studies. GOSAT-2 carries two mission instruments, Fourier Transform Spectrometer 2 (FTS-2) and Cloud and Aerosol Imager 2 (CAI-2). They are successors of GOSAT FTS and CAI.

Several publicly available standard products will be generated from GOSAT-2 FTS-2 and CAI-2 data. One of these is CAI-2 Level 2 Cloud Discrimination Product and will be used for the detection of clouds within the field of view of FTS-2. CAI-2 cloud discrimination product is generated by one of two different algorithms. One of those is CLAUDIA1 used for GOSAT CAI Level 2 cloud mask product and the other is newly developed CLAUDIA3. And CLAUDIA3 is default algorithm for CAI-2 cloud discrimination product generation.

In this presentation, we will present a very preliminary initial check results of CAI-2 Level 2 cloud discrimination products, including comparison of cloud discrimination results by CLAUDIA1 and CLAUDIA3.

# Drought monitoring and evaluation performance of temperature vegetation drought index (TVDI) over Eurasia

*Fengmei Yao[1], Siqi Shi[1], Jiahua Zhang[2]

1. UCAS University of Chinese Academy of Sciences, 2. Institute of Remote Sensing and Digital Earth, Chinese Academy of Sciences

Drought has been a common concern recent years as it is one of the high frequent nature disasters in Eurasia that is included in the Belt and Road Initiative under the background of global warming. Thus, it is of great significance to study the drought monitoring and assessment in the region to develop effective plans to mitigate the effects of disasters. This study explored applicability of Temperature Vegetation Drought Index (TVDI) derived from MODIS normalized difference vegetation index (NDVI) and land surface temperature (LST) data as an index for drought monitoring in Eurasia in growing season (April - September) from 2005 to 2014. Three methods were used to compare TVDI against Standardized Precipitation Evapotranspiration Index in three time scales (SPEI-01, SPEI-03, SPEI-06) and the Essential Climate Variable surface soil moisture product (ECV-SM) at continental scales and Land Cover scales, as well as records of drought events from Emergency Events Database (EM-DAT) and relative literatures. The results indicated acceptable correlations between TVDI and SPEIs, ECV-SM in most areas, and TVDI had higher coefficients of correlation with ECV-SM than SPEIs at continental scale. Then we found that the correlation coefficient maps at continental scales were visually consistent with the land cover types, thus correlations between TVDI and SPEIs, ECV-SM were analyzed at Land Cover scales. TVDI showed strong correlation with SPEIs and ECV-SM in evergreen Needle leaf forest, deciduous broad leaf forest and grasslands. However, the accuracy of TVDI in open shrub lands that mainly distributed at high-latitudes remains to be further validated in the future. Finally, a comparison with typical drought-year and typical drought events also demonstrated TVDI could be used as a drought index to monitor drought events in study area over study time.

# IMPACT OF CHANGE IN LAND USE AND LAND COVER PATTERN ON LAND SURFACE TEMPERATURE AND THERMAL COMFORT USING MICRO-SCALE AREA MODEL: CASE STUDY OF AN EDUCATIONAL CAMPUS.

*DILJIT KUMAR NAYAK[1], MANJU MOHAN[1]

1. IIT DELHI

The influence of change in Land Use Land Cover pattern of an area due to rapid urbanization, over the increment in the Land Surface Temperature (LST) has always been a challenging area for research. This study covers the analysis of the influence of freshly built structure and the storey increment on the thermal comfort of the outdoor environment and Land Surface Temperature with a periodic remotely sensed observation for every three years at IIT Delhi (an educational institute campus). Numerical modelling approach using a 3D microclimate model ENVIMET is implemented for simulating the surface temperature in the presence of hostel residences and in the absence of hostel residences during a summer month of May during the period from 2002 to 2018. The effect of the Sky View Factor on Mean Radiant Temperature is likely to play a key role in influencing the thermal comfort of the residents of the campus. The entire IIT Delhi was classified under open high-rise as per Local Climate Zone (LCZ) categories. It was classified into 17 classes which included eight types of building classification from 4m to 36m and the rest of the nine classes included soil layer, asphalt roads, vegetation cover like trees, dense and light bushes, concrete roads, granite concrete and swimming pool PVC liner. The building class was sub-divided into different classes based on their height to study the effect of high rise buildings on the surface temperature. The model validation is carried out with the LST values obtained from the satellite observation of LANDSAT thermal band. The model estimated the surface temperature giving a correlation of (r=0.95) with the observed values. The RMSE value was found to be 1.28 for the student residence and 2.34 for the non-building structures. Temperature difference over the years as built structure influence was assessed approximately to the tune of 10 degrees. The model performed well in estimating the surface temperature with an accuracy of 94.97 per cent.

## [A-CG36] Earth & Environmental Sciences and Artificial Intelligence

convener:Tomohiko Tomita(Faculty of Advanced Science and Technology, Kumamoto University), Ken-ichi Fukui(Osaka University), Daisuke Matsuoka(Japan Agency for Marine-Earth Science and Technology), Satoshi Ono(Kagoshima University), Chairperson:Tomohiko Tomita(Kumamoto University, Faculty of Advanced Science and Technology)

In recent years, we have been required to explore the gigantic environmental data leading global environmental studies of modern meteorology, oceanography, and hydrology to accomplish Society 5.0 and Sustainable Development Goals (SDGs). Such environmental data, which are typical "big data," include the reliable long-term observatory data, ground radar data, satellite observation, oceanographic observation, global objective analysis data, and so on. However, it is hard to say that such big data are fully utilized, or nobody may have examined many of them. Therefore, to examine the global environment more faithfully, we need to apply the techniques of artificial intelligence/machine learning on such big data, that is, spatiotemporal data modeling of artificial intelligence, prediction and detection by machine learning, techniques of automated data mining, and so forth. Only cross-cutting diagnosis of the gigantic environmental data could resolve a wide variety of environmental problems including measures against global warming. In addition, the application of artificial intelligence/machine learning on the big data would raise us to the 4th paradigm of science (the 1st paradigm, observation/experiment; 2nd, theory; 3rd, simulation; 4th, data driven). This session sincerely invites various research initiatives that accelerate the application of artificial intelligence/machine learning on such gigantic environmental data.

# Recent Progress in Deep Neural Network Architectures and their Applications

*Shinichi Shirakawa[1]

1. Yokohama National University

A deep neural network (DNN) is a powerful machine learning model that shows remarkable performance in various artificial intelligence domains such as computer vision and natural language processing. A DNN is composed of a number of non-linear, differentiable units that have tunable parameters. In the training phase, DNN parameters (called connection weights) are trained so as to minimize training loss. After training the DNN, we expect it to be able to produce the generalized rule for the target task, i.e., the trained DNN is expected to return the ideal outputs from inputs for unknown data.

Researchers in the deep learning community are actively proposing a novel DNN architecture (i.e., the network structure of DNNs) to improve the performance and applicability of DNNs. For instance, a convolutional neural network (CNN) is frequently used as the network model for computer vision tasks, and the recurrent connection and long short-term memory (LSTM) cell is suitable for treating time series and sequential data. Besides these network structures, many extended network modules and architectures have been developed.

In this talk, we provide an overview of the recent progress in deep neural network architectures and their amazing applications. We also overview how to handle multimodal data in DNNs and present several studies on modality translation such as image-to-text (image captioning) and text-to-speech.

Although a lot of DNN architectures have been proposed so far, the selection and design of the architectures are still the users' task. Such a task is not trivial because the appropriate architecture heavily depends on the target problem and dataset, meaning that trial and error and expert knowledge are required for users. The second topic of this talk is the automatic design of DNN architectures, called neural architecture search (NAS). Recent studies show that NAS can improve the performance of DNNs depending on the dataset. Particularly, we present the computationally efficient NAS methods that can work on a single GPU with reasonable computational time.

At the end of this talk, we would like to discuss the applicability of deep neural networks to the field of global environmental science.

# Improving performance of oxidant prediction using machine learning by optimizing input data based on atmospheric science knowledge

*Tomohiro Sato[1], Peijiang Zhao[1], Koji Zettsu[1]

1. National Institute of Information and Communications Technology

[Background] Air pollution was the cause of 3.7 million premature deaths globally in 2012 (WHO, 2014). In Japan, the amount of oxidant (Ox) keeps high level or has been still increasing, although other air pollutants, such as $NO_2$ and $PM_{2.5}$. has been decreasing. High level of Ox affects human health and crop yields (e.g., Zheng et al., 2018). There are many factors for Ox generation, such as precursors especially $NO_2$ and VOC, sunlight and wind. They are non-linearly connected, thus, modeling of physical and chemical processes for Ox amount prediction is difficult and requires large calculation costs. There are many studies for Ox prediction using machine learning (ML) as an alternative of traditional modeling. Keller et al., (2017) showed that the random forest demonstrated the GEOS-Chem model calculation of ozone ($O_3$), major component of Ox, within an error less than 10% during the first 10 days with a 1/100 calculation cost. Other ML methods have been tested for $O_3$ prediction, Multi Linear Regression, Artificial Neural Network (Pires and Martins, 2011), Gene Expression Programming (Samadianfard et al., 2013).

[Aim] Previous studies of air pollution prediction by ML have well developed the model algorithm. Guennec et al., (2016) reported that improvement of input data, such as data augmentation, also increased the prediction performance. In this study, we approached to improve the Ox prediction using ML technique by optimizing the input data.

[Dataset and Method] Ox, especially $O_3$, is formed via photo-chemical reaction. The $O_3$ amount increases after the sunrise (e.g., $NO_2 + hn \rightarrow NO + O$, $O + O_2 + M \rightarrow O_3 + M$), takes a maximum during the day, and decreases during the night due to collision with surface and other species. This $O_3$ trend is observed throughout a year with a variation depending on whether, season and human activity. In this study, we compared the predicted results of Ox amount using two types of input data; in case 1, the Ox amount data itself ($V_{obs}$) and case 2, difference ($DeltaV = V_{obs} - V_{diurnal}$) from the reference diurnal variation ($V_{diurnal}$). We used data of amounts of major air pollutants (such as Ox, $NO_2$, SPM, $PM_{2.5}$, $SO_2$, CO), temperature, humidity, and wind at 16 points in Fukuoka city in 2014 to 2016 (Atmospheric Environmental Regional Observation System). The reference diurnal variation $V_{diurnal}$ was mean in each local hour and year. The ML model that we employed was a Convolutional Recurrent Neural Network (CRNN) based on a Convolutional Neural Network (CNN) and Long Short-Term Memory (LSTM) (Zhao and Zettsu, 2018). The value of measurement at each point was translated into 2-D map based on the longitude and latitude in the CNN part and the spatial features was extracted. A short-term prediction was performed by the LSTM part. We used the data for the last 24 hours as an input. The output was mean value of Ox amount in all points after six hours.

[Results and Discussion] We demonstrated the Ox prediction using the CRNN model with two types of input data ($V_{obs}$ for Case 1 and DeltaV for Case 2). Root mean squared error and accuracy for the two predictions were compared; Case 1: 10.3 ppb/75.4%, Case 2: 6.7ppb/84.7% (in 2014), Case 1: 11.0 ppb/72.7%, Case 2: 8.3ppb/79.6% (in 2015), Case 1: 9.4 ppb/76.7%, Case 2: 8.6ppb/79.4% (in 2016). Using DeltaV, the accuracy was increased at most 10%. We also compared the predictions in terms of time in a day. In case 1, the model overestimated the Ox amount during the night and underestimated during the day. This bias was significantly improved in case 2 for all years.

©2019. Japan Geoscience Union. All Right Reserved. 

[Conclusion and remarks] We demonstrated an optimization of input data for Ox prediction using the CRNN model. Our approach showed the accuracy of the Ox prediction was improved at most 10% using a difference from the reference diurnal variation instead of using a raw data. This study indicates an importance to optimize input data based on atmospheric science knowledge for air pollution prediction by ML.

# Spatiotemporal Climate Forecasting with ConvLSTM

*Ekasit Phermphoonphiphat[1], Tomohiko Tomita[3], Masayuki Numao[2], Ken-ichi Fukui[2]

1. Graduate School of Information Science and Technology, Osaka University, 2. The Institute of Scientific and Industrial Research, Osaka University, 3. Faculty of Advanced Science and Technology, Kumamoto University

Recent years, climate forecasting techniques with machine learning have been developing to get high accuracy result, unlike physical simulation that uses the techniques of ensemble mean and has already been employed by JMA (Japan Meteorological Agency) which cannot perform well for long term prediction because climate data is a very high non-linear relationship. Machine learning techniques can build a forecasting model by learning patterns from prior data while maintaining the spatial correlation that very important for climate data because the variable from one area could affect other areas. In this paper, we studied the spatial-temporal pattern of machine learning techniques can improve the forecasting result. The experiment compares 3 forecasting models. Linear regression model is a simple forecasting linear model that try to produce linear formula from the training dataset, we use this model with non-spatial correlation setup. CNN (Convolutional Neural Network) is a class of deep learning, the key idea is convolutional layer that is able to maintain spatial correlation through the network. ConvLSTM (Convolutional Long Short-Term Memory) is the improvement version of Fully Connected Long Short-Term Memory that combines convolution operator inside every gate (the control unit that measures how much information will pass through) in the memory cell; therefore, spatial correlation is preferably maintained on the arbitrary of times. We run the experiment to forecast temperature at 2 meter height of the Japan area, we used the monthly mean data of ERA-Interim dataset that started from 1979 to the present. The result has shown that ConvLSTM performs the best accuracy compares to CNN and non-spatial correlation setup linear regression model.

# Deep-Learning Based Short-Term Prediction Method for Sea Ice Concentration Using Explanatory Variables

*Issei Kawashima[1], Toru Kouyama[1], Ryu Sugimoto[1], Ryosuke Nakamura[1]

1. National Institute of Advanced Industrial Science and Technology

Importance of short-term future and middle-term future prediction techniques of sea ice concentration (SIC) has been significantly increasing for navigation of vessels which uses the Northern Sea Route. High frequent updating of the short-term prediction for adopting to SIC is required and thus its calculation load is an important issue same as the accuracy of the prediction. We have been developing a deep-learning based sea ice prediction method and adopting it to Sea of Okhotsk where sea ice coverage dramatically changes during a season. The proposed method can predict SIC immediately once we have sufficient observation or simulation data and the calculation time is very short. In addition, we have confirmed that the predicted SIC has basically good correlation with actual SIC, even though this method only uses previous and current observed SIC by AMSR2. However, considering actual applications, such as navigation for vessels, it is necessary to improve the accuracy of the proposed method as much as possible.

In this study, we proposed a new short-term prediction method for temporal variation of SIC. The new method uses not only SIC but also other variables which can be obtained from observations and/or simulations. The new method can improve the prediction accuracy than that in the previous method.

## [A-CG36] Earth & Environmental Sciences and Artificial Intelligence

convener:Tomohiko Tomita(Faculty of Advanced Science and Technology, Kumamoto University), Kenichi Fukui(Osaka University), Daisuke Matsuoka(Japan Agency for Marine-Earth Science and Technology), Satoshi Ono(Kagoshima University), Chairperson:Tomohiko Tomita(Kumamoto University, Faculty of Advanced Science and Technology)

In recent years, we have been required to explore the gigantic environmental data leading global environmental studies of modern meteorology, oceanography, and hydrology to accomplish Society 5.0 and Sustainable Development Goals (SDGs). Such environmental data, which are typical "big data," include the reliable long-term observatory data, ground radar data, satellite observation, oceanographic observation, global objective analysis data, and so on. However, it is hard to say that such big data are fully utilized, or nobody may have examined many of them. Therefore, to examine the global environment more faithfully, we need to apply the techniques of artificial intelligence/machine learning on such big data, that is, spatiotemporal data modeling of artificial intelligence, prediction and detection by machine learning, techniques of automated data mining, and so forth. Only cross-cutting diagnosis of the gigantic environmental data could resolve a wide variety of environmental problems including measures against global warming. In addition, the application of artificial intelligence/machine learning on the big data would raise us to the 4th paradigm of science (the 1st paradigm, observation/experiment; 2nd, theory; 3rd, simulation; 4th, data driven). This session sincerely invites various research initiatives that accelerate the application of artificial intelligence/machine learning on such gigantic environmental data.

Discussion

# Remote sensing of cloud using the deep learning based on three-dimensional radiative transfer

*Hironobu Iwabuchi[1], Ryosuke Masuda[1], K. Sebastian Schmidt[2,3], Alessandro Damiani[4], Rei Kudo[5]

1. Graduate School of Science, Tohoku University, 2. Department of Atmospheric and Oceanic Sciences, University of Colorado, 3. Laboratory for Atmospheric and Space Physics, University of Colorado, 4. Center for Environmental Remote Sensing, Chiba University, 5. Meteorological Research Institute, Japan Meteorological Agency

Remote sensing is a field of active research to which the machine learning techniques are applied. Machine learning models can be trained to detect characteristics and estimate properties of spatial and temporal variations of geophysical features. The deep learning uses a deep neural network and is rapidly developing in wide areas of industrial applications and scientific research. The deep neural network generally offers high capabilities of automatic feature extraction from multi-variate, multi-modal data and a good approximation of non-linear functions. If a deep learning model is trained well, its advantages are high accuracy with reasonable speed of calculation, which is suitable for practical applications to processing a large amount of data.

We will present a few applications of the deep learning to remote sensing of cloud from satellite- and ground-based optical measurements. In optical remote sensing of clouds, three-dimensional (3-D) radiative transfer effects are a major source of retrieval errors. Radiative interactions operate across spatial elements of the cloudy atmosphere at a wide range of spatial scales. Radiance measured at each pixel of an image taken by a satellite-based imager or ground-based camera is influenced by not only cloud density and microphysical properties along the line of sight but also the spatial distribution of clouds in a wide domain surrounding the line of sight. Although the retrieval of cloud properties is usually based on the independent pixel approximation assuming a plane-parallel, homogeneous cloud for each image pixel, the 3-D radiative interaction makes it difficult to retrieve cloud properties at pixel level if one uses single-pixel radiances solely. Thus, use of multiple pixels looks attractive, offering a great potential to accurately retrieve cloud properties from an image. Convolutional neural networks (CNNs) naturally traces the 3-D radiative effects that appear across image pixels, which traditional single-pixel approaches cannot capture. We have thus developed deep learning models to estimate the spatial distribution of cloud properties from multi-spectral, multi-pixel cloud retrieval from satellite imagery and images taken by a ground-based digital camera. Training data of pseudo-observation radiances are made from simulations using a Monte Carlo 3-D radiative transfer model for cloud fields simulated by a large eddy simulation model with high spatial resolution. In this case, the deep learning model is trained to learn the multi-scale spatial structure of clouds in addition to the complicated relationships between cloud properties and radiances. Deep CNNs show high retrieval accuracy for cloud properties such as cloud optical thickness and effective droplet radius from multi-spectral images of visible, near-infrared, and shortwave infrared channels, efficiently deriving the spatial distribution of cloud properties at multiple pixels all at once from radiances at multiple pixels. By using multi-scale features in the images, it is possible to recover the information lost in 3-D radiative transfer. Results show significantly better accuracy compared with traditional approaches.

# Time series of cloud cover during the night derived from an omnidirectional camera

*Karin miyabe[1], Kazunori Ogohara[1]

1. University of Shiga Prefecture

Surrounding atmospheric environment have a big influence on our lives. For example, fog causes various accidents due to poor isibility. Leisure facilities must be stopped when wind speed is high. Meteoropathy tends to increase depending on perature or weather. Therefore, environmental prediction with higher temporal and spatial resolution than that of daily ather forecast is needed. Cloud cover (CC) will have a large impact on prediction of environmental changes in other tities (e.g. temperature, humidity, wind speed and direction). The method for deriving CC from RGB images taken by an omnidirectional camera has been investigated so far. However, it was not applicable to nighttime images, which is usually grayscale images, due to low SN and low brightness. Therefore, we develop a method for deriving CC from grayscale images taken by an omnidirectional camera during the night using deep learning. Also, we investigate he distortion of the whole-sky images because CC measured in the celestial sphere has a different value from that measured in whole-sky images.We separate cloud areas from sky areas in the whole-sky images using a deep learning technique for semantic segmentation, U-net. U-net is a encoder-decoder type of convolutional neural network. Area under an ROC curve (AUC), which is an evaluation index commonly used in the discipline of machine learning, for nighttime images is 0.985 and that for rainy images during the night is 0.984. However, that for evening and morning images is lower than them, 0.952. Therefore, the proposed method may not be applicable to evening and morning images.

# Time series prediction of cloud cover using whole-sky images and meteorological elements

*Kazunori Ogohara[1], Teppei Sonoda[2]

1. School of Engineering, University of Shiga Prefecture, 2. Graduate School of Engineering, University of Shiga Prefecture

Prediction of the sky conditions is becoming important in several sectors of society. The most typical codition of the sky is cloud cover (CC). CC should have a correlation to air temperature, ground temperature, humidity, and solar radiation, etc. Therefore, prediction of CC is highly significant from the perspective of social application and should have a large impact on accuracy of time-series prediction of other variables.
We have developed a novel method for segmentation of cloud areas in whole-sky images using an encoder-decoder based convolutional neural network to derive CC from images observed by an omnidirectional camera. F-measure for cloud obtained by 10-fold cross validatoin was 0.86. We could generate time series of daytime CC for 1.5 years using the proposed method.
We have tried to predict CC after one hour based on time series of CC itself and solar radiation using recurrent neural network. RMSE of CC between the observed and predicted time series is 0.022 and the predicted time series of CC is more accurate than the persistence model. However, predicted CC tends to get close to 0.4-0.5 and the phase shift like the persistence model is partially seen.

# Fundamental investigation about the inductive prediction of precipitation based on the time series data

*Naoki Matsumoto[1], Tomohiko Tomita[1], Kenichi Fukui[2]

1. Kumamoto Univ., 2. Osaka Univ.

This work applied the artificial neural network (ANN) to observatory data and conducted a fundamental investigation about improving the prediction accuracy in precipitation. Especially, this work focused on the improvement of training data for the short-term prediction in precipitation.
The used data were precipitation, temperature, pressure, vapor pressure, wind speed, and wind direction with hourly interval edited by the Japan Meteorological Agency, and the ANN prediction model was constructed based on multilayer perceptron. Using these data and the ANN prediction model, this work tentatively predicted the time variation of hourly precipitation at Kumamoto, Japan. Then, through systematic changes of the training data, this work investigated how the accuracy of short-term predicton was improved. Especially, the contributions of each observation parameter and of increase of observatories were investigated. For the evaluation of prediction, this work emploied the verification by comparing the peak values between prediction and observation and the appearance time of the peak that are both important for heavy rainfall prediction, and the sum of squared errors between predicted and real values.
This work found that setting the data to the west into the training data is effective for predicting Kumamoto's hourly precipitation. This work also found that the peak value in prediction was greatly improved from 30% to 80% by deleting the data at the time when no precipitation occurs in the training data. Then, the contribution of vapor pressure increases. We will continue to investigate how the precipitation prediction can be improved through the changes of parameters, observatories, and forecast lead times in the training data.
The results of this work will contribute to the construction of a simple precipitation prediction scheme at the location where sophisticated observation data can not be obtained.

# Identification of ships image on SAR data using machine learning

*Takashi Sonoke[1], Hirohide Demura[1]

1. University of Aizu

SAR(Synthetic Aperture Radar) has been popular in Earth remote sensing because this is available for all-weather and night time, unlike optical sensors. The identification of ships has been remarked from viewpoints of coast guard such as finding and monitoring marine accidents and poaching boats without Automatic Identification System (AIS). Current monitoring such situations still has been a visual inspection. This brings some difficulties such as too huge area, too time-consuming processes and so on to monitor them. So, screening candidates of ships have been required for helping the watchers. Machine learning is one of the best solutions because usual visual inspections have been substituted by the recent AI trend.
This research adopts the Convolutional Neural Network (CNN) because this is the most popular approach in image analysis. We have many uses with CNN in image recognition. This research verifies whether a ship image on SAR can be identified by CNN. This research used SAR images of PALSAR2/ALOS2 with a resolution of 10 m/pixel, polarization is HV (horizontal transmitting, vertical receiving) for the identification of ships. This machine learning needs a set of labeled data with positive/negative. The label is given to ship image on SAR using AIS. Results with PALSAR 2 data with a resolution of 10 m / pixel showed high accuracy of 95%. This research showed the availability of a method to discover ships from SAR images using CNN. In the future, this research will classification of ships not only identification. This research will examine how the change of SAR image due to marine weather affect machine learning. I would like to discuss with marine weather experts at JpGU.

# Automatic Detection of Illegal Waste Sites in UAS Orthoimages

Wei-De Chen[1], *Yu-Ching Lin[1], Hsien-Min Wu[1]

1. Chung Cheng Institute of Technology, Taiwan

With the force of technological development and growing human population, it is important for the government to understand the rate of land use/land-cover change. Remotely sensed data has been popularly employed for land use monitoring, in order to avoid improper land use or illegal expansion. Over the past decade, medium-resolution satellite images have been exploited to find out where illegal waste disposal sites are in Taiwan. However, acquiring satellite imagery often takes long revisit time. In recent years, Unmanned Aircraft System (UAS) attached with a non-metric camera has become a popular platform for acquisition of aerial images. It is cost-effective for acquiring temporal images over large geographic areas. This study employed a sensfly Ebee drone to acquire aerial images for monitoring land use activity. An orthoimage can be generated using state-of-the-art Structure-from-Motion (SfM) photogrammetry. With the help of object detection technique in artificial intelligence, illegal activity can be rapidly identified in the orthoimages. The Tensorflow Object Detection API was applied. In this study, a faster region-based Convolutional Neural Network (R-CNN) with Resnet-101model was retrained for detecting the location of illegal waste. The results achieved a recall of 86.9% and a precision of 72.2%. This study demonstrated that it is possible for department of land monitoring to know the hot spot of illegal waste sites. Surveillance operations become active and effective. In the future, hard sampling mining method would be investigated to reduce false alarm cases. Also, a faster detection procedure, such as YOU ONLY LOOK ONCE (YOLO) v3 will be further assessed.

# Using machine learning models to predict the benefits of solar power generation in northern Taiwan

*SHIH-CHIAO TSAI[1], KUO-CHIH HUANG[1], DUN-REN GUO[1]

1. National Defense Univ.

In recent years, the use and development of solar power has been promoted due to climate change and energy crisis. However, solar power generation is highly dependent on local weather characteristics, since the amount of solar radiation is closely related to the atmospheric transparency, water vapor content, cloud coverage and suspended particulate content. In particular, the problem of air pollution in Taiwan is getting worse, and the aerosol in the atmosphere can reflect, scatter or absorb solar radiation, reducing the amount of solar power generation. Therefore, if we want to increase the proportion of solar power generation, it is important to develop a solar energy forecasting technology that combines environmental parameters. This study utilized meteorological data from the Banqiao, Hsinchu, and Xinwu observatories of the Central Weather Bureau, and PM2.5 observation data from the Longtan Station of the Environmental Protection Administration from July 2013 to June 2018, to analysis the relationship between various environmental factors and solar radiation. Then put the data into the mechanical learning models to obtain the solar radiation prediction value (the first half of the data is used for model training and the second half is used for model testing), and compare with the measured values of solar radiation to find the best performing parameter series and model. The results show that a series of 10 weather parameter used in the decision tree algorithm has better training and test scores on the 8th floor (training score 0.821261, test score 0.674572), and the random forest algorithm has the best training and test performance (training score 0.964738, test score 0.716649).

# Change Point Detection and Visualization of Region of Interests on Weather Time Series Data Using Three-dimensional Convolutional Neural Network

*Satoshi Ono[1], Sotaro Maehara[1], Takahiro Kinoshita[1], Ken-ichi Fukui[2], Tomohiko Tomita[3]

1. Kagoshima University, 2. Osaka University, 3. Kumamoto University

To understand long-term natural variation on meteorological observation data, it is necessary to exclude artificial variation factors. This research proposes a 3D Convolutional Neural Network (3D-CNN)–based method to detect changes caused by artificial factors such as relocation of an observation station which appear small perturbation patterns in observed data. The proposed method allows supervised learning by synthesizing training data with supervisory signal. This research conducts experiments with observation data by Automated Meteorological Data Acquisition System (AMeDAS). By cutting off the temperature change pattern observed at two neighboring stations at a certain time and exchanging the subsequent observation data, training data can be synthesized including the virtual observation station movements. Experimental results showed that it is possible to detect the observation station movements in a short distance of several kilometers or less even when using training data synthesized from observation stations that are several tens of kilometers away. In addition, by using guided gradient-weighted class activation mapping, the proposed method could visualize the region of interests on the observation data when detecting change points.

# Estimation of sediment disaster risk around the Fuji River Basin using a machine learning method that considers trigger and inherent factors

*Kazuyoshi Souma[1], Sei Kuroda[2], Takeru Kurakami[2], Takashi Miyamoto[1]

1. Interdisciplinary Graduate School, University of Yamanashi, 2. Integrated Graduate School of Medicine, Engineering, and Agricultural Sciences

Many regions within the Fuji River Basin are vulnerable to sediment disasters. The Fuji River flows through Shizuoka, Yamanashi, and Nagano prefectures and includes the Itoigawa–Shizuoka structural line. As a non-structural countermeasure, the Japan Meteorological Agency (JMA) and prefectural governments operate the Sediment Disaster Alert Information System, which considers detailed rainfall information based on weather radar to determine trigger factors of sediment disasters. However, this system does not directly consider inherent factors such as slope gradient and land surface geology. It is therefore necessary to develop a sediment disaster risk estimation method that considers both trigger and inherent factors.

In this study, we developed a method to estimate sediment disaster risk that considers trigger and inherent factors in the areas around the Fuji River Basin (Yamanashi and Shizuoka prefectures) using neural network and k-means method. The targets of this method are shallow landslides, including debris flows and large slope failures.

As a target for training and validation, we selected the typhoons ROKE (September 21, 2011) and TALAS (September 2-4, 2011), which caused severe damage due to sediment disasters in Yamanashi and Shizuoka prefectures. To determine the inherent factors, we collected 1-km-resolution data for Yamanashi and Shizuoka prefectures using the Elevation Degree of Slope Tertiary Mesh Data, Land Use Tertiary Mesh, and Land Classification Mesh (surface layer geology) products from National Land Numerical Information. To obtain trigger factors, we extracted 60-minute accumulated rainfall (ca. 1-km resolution) from C-band radar data provided by the JMA. We also calculated the soil water index (SWI) using the 3-layer tank model. As training data, we used the occurrence of shallow landslides within each 1-km cell based on disaster reports provided by Yamanashi and Shizuoka prefectures. In this dataset, cells where shallow landslides occurred were assigned a value of 0, and those where shallow landslides did not occur were assigned a value of 1.

We began with binary classification, using a neural network to output values from 0 to 1. We then inputted trigger factors (2 elements) and inherent factors (30 elements) to the neural network. The error (loss function) of the training process did not decrease as epochs increased, due to the presence of several 0 values in the training dataset, which indicated a lack of sediment disaster. We then applied an undersampling method to the input data; however, the error still did not decrease.

In the next step, we reconstructed the neural network (which had two hidden layers) for a regression problem using risk levels from 0 to 1 for each 1-km cell as training data. The input data were classified into 40 clusters using the k-means method, and the risk level for each cell was determined based on the ratio of sediment disaster occurrence cells in each cluster. To equalize the weights of the trigger and inherent factors used in the k-means method, two trigger factors (60-minute accumulated rainfall and SWI) and two inherent factors (slope gradient, fault presence) were selected. The error of the training process (using data for 15:00 Japan Standard Time [JST], September 21, 2011) decreased as the number

©2019. Japan Geoscience Union. All Right Reserved. 

of epochs increased. In the validation phase (using data for 11:00 JST on September 3, 2011), the neural network output showed high values in cells where debris flows actually occurred.

In conclusion, we found that the outputs of the proposed method can be used to determine sediment disaster risk. Adequate selection of input data was important to the validity of the results, as was assignment of equal weight to trigger and inherent factors. Future studies should increase the number of sediment disasters used in the training process.

# Application of deep learning techniques to precipitation guidance in short-term weather predictions

*TAKERU KURAKAMI[1], Kazuyoshi Souma[1], Takashi Miyamoto[1], Takahiko Huruya[1], Jun Magome[1], Hiroshi Ishidaira[1]

1. University of Yamanashi

Introduction
Although numerical weather prediction models are useful methods for predicting rainfall in the short-term, it is difficult to avoid errors when making these predictions. The application of deep learning techniques, which have had remarkable results in processing big data, can effectively correct the outputs of numerical weather prediction models.

Objectives
In this study, we developed a method using deep learning techniques to correct numerical weather prediction model outputs. Using this method, the output rainfall amounts can be used as precipitation guidance.

Methods
We used a Convolutional Neural Network (CNN) as the deep learning model. The data augmentation and data selection (rejection of no rainfall data) were applied. We assumed a regression problem and the sum of squared errors was adopted as the loss function in the CNN. The rainfall amount should not be zero and should be a continuous value, so the Rectified Linear Unit (ReLU) was adopted as the activation function.
The input data for the deep learning model was acquired from numerical weather prediction models between August 1-to 31 2001 in the Keihanshin region of Japan. As input variable, vertical near-ground wind speeds was selected. For the numerical weather prediction model, we used the Heavy Rainfall Event by a CReSiBUC, which consists of Cloud resolving atmospheric model CReSS and a land surface model SiBUC. CReSiBUC considers detailed information regarding urban activity.
For the training data we used observed rainfall amounts based on Radar/Raingauge-Analyzed Precipitation data provide by the Japan Meteorological Agency. The observed data were interpolated, using the nearest neighbor method into the same meshes simultaneously with the prediction results.

Results and discussions
The two-dimensional rainfall distributions before and after being corrected by the deep learning method were compared with the observed data from the Radar Raingauge Analyzed Precipitation. The accuracy was improved by the introduction of the deep learning technique at 01:00JST (Japan Standard Time) on August 21, 2001 during a typhoon rainfall event. We found that the introduction of the deep learning technique effectively improved the accuracy of a precipitation event at a large spatial scale during a typhoon. Conversely, the deep learning technique did not improve the accuracy at 14:00JST on August 6, 2001 during a localized heavy rainfall event. Therefore, errors in the position of the precipitation area cannot be completely corrected in the case of rainfall events at small spatial scales.

Summary
In this study, we have used deep learning techniques to develop a method of precipitation guidance to correct numerical weather prediction model outputs. When comparing these results with observed rainfall

©2019. Japan Geoscience Union. All Right Reserved. 

distribution, the method is effective for large spatial scale precipitation events such as typhoons. However, errors in the position of the area of precipitation cannot be corrected completely in the case of precipitation events at small spatial scales and this needs to be investigated in future research.

# Characteristics of precipitation in Japan evaluated from the ratio of precipitation events

*Kenta Ogino[1], Tomohiko Tomita[1], Naoki Matsumoto[1]

1. Kumamoto University

This study quantitatively evaluated the spatial difference in characteristics of precipitation in Japan based on the time variability in precipitation events and the occurrence ratio of each of clustered events at 47 points (prefectural capitals) in Japan. First, the time variation patterns in precipitation events were classified by the method of hierarchical clustering. In this study, the precipitation event was been defined as follows: (1) the total precipitation is 0.5 mm and over; (2) the start value is 0 mm/h; (3) the time period of a precipitation event is set to be 72 hours; (4) when two-hour break appears, the value of 0 mm/h is set into the subsequent period in the 72 hours. Based on this definition, the precipitation events were extracted in the time period from 1978 to 2018. Then, the precipitation events were separately investigated for “warm” (May to October) and “cold” (November to April) seasons.
The results show that the number of annual precipitation events tends to be large in the area with heavy snowfall and to the south of Kagoshima. In addition, in the warm season, light rain events account for 60 % and more at all points in Japan, and the events lasting for one day are less than 10 %. On the other hand, in the cold season, light rain events are more than 60 % at all points in Japan, and the events lasting for one day are less than 15 %.
From the above results, the characteristics of precipitation in Japan is divided into five; (1) winter light rain area, (2) summer light rain area, (3) summer long-term rain area, (4) winter long-term rain area, (5) all year round rain area.

## [A-CG36] Earth & Environmental Sciences and Artificial Intelligence

convener:Tomohiko Tomita(Faculty of Advanced Science and Technology, Kumamoto University), Ken-ichi Fukui(Osaka University), Daisuke Matsuoka(Japan Agency for Marine-Earth Science and Technology), Satoshi Ono(Kagoshima University)

In recent years, we have been required to explore the gigantic environmental data leading global environmental studies of modern meteorology, oceanography, and hydrology to accomplish Society 5.0 and Sustainable Development Goals (SDGs). Such environmental data, which are typical "big data," include the reliable long-term observatory data, ground radar data, satellite observation, oceanographic observation, global objective analysis data, and so on. However, it is hard to say that such big data are fully utilized, or nobody may have examined many of them. Therefore, to examine the global environment more faithfully, we need to apply the techniques of artificial intelligence/machine learning on such big data, that is, spatiotemporal data modeling of artificial intelligence, prediction and detection by machine learning, techniques of automated data mining, and so forth. Only cross-cutting diagnosis of the gigantic environmental data could resolve a wide variety of environmental problems including measures against global warming. In addition, the application of artificial intelligence/machine learning on the big data would raise us to the 4th paradigm of science (the 1st paradigm, observation/experiment; 2nd, theory; 3rd, simulation; 4th, data driven). This session sincerely invites various research initiatives that accelerate the application of artificial intelligence/machine learning on such gigantic environmental data.

# Automatic Detection of Illegal Waste Sites in UAS Orthoimages

Wei-De Chen[1], *Yu-Ching Lin[1], Hsien-Min Wu[1]

1. Chung Cheng Institute of Technology, Taiwan

With the force of technological development and growing human population, it is important for the government to understand the rate of land use/land-cover change. Remotely sensed data has been popularly employed for land use monitoring, in order to avoid improper land use or illegal expansion. Over the past decade, medium-resolution satellite images have been exploited to find out where illegal waste disposal sites are in Taiwan. However, acquiring satellite imagery often takes long revisit time. In recent years, Unmanned Aircraft System (UAS) attached with a non-metric camera has become a popular platform for acquisition of aerial images. It is cost-effective for acquiring temporal images over large geographic areas. This study employed a sensfly Ebee drone to acquire aerial images for monitoring land use activity. An orthoimage can be generated using state-of-the-art Structure-from-Motion (SfM) photogrammetry. With the help of object detection technique in artificial intelligence, illegal activity can be rapidly identified in the orthoimages. The Tensorflow Object Detection API was applied. In this study, a faster region-based Convolutional Neural Network (R-CNN) with Resnet-101model was retrained for detecting the location of illegal waste. The results achieved a recall of 86.9% and a precision of 72.2%. This study demonstrated that it is possible for department of land monitoring to know the hot spot of illegal waste sites. Surveillance operations become active and effective. In the future, hard sampling mining method would be investigated to reduce false alarm cases. Also, a faster detection procedure, such as YOU ONLY LOOK ONCE (YOLO) v3 will be further assessed.

# Using machine learning models to predict the benefits of solar power generation in northern Taiwan

*SHIH-CHIAO TSAI[1], KUO-CHIH HUANG[1], DUN-REN GUO[1]

1. National Defense Univ.

In recent years, the use and development of solar power has been promoted due to climate change and energy crisis. However, solar power generation is highly dependent on local weather characteristics, since the amount of solar radiation is closely related to the atmospheric transparency, water vapor content, cloud coverage and suspended particulate content. In particular, the problem of air pollution in Taiwan is getting worse, and the aerosol in the atmosphere can reflect, scatter or absorb solar radiation, reducing the amount of solar power generation. Therefore, if we want to increase the proportion of solar power generation, it is important to develop a solar energy forecasting technology that combines environmental parameters. This study utilized meteorological data from the Banqiao, Hsinchu, and Xinwu observatories of the Central Weather Bureau, and PM2.5 observation data from the Longtan Station of the Environmental Protection Administration from July 2013 to June 2018, to analysis the relationship between various environmental factors and solar radiation. Then put the data into the mechanical learning models to obtain the solar radiation prediction value (the first half of the data is used for model training and the second half is used for model testing), and compare with the measured values of solar radiation to find the best performing parameter series and model. The results show that a series of 10 weather parameter used in the decision tree algorithm has better training and test scores on the 8th floor (training score 0.821261, test score 0.674572), and the random forest algorithm has the best training and test performance (training score 0.964738, test score 0.716649).

To understand long-term natural variation on meteorological observation data, it is necessary to exclude artificial variation factors. This research proposes a 3D Convolutional Neural Network (3D-CNN)–based method to detect changes caused by artificial factors such as relocation of an observation station which appear small perturbation patterns in observed data. The proposed method allows supervised learning by synthesizing training data with supervisory signal. This research conducts experiments with observation data by Automated Meteorological Data Acquisition System (AMeDAS). By cutting off the temperature change pattern observed at two neighboring stations at a certain time and exchanging the subsequent observation data, training data can be synthesized including the virtual observation station movements. Experimental results showed that it is possible to detect the observation station movements in a short distance of several kilometers or less even when using training data synthesized from observation stations that are several tens of kilometers away. In addition, by using guided gradient-weighted class activation mapping, the proposed method could visualize the region of interests on the observation data when detecting change points.

# Estimation of sediment disaster risk around the Fuji River Basin using a machine learning method that considers trigger and inherent factors

*Kazuyoshi Souma[1], Sei Kuroda[2], Takeru Kurakami[2], Takashi Miyamoto[1]

1. Interdisciplinary Graduate School, University of Yamanashi, 2. Integrated Graduate School of Medicine, Engineering, and Agricultural Sciences

Many regions within the Fuji River Basin are vulnerable to sediment disasters. The Fuji River flows through Shizuoka, Yamanashi, and Nagano prefectures and includes the Itoigawa–Shizuoka structural line. As a non-structural countermeasure, the Japan Meteorological Agency (JMA) and prefectural governments operate the Sediment Disaster Alert Information System, which considers detailed rainfall information based on weather radar to determine trigger factors of sediment disasters. However, this system does not directly consider inherent factors such as slope gradient and land surface geology. It is therefore necessary to develop a sediment disaster risk estimation method that considers both trigger and inherent factors.

In this study, we developed a method to estimate sediment disaster risk that considers trigger and inherent factors in the areas around the Fuji River Basin (Yamanashi and Shizuoka prefectures) using neural network and k-means method. The targets of this method are shallow landslides, including debris flows and large slope failures.

As a target for training and validation, we selected the typhoons ROKE (September 21, 2011) and TALAS (September 2-4, 2011), which caused severe damage due to sediment disasters in Yamanashi and Shizuoka prefectures. To determine the inherent factors, we collected 1-km-resolution data for Yamanashi and Shizuoka prefectures using the Elevation Degree of Slope Tertiary Mesh Data, Land Use Tertiary Mesh, and Land Classification Mesh (surface layer geology) products from National Land Numerical Information. To obtain trigger factors, we extracted 60-minute accumulated rainfall (ca. 1-km resolution) from C-band radar data provided by the JMA. We also calculated the soil water index (SWI) using the 3-layer tank model. As training data, we used the occurrence of shallow landslides within each 1-km cell based on disaster reports provided by Yamanashi and Shizuoka prefectures. In this dataset, cells where shallow landslides occurred were assigned a value of 0, and those where shallow landslides did not occur were assigned a value of 1.

We began with binary classification, using a neural network to output values from 0 to 1. We then inputted trigger factors (2 elements) and inherent factors (30 elements) to the neural network. The error (loss function) of the training process did not decrease as epochs increased, due to the presence of several 0 values in the training dataset, which indicated a lack of sediment disaster. We then applied an undersampling method to the input data; however, the error still did not decrease.

In the next step, we reconstructed the neural network (which had two hidden layers) for a regression problem using risk levels from 0 to 1 for each 1-km cell as training data. The input data were classified into 40 clusters using the k-means method, and the risk level for each cell was determined based on the ratio of sediment disaster occurrence cells in each cluster. To equalize the weights of the trigger and inherent factors used in the k-means method, two trigger factors (60-minute accumulated rainfall and SWI) and two inherent factors (slope gradient, fault presence) were selected. The error of the training process (using data for 15:00 Japan Standard Time [JST], September 21, 2011) decreased as the number

## [A-CG37] Science in the Arctic Region

convener:NAOYA KANNA(Arctic Research Center, Hokkaido University), Masashi Niwano(Meteorological Research Institute), Tetsu Nakamura(Faculty of Environmental Earth Science, Hokkaido University), Shunsuke Tei(Arctic Research Center, Hokkaido University), Chairperson:Tetsu Nakamura(Faculty of Earth Environmental Science, Hokkaido University), Shunsuke Tei(Arctic Research Center, Hokkaido University)

The Arctic and circumpolar region is the key area for the study of global change because the anthropogenic impact is projected to be the largest in this area due to the complicated feedback processes of the nature. A number of international and interdisciplinary research projects have been conducted for the studies on the land-atmosphere-ocean system. In order to understand the feedback processes occurring in the Arctic and to project the global warming in the future, we need to establish the intense observational network and to exchange the knowledge and information by combining the different scientific communities under the common interest of the Arctic. The objectives of this session are 1) to exchange our knowledge on the observational facts and integrated modelling and 2) to deepen our understanding on wide range of natural sciences related to the Arctic and the circumpolar region. Studies on humanities, social sciences, and interdisciplinary fields are also welcomed.

# Arctic midlatitude linkage modulated by the QBO

*Jinro Ukita[1], Kazuhiro Hoshi[1], Meiji Honda[1], Tetsu Nakamura[2], Koji Yamazaki[2]

1. Niigata University, 2. Hokkaido University

We examined an observed relationship between the BKS sea ice variability and the midlatitudes cold anomaly and found that this relationship is highly dependent on the QBO phase, easerly (QBO-E) or westerly (QBO-W). For the QBO-E winters midlatitude cold (warm) anomalies appear significantly under the low (high) sea ice condition. On the other hand, such a relationship is not found in the QBO-W winters. This dependence is a robust feature. Atmospheric circulation anomalies related to the high and low sea ice conditions are also different between the two QBO phases. In the troposphere, stationary Rossby wave propagation from the BKS region and the negative NAO appear in QBO-E, along with weakened stratospheric polar vortex and downward propagation of the signals. For QBO-W, such tropospheric and stratospheric signals are mainly absent. Our results may provide an explanation for why some simulations suggest the presence of Arctic sea ice impacts on midlatitude surface temperature while others do not. The most important implication is that in the Arctic-midlatitudes climate linkage tropics also plays a key role.

**Abstract**

Teleconnections between lower and higher latitude regions are widely known in both the Northern and Southern Hemispheres. To broaden our view of these teleconnections, we searched a reanalysis dataset for evidence of a teleconnection between the Arctic Oscillation (AO) and the Antarctic Oscillation (AAO), two widely separated circumpolar phenomena. Statistical analysis of the Japanese 55-year reanalysis dataset showed significant in-phase synchronization between the AO and AAO, particularly in October and February, with a vertical structure extending from the troposphere to the stratosphere. This vertical structure may suggest a stratospheric control, and we did not find a significant signature indicating a tropical ocean control. We also observed decadal-scale modulation of the synchronicity. Observational evidence implies that the stratospheric meridional circulation may be responsible for AO–AAO synchronization. This paper was published in ***GRL,*** 45, DOI:10.1029/2018GL081002 by Tachibana et al., 2018.

**Plain Language summary**

The Arctic Oscillation (AO) and the Antarctic Oscillation (AAO) are dominant atmospheric variability patterns in the Northern and Southern hemispheres, respectively. Each is a pressure seesaw between the pole and the midlatitudes that remotely affects weather, climate, and environment around the world. We showed interhemispheric in-phase synchronization between the AO and AAO in October and February, and we also found decadal-scale variation of the synchronicity. Because the vertical structure of the AO–AAO synchronization extends from the troposphere to the stratosphere, stratospheric variations may be responsible for the synchronization. This finding of AO–AAO synchronization points the way to a better understanding of past, present, and future pole-to-pole climatic relationships and improvements in long-term weather forecasts.

# Marginal ice zone sea ice observations in the refreezing Chukchi Sea

*Takehiko Nose[1], Tsubasa Kodaira[1], Takuji Waseda[1], Jun Inoue[2]

1. The university of Tokyo, 2. National Institute of Polar Research

Regions in the Arctic Ocean that were inaccessible in November are now open for navigation, even for non-icebreakers, and R/V Mirai, a Polar Class 6 vessel, carried out a late autumn voyage in 2018. It conducted a 12-day sea ice observation campaign during the 9th–20th of November along a fixed Marginal Ice Zone (MIZ) transect in the eastern Chukchi Sea and obtained first-hand observations at a time when research vessels are rarely in the sea. Satellite sea ice data were compared with the shipboard observations and compared relatively well. A sequence of events to describe the observations are grouped and described in four phases: 9th–13th, “Sea ice growth under relatively calm wind conditions”; 14th–16th, “the on-ice wave event, sea ice break up, and subsequent sea ice advance”; 17th–18th, “sea ice retreat or a mass shift under moderate easterly winds”; and 19th–20th, “warming sea surface temperature (SST) under strengthening cold off-ice winds and air temperatures below -10 ˚C”. Shipboard and ERA5 reanalysis data were analysed to identify physical processes that affect the Chukchi Sea refreezing process. Sea ice conditions during the first two phases appear to be influenced primarily by surface winds whereas the analysis suggests a driver of sea ice conditions in the latter phases were due to ocean interior processes. The MIZ transect waters became heavily ice covered within five days after R/V Mirai began its return voyage, so the observation period covered most of the refreezing process along the transect water.

# Prediction of wildfire and air pollution with machine learning over the five domains of Eastern Eurasia

*Teppei J Yasunari[1,2], Ichigaku Takigawa[3], Kyu-Myong Kim[4], Arlindo M da Silva[4]

1. Faculty of Engineering, Hokkaido University, 2. Arctic Research Center, Hokkaido University, 3. Graduate School of Information Science and Technology, Hokkaido University, 4. NASA Goddard Space Flight Center

Under the ongoing global warming, necessity of better forecasting on wildfires and its air pollutions is increasing. In the last year, we carried out a preliminary wildfire prediction using the areal-averaged monthly mean data over a large Siberian domain (Yasunari et al., 2018, presented at AGU Fall Meeting 2018: http://bit.ly/2PG1bmK). Here we extend our previous analysis of machine learning and prediction into the five separated domains over the Arctic and sub-Arctic regions over Eastern Eurasia including Siberia, East Asia, Far East, etc. We use the same monthly mean dataset during 2003-2017 as we did in the last year above (i.e., NASA's FEER fire data, MODIS Snow Cover Fraction, SCF, Modern-Era Retrospective analysis for Research and Applications, Version 2, MERRA-2). The time periods of 2003–2014 and 2015–2017 focus on learning and prediction. Areal averaged data for objective (i.e., wildfire and air pollution variables) and explanatory variables (i.e., snow, temperature, wind, surface soil wetness, precipitation, geopotential height, etc.) over the defined five domains over Eastern Eurasia (Domain 1: 57°–70°N, 60°–90°E; Domain 2: 57°–70°N, 90°–140°E; Domain 3: 60°–70°N, 140°–180°E; Domain 4: 42.5°–57°N, 60°–90°E; Domain 5: 42.5°–57°N, 90°–140°E) are calculated, together with producing monthly time-lagged data for explanatory variables up to six months (i.e., total 174-month data available during 2003 and 2017). In addition, we made different areal-averaged fire pixel count data in which some smaller fires were removed with defined thresholds to remove expected human-made fires such as bonfires (i.e., assumed natural fire cases). If the areal-averaged fire data under the thresholds on a specific month showed no fire, we replaced that data to zero (i.e., used for our analyses but treated as zero fire data on that month).
Using Random Forest Regression, for example, in the machine learning, except for Domain 5, all the fire-included case showed the worse prediction score than those of the assumed natural fire cases. This implies that smaller fire cases, which were likely ignited by human activities or others, would be one of the causes for making wildfire predictions worse. However, over Domain 5, all the fire-included case showed the best probably because the assumed natural fire case was probably affected by the unusual large-scale wildfire events (i.e., outliers). These significantly large-scale wildfire cases also likely to make predictions worse because of not enough such cases existing in the training data (i.e., not frequent). In addition, these outliers might happen under unusual climatic and environmental conditions. How to include more large-scale fire cases in training data would be one of the important future targets on wildfire prediction with machine learning. On the day of the presentation, we'll also show the results for air pollution prediction.

# Hydrological Changes in the Four Largest Siberian Arctic River Basins

*Kazuyoshi Suzuki[1], Tetsuya Hiyama[2], Kazuhito Ichii[3], Yoshihiro Iijima[4], Koji Matsuo[5], Dai Yamazaki[6,1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Institute for Space-Earth Environmental Research, Nagoya University, 3. Chiba University, 4. Graduate School of Bioresources, Mie University, 5. Geospatial Information Authority of Japan, 6. Institute of Industrial Sciences, The University of Tokyo

The Arctic freshwater budget affects global climate and is critical for understanding the climate in polar regions. However, the hydrology of the largest Eurasian Arctic rivers is still not understood well. In this paper, we analyze spatiotemporal variations in hydro-climatological factors related to four of the largest Siberian Arctic river basins (Ob, Yenisey, Lena, and Kolyma). To examine recent hydro-climatological changes in these river basins, we utilize monthly observation-based gridded meteorological and evapotranspiration data, Moderate Resolution Imaging Spectroradiometer (MODIS)-based products such as the snow area fraction (SAF) and normalized vegetation index (NDVI), global land data assimilation system products, and Gravity Recovery and Climate Experiment (GRACE) data from 2000 to 2016. Combining these with river runoff data, we identify how river runoff shifted from June to May during the study period. River runoff in May significantly increased although there was no clear trend in annual discharge. In addition, SAF decreased drastically in April and this is evidence that spring snow coverage in Siberian basins is shrinking and snowmelt is shifting toward earlier. On the other hand, we found the positive trend in summer NDVI. Focusing on permafrost distribution, this paper will discuss the correlation in the temporal lag between the water cycle and vegetation activity.

# Mapping thermokarst subsidence in Central Yakutia using L-band SAR interferometry

*Takahiro Abe[1], Go Iwahana[2,3], Takeo Tadono[1]

1. Earth Observation Research Center, Japan Aerospace Exploration Agency, 2. International Arctic Research Center, University of Alaska, Fairbanks, 3. Arctic Research Center, Hokkaido University

Thermokarst is an irreversible phenomenon with geomorphological change, resulted from the thawing of ice-rich permafrost or the melting of massive ice. The formation of large depressions in the ground surface by thermokarst processes results in surface inundation, and causes damages on infrastructure. Central Yakutia in Eastern Siberia is one of the regions where ice-rich permafrost is broadly distributed. The remarkable surface subsidence due to thermokarst has been observed in recent years, which could cause destruction of building and infrastructure in this area (Shiklomanov et al., 2017; Hjort et al., 2018). The thermokarst settlement are frequently observed in continuous permafrost zones in arctic regions, especially in Alaska and the Northeastern Siberia. However, it is so difficult to know where and how surface deforms in vast permafrost zones.

Remote sensing technique, especially Interferometric Synthetic Aperture Radar (InSAR), has a great potential to monitor the thermokarst subsidence, and seasonal permafrost melting and heaving. SAR sends microwave toward ground, and receive the reflected and scatter signals under all-weather and day-and-night condition without any instrument on ground. Thus, InSAR can provide essential information to understand thawing process of ice-rich permafrost and to predict the future stage over arctic permafrost region. Many studies about permafrost dynamics using SAR images have been reported so far (e.g., Liu et al., 2010; Iwahana et al., 2016; Antonova et al., 2018; Strozzi et al., 2018), but there is no study using SAR in Central Yakutia.

In this study, we used ALOS/PALSAR (2007-2010) and ALOS-2/PALSAR-2 (2014-2018) images to examine ground subsidence caused by thermokarst development. GAMMA software was used to generate Single Look Complex data from Lv1.0 data in ALOS/PALSAR and Lv1.1 data in ALOS-2/PALSAR-2. ALOS world DEM derived from ALOS/PRISM was used to simulate and remove topographic effect. We generated many interferograms, selected some of them, and applied stacking procedure weighted on period between two SAR data acquisition time, estimating the mean change rate along line of sight (LOS). Assuming ground displacement is only vertical component, the LOS change was converted to vertical displacement using incidence angle.

At the last JpGU, we reported ground subsidence in Mayya, on the right bank of Rena River, Central Yakutia, derived from ALOS/ALOS-2 InSAR stacking. To validate the InSAR signals, we carried out the ground observation in Mayya at the end of September, 2018. As a result, the subsidence rate of 2-3 cm/yr was obtained at the two measurement points in 2017-2018. The result of ground observation is consistent with that of InSAR result from ALOS-2. We also went to some places where there are subsidence signals in the ALOS-2 results. As a consequence, the two large subsidence signals were found in alasses. Alas is considered as a final geomorphological stage of old thermokarst development. Significant amount of the subsidence may be due to consolidation settlement associated with soil desiccation under recent dry climate conditions. However, judging from new developments of polygonal subsidence in the bottom areas of alasses, ground ice still remains under the alasses, which may cause further thermokarst progress.

©2019. Japan Geoscience Union. All Right Reserved. 

Moreover, we extended our target to other cities, Amga, and Churapcha, where thermokarst has been also developing (e.g., Saito et al. 2018). The similar subsidence signals were obtained in the two cities, where it is in area of many polygons. It suggests that the signals be presumably due to thermokarst development.

## [A-CG37] Science in the Arctic Region

convener:NAOYA KANNA(Arctic Research Center, Hokkaido University), Masashi Niwano(Meteorological Research Institute), Tetsu Nakamura(Faculty of Environmental Earth Science, Hokkaido University), Shunsuke Tei(Arctic Research Center, Hokkaido University), Chairperson:Shunsuke Tei(Arctic Research Center, Hokkaido University), Masashi Niwano(Meteorological Research Institute)

The Arctic and circumpolar region is the key area for the study of global change because the anthropogenic impact is projected to be the largest in this area due to the complicated feedback processes of the nature. A number of international and interdisciplinary research projects have been conducted for the studies on the land-atmosphere-ocean system. In order to understand the feedback processes occurring in the Arctic and to project the global warming in the future, we need to establish the intense observational network and to exchange the knowledge and information by combining the different scientific communities under the common interest of the Arctic. The objectives of this session are 1) to exchange our knowledge on the observational facts and integrated modelling and 2) to deepen our understanding on wide range of natural sciences related to the Arctic and the circumpolar region. Studies on humanities, social sciences, and interdisciplinary fields are also welcomed.

# Spatiotemporal variation of thaw subsidence and frost heave of permafrost caused by wildfire around Batagay, East Siberia

*Kazuki Yanagiya[1], Masato Furuya[2]

1. Graduate School of Science, Hokkiado University, 2. Faculty of Science, Hokkaido University

Thawing permafrost release soil organic carbon as a greenhouse gases, and it can be positive feedback on global warming (Shuur et al. 2015). To estimate terrestrial carbon budget precisely, permafrost degradation should be observed in the entire circumpolar region. However, it is impractical to perform field observation over all the permafrost areas in northern hemisphere. Especially in Siberia, observation sites by the international network (e.g. GTN-P, CALM) is very few despite the largest area in terms of permafrost distribution. Therefore, remote sensing techniques to cover wide areas are indispensable. Observing ground deformation by InSAR (Interferometric Synthetic Aperture Radar) can tell us the state of permafrost with high spatiotemporal resolution. Some previous studies are conducted in a part of Alaska, Canada and Siberia that can be easy to compare with field work (Liu et al. 2010; Short et al. 2011; Antonova et al. 2018).

We focused on East Siberia, where no previous studies by InSAR are conducted. Study area is around Batagay town (67’ 39N, 134’ 39E). At ~10 km southeast of Batagay, there is a well-known and one of the largest slump terrains caused by thawing of permafrost (Murton et al. 2017). Processing ALOS and ALOS2 InSAR images, we found the deformation signal due to wildfire at the hill to the 20 km northwest of Batagay. Loss of surficial vegetation layer by wildfire accelerates permafrost thawing, and the degradation continues for several years to decades after a fire (Yoshikawa et al. 2002). Furthermore, given the fact that the frequency and intensity of wildfires are increasing in the Arctic region with global warming (Alexander et al. 2018; Gibson et al. 2018; Masrur et al. 2018), it is important to reveal the spatiotemporal variation of the ground deformation in the post-wildfire area.

Here, we report our detection of the post-wildfire ground deformation in the place where the fire occurred in 2014. We used SAR images obtained from ALOS 2 (L-band) and Sentinel-1 (C-band) satellites from 2014 to 2018. Secular deformation is detected by ALOS2 data. The results indicated that thawing subsidence up to 10cm in the satellite line of sight direction continued after 2-3 years after the fire. Seasonal deformation from 2017 to 2018 is detected and compared with both satellites data. The magnitude and spatial patterns of subsidence and uplift was consistent in both satellites. Especially, short-term InSAR images with Sentinel-1 data revealed detailed temporal variation from the start to the end of thawing and freezing. Estimation of permafrost thawing amount from ground deformation amount detected by InSAR can contribute to reducing uncertainty of terrestrial carbon budget. Those physical models are under discussion (Liu et al. 2014; Hu et al. 2018; Molan et al. 2018). In this study, we verified the Molan model in our study area, and developed it taking into account the deformation in the slope direction.

Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Science, Russia

Recent years of increasing air temperature in the Arctic have known to lead a significant increase in the retreat speed of permafrost coast, which has threatened livelihoods and infrastructure along the coasts. The Kara Sea hosts more than 25% of the total length of Arctic coasts. Despite many works for more than six decades, little is known about how the Kara Sea coasts, affected by permafrost and sea-ice, may have changed through time and what the climatic and environmental drivers are. To understand the dominant climatic factors influencing the dynamic processes along the permafrost and sea-ice affected coastline, we study dynamics of permafrost coast along the Baydaratskaya Bay of Kara Sea, Western Siberia, during the rapidly retreated period 2005–2016, by handheld differential GPS mapping, satellite imagery, measurements of ground temperature and subsurface resistivity, and meteorological data. These multidisciplinary data reveal that the activity of wind-driven ocean wave during the sea ice-free (open water) days influences the magnitude of coastal retreat in the study area, while that recent temperature rise less contributes to enhancing coastal retreat during the study period. This suggests that the magnitude of wave activity over the sea ice-free days controls the quantities of the eroded sediment and the associated release of nutrient to the nearshore zone, which might result in influencing infrastructure along the permafrost coast and marine ecosystem in the proximal ocean.

# Ice front variations of Heilprin Glacier in northwestern Greenland controlled by the ocean and glacier bed geometries

*Izumi Asaji[1,2], Daiki Sakakibara[3], Takuto Ando[3], Shin Sugiyama[1]

1. Institute of Low Temperature Science, Hokkaido University, 2. Graduate School of Environmental Science, Hokkaido University, 3. Arctic Research Center, Hokkaido University

The Greenland ice sheet is losing mass under the influence of increasing surface melting and ice discharge from marine-terminating outlet glaciers. Better understanding of mechanisms controlling ice dynamics of marine-terminating glaciers is crucial for predicting future mass loss from the ice sheet. However, processes controlling rapid retreat of the glaciers are not well explained. As many Greenlandic glaciers thinned recent years, ice thickness near the current front position is possibly close to the hydrostatic equilibrium condition. Therefore, we hypothesize that a possible cause of recent rapid retreat of marine-terminating glaciers is surface lowering below the flotation level (ice surface elevation at which buoyancy and gravitational forces balance). Validation of this hypothesis requires detailed ice surface and bed elevation data near the calving front.

In this study, we measured bed topography and surface elevation of Heilprin Glacier in northwestern Greenland. Heilprin Glacier has a 6 km-wide terminus, which is currently separated to three calving fronts. The front position advanced by 800 m from 1990 to 2000, and retreated by 1 km from 2000 to 2009. We measured the ocean bed topography near the one of the calving front situated in the north, using a sonar fixed on a boat from 13 to 15 August, 2018. The surface elevation change from 2001 to 2012 was analyzed by using digital elevation models generated from satellite images acquired by an optical sensor ASTER (Advanced Spaceborne Thermal Emission and Reflection Radiometer) mounted on the Terra satellite. We computed the flotation level from the bed elevation, and compared it with glacier surface elevation before and after the rapid retreat.

Near the studied glacier front, the fjord is deeper in the northern side of the glacier, and the maximum water depth in the region was 340 m. The glacier retreated by 1 km over this deepest area from 1998 to 2008. Analysis of the data showed that the glacier surface near the front in 2000 was 10 m below the flotation level, suggesting significant ice thinning prior to the rapid retreat. It is likely that the retreat of northern front of Heilprin Glacier was driven by thinning and ice flotation at the deepest area of the fjord.

# Meltwater discharge and flooding of the outlet stream of Qaanaaq Glacier, northwestern Greenland

*Ken Kondo[1,2], Daiki Sakakibara[3,2], Shungo Fukumoto[1,2], Shin Sugiyama[2]

1. Graduate School of Environmental Science, Hokkaido University, 2. Institute of Low Temperature Science, Hokkaido University, 3. Arctic Research Center, Hokkaido University

Glacial meltwater discharge is increasing in Greenalnd under recent warming climate. As a consequence, floods and damages on infrastructures are reported at outlet streams of land terminating glaciers. For instance, discharge from Qaanaaq Glacier in northwestern Greenland rapidly increased on 21 July 2015 and 2 August 2016, leading to floods of a proglacial stream and destruction of a road between a settlement and Qaanaaq Airport. To better understand the mechanisms of the flood events at Qaanaaq Glacier, we investigated meteorological conditions during the 2015 and 2016 events by using AWS operated on the ice cap at 944 m a.s.l. (SIGMA-B) (Aoki et al., 2014). We performed field measurements in the summer 2017 and 2018 to investigate melting process of Qaanaaq Glacier and the response of the outlet discharge. These data were combined with surface mass balance of Qaanaaq Glacier observed from 2012 to 2018 to analyse the cause of floods in 2015 and 2016.

Surface mass balance was significantly more negative in 2015 and 2016 as compared to the other years. Glacier wide mass balance was −0.76±0.13 m w.e. in 2014/2015 and -0.28±0.7 m w.e. in 2015/2016. Before the floods, daily mean temperature rose above 5 ˚C for 5 days in 2015 and above freezing for almost a month in 2016 at SIGMA-B. Such warm conditions caused intensive melting over the entire glacier, resulting in saturation and disappearance of snowpack from the glacier below 950 m a.s.l. In addition to large exposure of ice surface, heavy rainfall (90 mm $d^{-1}$) occurred on the date of the flood in 2016. we assume that the exposed ice surface helped immediate runoff of a large amount of rainwater. These analyses suggested the loss of snow cover played a key role in the flood events in 2015 and 2016.

We measured discharge from Qaanaaq Glacier from 21 July to 3 August 2017. Stream discharge rapidly increased on 28 July 2017, leading to a peak value of 8.11 $m^3$ $s^{-1}$. From 21 to 28 July, snowline elevation rose from 500 to 650 m a.s.l. after intensive melting. Runoff measured before the peak discharge accounted for only 60 % of the estimated total glacier melt, indicating the rest of meltwater remained in snowpack on the glacier. These data suggested snowpack was saturated with meltwater, and rapidly released water during the period of rapid melting and upglacier snowline migration. Together with data obtained by similar measurements in 2018, we conclude that saturation and disappearance of snowpack are the key to predict rapid increase in stream discharge and flooding.

# Occurrence frequency of lee-side downslope winds near Siorapaluk in northwest Greenland

*Akihiro Hashimoto[1], Tetsuhide Yamasaki[2], Teruo Aoki[3,1], Masashi Niwano[1], Satoru Yamaguchi[4]

1. Meteorological Research Institute, 2. Avangnaq, 3. The Graduate School of Natural Science and Technology, Okayama University, 4. Snow and Ice Research Center, National Research Institute for Earth Science and Disaster Resilience

In early April 2018, Niwano et al. (2018) conducted the scientific traverse expedition “Snow impurity and glacial microbe effect on the abrupt warming in the Arctic (SIGMA) Traverse 2018”. The expedition crews had initially planned to depart Siorapaluk on April 2, 2018. However, their departure was delayed by four days because of strong winds and snow blocking the way. Numerical experiment showed that the strong wind had characteristics of a lee-side downslope wind (Hashimoto et al., 2018). Matoba and Yamasaki (2018) reported a sea ice outflow event and its damage to fishery along the coast of Qaanaaq (50-km southeast of Siorapaluk) in early December 2016, which was the first time experience for residents of Qaanaaq over the last 30 years. They assumed that northeasterly winds of more than 30 $ms^{-1}$ on 6-hour average dispersed sea ice from the coast, based on observation data at Qaanaaq airport.

These strong wind events seriously affected the scientific activity and residents’ living, which motivate the authors to study occurrence characteristics of strong winds in the northwest Greenland. According to observation performed during 2016-2017 and 2017-2018 winter seasons in Siorapaluk, strong winds more than 15 $ms^{-1}$ occur in several times. These winds are always from the north-northeast to the observation point, which means that these winds blow beyond the ridgeline in the north of Siorapaluk. Year-round observation in Qaanaaq shows that strong winds appear also in summer as well as in winter. Some strong wind events are found to occur simultaneously in Siorapaluk and Qaanaaq. Numerical simulations are conducted for the period from May 2017 to April 2018 by using the Japan Meteorological Agency’s non-hydrostatic model (JMA-NHM) with the 1-km horizontal resolution to reveal temporal and spatial distributions of strong winds and mechanisms causing them. Statistical features of strong winds and dynamical connections between synoptic and local wind systems will be presented in the meeting.

# Impacts of clouds on the Greenland ice sheet surface melt and mass balance

*Masashi Niwano[1], Akihiro Hashimoto[1], Teruo Aoki[2]

1. Meteorological Research Institute, 2. Graduate School of Natural Science and Technology, Okayama University

Clouds have been recognized to enhance surface melt on the Greenland Ice Sheet (GrIS). However, quantitative estimates of the effects of clouds on the GrIS melt area enhancement and resultant ice-sheet-wide surface mass balance modulations are still lacking. Here we assessed the effects of clouds with the state-of-the-art regional climate model NHM-SMAP (Niwano et al., 2018), conducting a numerical sensitivity test in which clear-sky downward radiations and adiabatic atmospheric conditions were assumed, although the precipitation rate was the same as in the control all-sky simulation. By including or excluding cloud effects, we quantified time-integrated feedbacks for the first time. We found that the surface melt area extent increased by 3.1%, 0.3%, and 0.7% (of the total GrIS area) by the presence of clouds during summer (June to August) in 2012, 2013, and 2014, respectively. During the same periods, clouds reduced solar heating and thus daily runoff by 1.6, 0.8, and 1.0 Gt $day^{-1}$, respectively: clouds did not enhance the GrIS surface mass loss. In the ablation area, the presence of clouds results in a reduction of downward latent heat flux at the snow/ice surface so that much less energy is available for the surface melt, which highlights the importance of indirect effects of clouds.

Thu. May 30, 2019 1:45 PM - 3:15 PM JST | Thu. May 30, 2019 4:45 AM - 6:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_4

## [A-CG37] Science in the Arctic Region

convener:NAOYA KANNA(Arctic Research Center, Hokkaido University), Masashi Niwano(Meteorological Research Institute), Tetsu Nakamura(Faculty of Environmental Earth Science, Hokkaido University), Shunsuke Tei(Arctic Research Center, Hokkaido University)

The Arctic and circumpolar region is the key area for the study of global change because the anthropogenic impact is projected to be the largest in this area due to the complicated feedback processes of the nature. A number of international and interdisciplinary research projects have been conducted for the studies on the land-atmosphere-ocean system. In order to understand the feedback processes occurring in the Arctic and to project the global warming in the future, we need to establish the intense observational network and to exchange the knowledge and information by combining the different scientific communities under the common interest of the Arctic. The objectives of this session are 1) to exchange our knowledge on the observational facts and integrated modelling and 2) to deepen our understanding on wide range of natural sciences related to the Arctic and the circumpolar region. Studies on humanities, social sciences, and interdisciplinary fields are also welcomed.

# Increasing trend of downward long-wave radiation at the surface in the winter Arctic

*Yuta Miwa[1], Toru Nozawa[2]

1. Faculty of Science, Okayama University , 2. Graduate School of Natural Science and Technology, Okayama University

In recent years, observations show that warming in the Arctic is remarkable and rate of the warming after the 1950s is about twice that of the global average. This feature is called "Arctic amplification", and the Arctic warming is especially significant in autumn and winter. According to the previous studies, analysis based on the thermal energy balance on the surface suggests that the warming in the Arctic winter has the largest influence of the downward longwave radiation. On the other hand, factors that increase downward longwave radiation are not necessarily clearly shown. In this study, after analyzing the same as the previous studies, we considered the factor that causes downward longwave radiation increase in winter Arctic warming.

We used the Japanese 55-year Reanalysis (JRA-55) dataset. We analyzed the 30 winter season from 1988 to 2018, taking the average for the three months from November to January, where the influence of solar radiation can be ignored for the Arctic region north of 60 ˚N. It was found that, although it is different dataset and different period from the previous studies, increases in the downward longwave radiation has the largest influence on the surface warming. The downward longwave radiation can be divided into the following two components: clear-sky radiation and cloud radiative forcing (CRF), both of which are consistent with the trend pattern of the surface warming, and the clear-sky radiation has relatively larger influence on the surface warming than the CRF. Increase in clear-sky radiation is brought about by increase either in atmospheric water vapor or well-mixed greenhouse gases. From the diagnosis of radiative forcing due to an increase in greenhouse gas concentration, however, it is suggested that the increase in water vapor dominates. Trend pattern of the precipitable water is also consistent with that of the downward longwave radiation in the clear-sky. In addition, it is suggested that an increase in the CRF is due to that in the low-level clouds. It is also suggested that decreases in sea ice area and increases in net evaporation over the ice-retreated area may cause increases in the atmospheric water vapor and low-level clouds, but due to a problem of the JRA-55, further analysis is necessary.

# Climate memory of the Eurasian land process for the Arctic amplification

*Tetsu Nakamura[1], Koji Yamazaki[1], Tomonori Sato[1], Jinro Ukita[2]

1. Faculty of Environmental Earth Science, Hokkaido University, 2. Faculty of Science , Niigata University

Amplified warming over the Arctic region, so called Arctic amplification (AA), and its relevance to the mid-latitude cooling in winter have recently been intensively studied. Recognizing rapid decline of the Arctic sea ice as to coincide with AA, sea ice-climate impacts have been examined in both observational and modeling studies. However, there is a serious gap between diverged simulation results among models/studies and observational evidence showing strong relevance of sea ice variation to AA signals on the interannual to decadal timescales. To fill the gap, we assume the climate memory effect of the land process that achieves amplification and recurrence of the sea ice-climate impacts. Here we designed and performed a set of general circulation model experiments that is able to extract the memory effect of land process. The memory of the northern Eurasian cooling anomalies that originally induced by sea ice loss are stored as snow amount and soil temperature. Memorized anomalies could induce the atmospheric circulation resembling the negative Arctic oscillation and amplify the Arctic warming in the later years. Estimated atmospheric circulation change due to this memory effect is comparable with that directly induced by sea ice loss. Reducing uncertainty of the land process operated in the climate models, which is expected to have large model dependency, would be a major choice to achieve the robust simulation results to evaluate sea ice-induced AA.

# Interannual variation of summer precipitation and atmospheric water circulation over and around Alaska

*Shohei Morino[1], Tetsuya Hiyama[2], Hatsuki Fujinami[2], Hironari Kanamori[2], Masahito Ueyama[3]

1. Graduate School of Environmental Studies, Nagoya University, 2. Institute for Space-Earth Environmental Research, Nagoya University, 3. Graduate School of Life and Environmental Sciences, Osaka Prefecture University

Arctic warming is more apparent than global average. Water cycle in the region is also changing due to the climate warming. The variation of atmospheric water circulation influences terrestrial ecosystems through precipitation and soil water content. Hiyama et al. (2016) revealed the atmospheric circulation associated with the increase in summer precipitation from 2005 to 2008 in eastern Siberia. Ohta et al. (2014) indicated that increased precipitation in eastern Siberia caused waterlogging and damaged the larch forest. On the other hand, a recent observational research indicated that recent increased summer precipitation caused increase in methane emission from the black spruce forest in the interior of Alaska. Therefore, this study investigated interannual variability of summer precipitation and associated atmospheric water circulation in the interior of Alaska using ERA-Interim reanalysis data and rain gauge observation data in Fairbanks from 2003 to 2017. We extracted dry and wet years based on summer precipitation time series and then conducted composite analyses. Geopotential height and horizontal wind at 850 hPa and vertically integrated moisture flux were composited. We found that the change in low-level westerly wind and moisture flux blowing into the interior of Alaska was a primary factor to induce the interannual variation of summer precipitation in the region. This westerly moisture flux is associated with the atmospheric circulation pattern with cyclonic and anticyclonic anomalies around and over the Alaska. Moreover, the anomaly pattern is related to cyclone activity. More cyclones are detected in the region of the cyclonic anomaly, while less cyclones in the region of the anticyclonic anomaly. Sea surface temperature may partly contribute to the cyclone activity. A planetary wave might influence precipitation variability in the interior of Alaska through a teleconnection in these latitudes.

# Detection of a climatological short break in the polar night jet in early winter and its relation to cooling over Siberia

*Yuta Ando[1], Koji Yamazaki[2], Yoshihiro Tachibana[1], Masayo Ogi[3], Jinro Ukita[4]

1. Graduate School of Bioresources, Mie University, 2. Hokkaido University, 3. Centre for Earth Observation Science, University of Manitoba, 4. Faculty of Science, Niigata University

The polar night jet (PNJ) is a strong stratospheric westerly circumpolar wind in winter, and the strength of the climatological PNJ is widely recognized to increase from October through late December. We found the PNJ stops increasing temporarily during late November, when the upward propagation of Rossby waves from the troposphere increases. The upward propagation of Rossby waves, which is strongest over Siberia, is related to strengthening of the low pressure over Siberia. We suggest that longitudinally asymmetric forcing by land–sea heating contrasts caused by their different heat capacities might cause the strengthening of the low pressure.

# Recent breakdown of the seasonal linkage between the winter North Atlantic Oscillation/Northern Annular Mode and summer Northern Annular Mode

*Koji Yamazaki[1], Yoshihiro Tachibana[2], Masayo Ogi[1], Tetsu Nakamura[1], Kazuhiro Oshima[3]

1. Hokkaido University, 2. Mie University, 3. Institute of Environmental Sciences

The summer Northern Annular Mode (NAM) and the winter North Atlantic Oscillation (NAO)/winter NAM have a positive correlation from the mid-1960s to the 1980s. Namely, when the winter NAO/NAM is in a positive phase, the following summer NAM tended to be a positive phase. During the period from the mid-1960s to 1980s, the NAO/NAM signals extended to the stratosphere in winter. Also, lower tropospheric warm anomaly over northern Eurasia in winter associated with the positive phase of NAO/NAM continued to spring. In summer, the annular anomalies in the temperature and 500-hPa height fields appeared and high-latitude westerly was enhanced following the winter positive NAO/NAM. However, after circa 1990, the seasonal linkage was broken, i.e., the winter-to-summer correlation became insignificant. The stratospheric signal in the winter NAO/NAM became weak and summer signals associated with the winter NAO/NAM almost disappeared. Seasonal evolutions of atmospheric circulation and sea surface temperature (SST) anomalies associated with the winter NAO are examined for early good linkage period and recent poor linkage period. We discuss the possible causes of the linkage breakdown such as stratospheric ozone, North Atlantic SST, and Atlantic multidecadal oscillation, besides chaotic internal variability in the climate system. Simulations with the Community Earth System model suggest that the ocean and/or sea ice with inter-seasonal memories possibly cause the linkage, besides large internal variability through which the linkage can take place by chance.

# Did an Arctic sea-ice hole cause hemispheric extreme cold winter in 2017/18?

*Keisuke Ota[1], Yoshihiro Tachibana[1], Kensuke K. Komatsu[1], Alexeev A. Vladimir[2], Cai Lei[2], Yuta Ando[1]

1. Graduate School of Bioresources, Mie University, 2. International Arctic Research Center, University of Alaska Fairbanks

While unprecedented cold weather characterized the American and Asian winter of 2017/18, the Pacific side of the Arctic experienced largely ice-free ocean, referred to as a “sea-ice hole.” The jet stream dividing cold Arctic air from warm persistently meandered northward with intrusion into the sea-ice hole. Large southward streams over Asia and America were also persistent, allowing cold air to spread there. We hypothesise that the sea-ice hole and Pacific atmospheric rivers were responsible for the cold winter, using data analyses and numerical experiments. We argue that the presence of the sea-ice hole resulted in formation of atmospheric rivers that penetrated into the Arctic with anomalous south winds toward the sea-ice hole, which led to more warm water injected into the sea-ice hole by the wind-driven current through Bering Strait. Poleward propagation of the atmospheric rivers made upper air warm, leading to their upgliding, which further heated the overlying air, causing poleward jet meanders. As a part of the response the jet meandered southward over Asia and North America, resulting in cold intrusions. This winter may be the first year when the sea-ice hole shifted the dynamics of hemispheric climate to the new state, with potential for self-sustainability.

# Flood affects vegetation at plant species level to regional level: *Arctagrostis latifolia* increased one year after flooding in Indigirka lowland, northeastern Siberia

*Tomoki Morozumi[1,2], Shihong Zhong[1], Ryo Shingubara[5,1], Shunsuke Tei[2], Shinya Takano[1], Rong Fan[1,2], Yumiko Miyamoto[2], Ruslan Shakhmatov[1], Shin Nagai[3], Hideki Kobayashi[3], Rikie Suzuki[3], Trofim C Maximov[4,6], Atsuko Sugimoto[2,7]

1. Graduate School of Environmental Science, Hokkaido University, 2. Arctic Research Center, Hokkaido University, 3. Japan Agency for Marine-Earth Science and Technology, 4. Institute for Biological Problems of Cryolithozone SB RAS, 5. Graduate School of Environmental Studies, Nagoya University, 6. North Eastern Federal University, 7. Station for Arctic Research, Global Institution for Collaborative Research and Education, Hokkaido University

In June-July 2017, unusual extensive (~10000 $km^2$) and long-time (~2 months) river floods were observed at coastal lowlands in northeastern Siberia. We focused on vegetation covered with dwarf shrub, sparse larch and polygonal wetlands, which were affected by the extreme flooding. We investigated plant species composition and in-situ phenology at site, and clarify the vegetation change after the flood in Indigirka river lowland, eastern Siberia (70°N, 148°E) for 2009-2018 July summer. We also recorded timing of leaf opening (greening) after flooding by digital time-lapse camera (GardenWatchCam, Brinno), and visible-near-infrared band satellite images (Landsat 8 OLI, USGS). In the field, forbs and graminoids (e.g. *Arctagrostis latifolia* as indicator of disturbance in arctic tundra) were increased among plots after the flood. On the other hand, dwarf shrubs (i.e. *Vaccinium vitis-idaea*) and moss species (i.e. *Hylocomium splendens*) were declined. The timing of leaf opening was delayed in the field. Fraction of leaf coverage per plot surface area were estimated from photo images. Leaf coverage on shrub were significantly smaller in 2017 summer (5.6%) than those in 2012-2016 (37%) in the plots (n=3, $p < 0.005$). Satellite images also supported that the greening of vegetation was delayed, and vegetation cover was declined in the region in 2017. Damaged moss cover and organic layers were remained to be exposed mud / bare soil in August 2018 (1 year after flood). However, leaf covers were even increased in some sedge-wetland plots, because of the increased growth of graminoids (e.g. *Arctagrostis latifolia*), forbs and sedges. Replacing to more graminoid might affect carbon and energy balances, and even might triggering permafrost thaw in some parts. Therefore, process changing and recovering from flood should be monitored in temporary and spatially multiscale.

# Extent and cause of an extreme flooding occurred in spring - summer 2017 over the Indigirka River lowland in Northeastern Siberia

*Shunsuke Tei[1], Tomoki Morozumi[2], Shin Nagai[3], Shinya Takano[2], Atsuko Sugimoto[1], Ryo Shingubara[4], RONG FAN[2], Alexander Fedorov[5], Trofim Maximov[6]

1. Arctic Research Center, Hokkaido University, 2. Graduate School of Environmental Science, Hokkaido University, 3. Japan Agency for Marine Earth Science and Technology, 4. Graduate School of Environmental studies, Nagoya University, 5. Melnikov Permafrost Institute, 6. North-Eastern Federal University

Flooding is one of the greatest disasters that produce strong effects on the ecosystem and livelihoods of local population. It is expected that the flood frequency will increase globally making its risk assessment an urgent issue. In spring - summer (June - July) 2017, an extreme flooding occurred in the Indigirka River lowland of Northeastern Siberia that covered a large area with water. In this study, the extent and cause of the flooding were determined using the results of field observations, satellite images, and climate re-analysis datasets, and its possible effects on the ecosystem were discussed. It was found that the flooding covered a significant lowland area equal to about 9530 $km^2$ and that the rise in the relative Indigirka River water level with respect to the average value determined for the period of nine years spanning from 2009 to 2017 amounted to about 350 cm. The largest annual maximum snow depth (snow water equivalent: SWE) in the lowland was observed in 2017 over the same period (2009-2017), and the surface of the lower reach of the lowland was partially covered with snow even in the end of June due to the extreme snowfall that occurred in fall - winter 2016. The climate re-analysis dataset obtained for temporal-spatial variations in SWE, snowmelt, and runoff over the lowland during 2015-2017 revealed that a large amount of snow-melted water had flown into the river system in June 2017, resulting in the extreme flooding. The latter also waterlogged most trees over the lowland, which caused serious ecosystem devastation and changes in the material cycling in the studied region.

# Monitoring of the light absorbing aerosols and the impact on radiation budget of atmosphere and snow

*Masahiro Hosaka[1], Hiroshi Ishimoto[1], Tomonori Tanikawa[1], Masashi Niwano[1], Kouji Adachi[1], Naga Oshima[1], Mizuo Kajino[1], Taichu Y Tanaka[1], Sumito Matoba[2]

1. Meteorological Research Institute, 2. Hokkaido University

The cryosphere is one of the most vulnerable regions to climate change. Snow/ice rapidly melts in the Arctic region under global warming. The light absorbing aerosols (black carbon and mineral dust) contribute to it by absorbing solar radiation and heating the atmosphere, and the deposition of these aerosols reduces the snow/ice surface albedo. In addition, snow grain size tends to increase in the warmer environment, which further reduces snow surface albedo. Therefore, we started the project, entitled "Monitoring of the light absorbing aerosols and the impact on radiation budget of atmosphere and snow ice (FY2017-2021)", which is supported by Ministry of the Environment.

In this research project, we will monitor the snow impurities originating from the light absorbing aerosols, the snow grain size, and the related surface albedo variations. These are to be accomplished by ground-based measurements and satellite remote sensing with special focuses on East Asia, one of the major sources of the light absorbing aerosols, and the Arctic region most affected by them. Field observation of weather, radiation and snowpack in Japan and the Arctic regions will be continued to create longer datasets while observation sites are added. We will implement new measurements and devices for analysis. The results of the observation measured in more detail will be utilized to improve the process models as well as the remote sensing algorithm. Such improvements should allow us to create longer-term datasets (i.e., shape advancement of snow particle and snow impurity particle) by remote sensing over the entire Northern Hemisphere.

The numerical models should allow us to assess the impact of physical processes described above on global warming. We will improve the MRI-ESM (Meteorological Research Institute - Earth System Model) and a new model NHM-Chem-SMAP which is a regional atmospheric model that incorporates chemical processes and snow physical processes. We will also investigate the dynamics and the radiation absorption of light absorbing aerosols and the influence of its deposition and snow grain size on albedo.

This research project is composed of three sub-projects. The results of them in FY 2017 are the followings:

(1) Monitoring by ground-based observation measurements: We continued observation of the weather, radiation and snowpack in winter at three stations in Japan. In addition to the continuous observation of weather and radiation by the automatic weather station (AWS; Automatic Weather Station), periodic snow pit observation with snow sampling was performed. Snow impurity concentration was measured by analysis of the snow samples. We visited Qaanaaq in northwest Greenland and Ny-Alesund in the Arctic Ocean. In addition to continuously obtaining valuable observation data with maintenance, we started the sampling of aerosol in the Arctic atmosphere and carried out the observation of sea ice albedo. By introducing a sublimation device, we developed a method to directly observe and analyze snow impurities in snow samples with a microscope without melting snow. The results will be used for the improvement of the remote sensing algorithm.

©2019. Japan Geoscience Union. All Right Reserved. 

(2) Monitoring by satellite remote sensing: Shape of real snow particles and their scattering characteristics were investigated. It was confirmed that they were consistent with those of virtual particles used for the algorithm. Using Himawari 8 with high temporal-spatial resolution, we developed an algorithm to improve the detection method of snow cover and sea ice. Therefore, high accuracy monitoring in the East Asian region including Japan became possible.

(3) Evaluation by numerical models: We improved the MRI-ESM results including the black carbon representation. The radiation effects were also investigated. We also improved the aerosol expression of NHM-Chem and investigated its effect. We also succeeded in coupling NHM-Chem with SMAP, so that we can now proceed with our research using this coupled model.

# Mass concertation and particle number of black carbon on glaciers in the eastern Alaskan Range, Alaska USA

*Keiko Konya[1], Takuma Miyakawa[1], Masayuki Takigawa[1], Masahiro Yamaguchi[1], Shad O'neel[2], Martin Truffer[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. USGS, 3. University of Alaska, Fairbanks

Black Carbon (BC) on snow reduces albedo lower and accelerates ablation. The Arctic demonstrates susceptibility to albedo feedbacks from non-local sources. We have estimated BC mass concentrations in snow from glacier surfaces (0-2 cm depth) and at subsurface (2-10 cm depth) in the Alaska range.
During April 2017, snow sampling was conducted on Gulkana, Black Rapids and Jarvis glaciers, which are all located within 50 km of each other. Between one and four sampling sites were selected at each glacier, at approximately 1500 m elevations. BC mass concentrations and particle size distributions was measured with a Single Particle Soot Photometer (SP2).
Measured BC mass concentrations are similar but less than previous studies. The mean value was about 6 $\mu$g/L and size distribution shows two modes around 0.3 and 0.7 $\mu$m. We have also measured the number of all aerosols by coulter counter and revealed that BC particles are about 1% of all aerosols.
We compared our measurements results to simulated BC deposition using the Weather Research and Forecasting model coupled to Chemistry (WRF-Chem). The simulated BC mass concentration agreed well with observed. We also reveaed by model result that contribution rate of biomass burning in Siberia was about 25 %. We will also estimate increase of surface melt rate caused by BC deposition.

# Remote estimation of phenological shifts in phytoplankton community in the Pacific Arctic Region

*Hisatomo Waga[1], Toru Hirawake[1]

1. Hokkaido University

Phytoplankton blooms in the Pacific Arctic Region (PAR) has been characterized as a huge single bloom in spring when light availability is high, the mixed layer is shallow and nutrients are abundant due to winter deep mixing. However, several studies have reported that recent increases in occurrence of a relatively small but evident second bloom in fall when light availability is still relatively high and storm-driven mixing replenishes nutrients in the upper well-lit layer. Here we explored interannual variations in phytoplankton phenology in PAR by focusing on biomass and size structure of phytoplankton community based on satellite data. In this study, phenology of phytoplankton community was divided into three types based on time-series chlorophyll-*a* (chl*a*) variations using a nonlinear least squares optimization function: fall bloom (FB), flat high (FH), and flat low (FL). The simple model for FH and FL was a straight line with slope 0, and FH and FL are divided by the chl*a* threshold of 2.5 mg $m^{-3}$. The complex parameterization of the time-series chl*a* variation for FB was a Gaussian model superimposed over a background concentration of phytoplankton. During our study period of 2003–2017, FB was dominant in the middle (65–67 ˚N) and southern PAR (62–65 ˚N), and accounted for 49.1 and 66.8%, respectively. On the other hand, FL was dominant and accounted for 45.9% in the northern PAR (67–70 ˚N). The proportions of FB and FL showed significant ($p < 0.05$) increasing and decreasing trends in northern PAR (67–70 ˚N), whereas both middle and southern PAR didn’ t show any significant trend for temporal variations in these proportions. In addition, the amplitudes of FB in northern and southern PAR exhibited increasing and decreasing trends, respectively. When we compared the phytoplankton size structure during each phenology, the largest phytoplankton size structure was found in FH, followed by FB and then FL. Moreover, higher amplitude was consisted by larger phytoplankton size structure, suggesting the phytoplankton size structure during the bloom period directly influenced on the amplitude of FB. Since the phytoplankton size structure determines the sinking rate of phytoplankton, these results indicate that benthic organisms in northern and southern PAR would receive more and less fresh phytoplankton during fall. Our findings suggest that the spatiotemporal monitoring of phytoplankton community not only in spring bloom period but also after the period is important for understanding of variations in PAR, because even small changes in the phytoplankton community would have cascading effects on the higher trophic levels via the short and efficient energy pathways in this region. Overall, satellite monitoring of phytoplankton community could improve our understanding about processes of marine ecosystem variations which occurred and/or would occur in PAR.

# Seasonality of diatom and silicoflagellate assemblages observed in settling particles of the western Arctic Ocean

*Jonaotaro Onodera[1,2], EIJI WATANABE[2], Naomi Harada[1,2]

1. Research and Development Center for Global Change, JAMSTEC, 2. Institute of Arctic Climate and Environment Change Research, JAMSTEC

Under the changing hydrographic condition of Arctic Ocean, production, species composition and the phenology of phytoplankton and ice-algae assemblages has been influenced. In order to observe the relationship between changing environmental condition and siliceous phytoplankton (diatoms and silicoflagellates), settling particle samples obtained by bottom tethered moorings with sediment trap were studied in the southern Chukchi Borderland and the southwestern Canada Basin from October 2010 to September 2014 and from September 2015 to September 2017, respectively. Settling flux of diatom valves increased in summer and occasional events of shelf matter advection. Settling flux of ice algae was relatively abundant around late July-early August probably reflecting seasonal sea-ice retreat. However, ice algae and planktic diatoms did not increase in summer 2012 when oligotrophic sea-surface water covered around the mooring station. Settling fluxes of silicoflagellate skeleton increased in July (with high dominance of Stephanocha speculum commonly observed in cold waters) and November-January (with S. medianoctisol which is relatively abundant in polar ocean with sea-ice).

# Iron and macronutrient distributions near the fronts of marine-terminating glaciers in Inglefield Gulf, northwestern Greenland

*NAOYA KANNA[1], Shin Sugiyama[2], Takuto Ando[1], Izumi Asaji[3,2], Yoshiki Fujishi[3,2], Jun Nishioka[2]

1. Arctic Research Center, Hokkaido University, 2. Institute of Low Temperature Science, Hokkaido University, 3. Graduate School of Environmental Science, Hokkaido University

The Greenland Ice Sheet drains freshwater into the ocean through land- and marine-terminating glaciers. Runoff from land-terminating glaciers is assumed to be iron (Fe) and silicate source to the ocean. However, influence of discharge from marine-terminating glaciers on Fe or macronutrient enrichment is poorly understood due to the difficulty of oceanographic observations in a proglacial fjord. Here we present Fe and macronutrient dataset obtained in Inglefield Gulf region of northwestern Greenland, which is fed by ~10 marine-terminating glaciers.

In the summers of 2016-18, we collected meltwater samples on Bowdoin Glacier, one of marine-terminating glaciers feeding Inglefield Gulf. Seawater was sampled in Inglefield Gulf with acid-cleaned Teflon-coated Niskin-X samplers and a Teflon coating messenger suspended on a Kevlar wire. Dissolved Fe (DFe, passes 0.2 $\mu$m acid-cleaned filters) in the seawater samplers was pre-concentrated using NOBIAS Chelate PA-1 resin (Hitachi High-Tech. Corp.). The DFe in the seawater and the glacial meltwater were analyzed with and without pre-concentration on a Graphite Furnace Atomic Absorption Spectrometer (Hitachi High-Tech. Corp.). Macronutrient in these water samplers was analyzed using an auto-analyzer (QuAAtro, BL TEC Inc.) with a continuous flow system.
Near the terminus of three marine-terminating glaciers (Melvill, Sharp, and Hart Glaciers), relatively cold (1~2°C) and fresh (as low as 28) waters were distributed in the upper 50 m. We deduce that the water masses in the upper 50 m have been modified by interaction with these glaciers, as previously reported. The DFe in the glacially modified waters ranged from 1.5 to 4.3 nmol/kg. On the Bowdoin Glacier, DFe in the meltwater ranged from 15.6 to 636 nmol/kg, with an average of 197 ±179 nmol/kg (n = 13). The glacial meltwater was significantly enriched in DFe, and thus discharge from marine-terminating glaciers is a potentially important DFe source of the glacially modified waters. The DFe:nitrate ($NO_3^-$) ratios in the glacially modified waters varied from 0.7 to 147 mmol/mol, which were notably higher than phytoplankton cellular Fe:N ratios (~0.02 mmol/mol, Sunda and Huntsman, 1995). This suggests that phytoplankton in the glacially modified waters were under Fe replete conditions in Inglefield Gulf.

# Paleoenvironmental reconstruction from sediments of Bowdoin fjord, northwestern Greenland

*Takuto Ando[1], NAOYA KANNA[1], Izumi Asaji[2,3], Yoshiki Fujishi[2,3], Shin Sugiyama[1,2,3]

1. Arctic Research Center, Hokkaido University, 2. Institute of Low Temperature Science, Hokkaido University, 3. Graduate School of Environmental Science, Hokkaido University

Evaluating impact of Arctic amplification on sea ice extent and the Greenland ice sheet is seriously important for predicting future environmental change. Calving glaciers that flow directly into the ocean are widely distributed in the north Greenland. In the ocean nearby calving glaciers, obvious seasonal variation results sea ice cover in winter and upwelling of deep water associated with the glacial meltwater in summer. Especially, freshwater plumes in summer season enhance primary production due to entrainment of nutrient-rich deep water and distribute glacial sediments in front of the glacier terminus. The present conditions of marine environment near the glacier terminus has been investigated in recent studies. However, it is necessary to reconstruct the variations in marine and depositional environments near the glacial terminus in the past for more accurate prediction of future environmental changes. In the Arctic regions, only a few researches have been performed on paleoclimate reconstruction from fjord sediments, while ice cores and lake sediment cores have often been used for the same purpose. We collected surface sediments and sediment cores from Bowdoin fjord in northwestern Greenland, which is in front of the carving glacier, in July 2018. In this presentation, we show preliminary results about sedimentation process and marine ecosystem in Bowdoin fjord, which are reconstructed from the sediments.

# A large-eddy simulation of upwelling meltwater plume at marine-terminating glacier fronts

*Yoshimasa Matsumura[1], Naoya Kanna[2], Shin Sugiyama[3,2]

1. Atmosphere and Ocean Research Institute, University of Tokyo, 2. Arctic Research Center, Hokkaido University, 3. Institute of Low Temperature Science, Hokkaido University

To investigate the behavior of subglacier discharge of meltwater and its impact on the oceanic environment in Greenland fjords, large-eddy simulations of upwelling meltwater plume were performed using a three-dimensional non-hydrostatic ocean model.

The model setup was idealized based on in-situ measurements at the glacier front in the Bowdoin fjold, northwestern Greenland. The model resolution was 2.0 m horizontally and vertically and the time step interval was less than 0.1 second, which were sufficiently fine to capture the turbulent nature of upwelling plume and its high frequency disturbance recorded in the in-situ data.

The buoyancy supply caused by the underwater discharge of fresh meltwater induced immediate and strong upwelling, then the plume reached the surface with vertical momentum that radially pushed out the surface water and clearly formed semicircular structure of ~200 m adjoined to the glacier front, which was visualized by high turbidity in reality.
Since the turbulent plume entrains the saline and nutrient-rich water of Atlantic origin below thermocline, the underwater meltwater discharge acts as a pump for providing nutrients to the photic layer, that may support primary production and ecosystem in the fjold.

In the presentation, we will introduce results of sensitivity experiments with different shapes of glacier front cavity and discharge conduit, and quantitative comparison with in-situ observations will be discussed.

# Impact of observation-based snow/ice albedo with starting temperature of −2˚C for surface melting effect on a global ocean simulation

*Takahiro Toyoda[1], Teruo Aoki[1,2], Masashi Niwano[1], Tomonori Tanikawa[1], Shogo Urakawa[1], Hiroyuki Tsujino[1], Hideyuki Nakano[1], Kei Sakamoto[1], Nariaki Hirose[1], Goro Yamanaka[1]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Graduate School of Natural Science and Technology, Okayama University

Based on detailed field observations, we conducted global ocean simulation experiments with modification of starting temperature for surface melting effect from −1˚C to −2˚C in the snow/ice albedo parameterization. An ensemble mean field of five experiments with the modified parameterization starting from December 1989–January 1990 were compared with the original experiment. Significance of the impact of the modification was evaluated by using the ensemble spread, which measures the internal variability.

In the Arctic Ocean, the mean albedo was reduced by up to 0.015 in June–July by the modification of the parameterization (i.e. lower albedo in the ensemble mean of the modified experiements than in the original experiment), which resulted comparably from both direct effect of the modification and indirect effect via changes of the snow and ice distributions by the albedo reduction. Snow thickness on the sea ice was reduced by up to 1.5 cm in June–July but afterward impact of the modification was diminished as the snow mostly melted away. Impact of the modification on the sea ice firstly appeared in the rim regions of the snow cover with the bare ice fraction extended and, in August–September, ice thickness decreases by 1.5 cm were achieved over most of the Arctic Ocean. On the other hand, ice thickness increases were seen in some marginal ice zones, which were attributed to reduced ocean surface circulation, such as in the Beaufort Gyre, resulting from reduced surface stresses with reduced ice cover.

In the Southern Ocean, the albedo reduction by up to 0.015 in December–January resulted from comparable contributions of the direct effect of the modification of the parameterization and the indirect effect via the snow thickness decrease, as in the Arctic Ocean. In contrast to the Arctic Ocean, the decrease impact of the snow thickness by up to 2.5 cm in the Weddell Sea partly remained through year. In addition, increases of the ice thickness were widely distributed in December–January. A detailed analysis revealed that the warming effect of the albedo reduction by the modification enhanced the reduction of the sea ice concentration, in particular that of thinner ice, which weakened the ice pressure and enhanced thicker ice formation via the rheology, leading to the increases of the ice thickness. Note that thicker ice is less affected by thermodynamical melting effect than thinner ice. This thickening impact of the sea ice remained through year in the Weddell Sea. These changes by the modification of the parameterization were robust compared with the ensemble spread.

Although the above experiments and results might be rather preliminary, we believe that our demonstration of the potential impact of the new observational insight on ocean general circulation model simulations would be of value for further enhancing both observation and modelling/prediction activities and their collaborative study.

[J] Poster | A (Atmospheric and Hydrospheric Sciences )：A-CG Complex & General

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_14

## [A-CG37] Science in the Arctic Region

convener:NAOYA KANNA(Arctic Research Center, Hokkaido University), Masashi Niwano(Meteorological Research Institute), Tetsu Nakamura(Faculty of Environmental Earth Science, Hokkaido University), Shunsuke Tei(Arctic Research Center, Hokkaido University)

The Arctic and circumpolar region is the key area for the study of global change because the anthropogenic impact is projected to be the largest in this area due to the complicated feedback processes of the nature. A number of international and interdisciplinary research projects have been conducted for the studies on the land-atmosphere-ocean system. In order to understand the feedback processes occurring in the Arctic and to project the global warming in the future, we need to establish the intense observational network and to exchange the knowledge and information by combining the different scientific communities under the common interest of the Arctic. The objectives of this session are 1) to exchange our knowledge on the observational facts and integrated modelling and 2) to deepen our understanding on wide range of natural sciences related to the Arctic and the circumpolar region. Studies on humanities, social sciences, and interdisciplinary fields are also welcomed.

# Increasing trend of downward long-wave radiation at the surface in the winter Arctic

*Yuta Miwa[1], Toru Nozawa[2]

1. Faculty of Science, Okayama University , 2. Graduate School of Natural Science and Technology, Okayama University

In recent years, observations show that warming in the Arctic is remarkable and rate of the warming after the 1950s is about twice that of the global average. This feature is called "Arctic amplification", and the Arctic warming is especially significant in autumn and winter. According to the previous studies, analysis based on the thermal energy balance on the surface suggests that the warming in the Arctic winter has the largest influence of the downward longwave radiation. On the other hand, factors that increase downward longwave radiation are not necessarily clearly shown. In this study, after analyzing the same as the previous studies, we considered the factor that causes downward longwave radiation increase in winter Arctic warming.

We used the Japanese 55-year Reanalysis (JRA-55) dataset. We analyzed the 30 winter season from 1988 to 2018, taking the average for the three months from November to January, where the influence of solar radiation can be ignored for the Arctic region north of 60 ˚N. It was found that, although it is different dataset and different period from the previous studies, increases in the downward longwave radiation has the largest influence on the surface warming. The downward longwave radiation can be divided into the following two components: clear-sky radiation and cloud radiative forcing (CRF), both of which are consistent with the trend pattern of the surface warming, and the clear-sky radiation has relatively larger influence on the surface warming than the CRF. Increase in clear-sky radiation is brought about by increase either in atmospheric water vapor or well-mixed greenhouse gases. From the diagnosis of radiative forcing due to an increase in greenhouse gas concentration, however, it is suggested that the increase in water vapor dominates. Trend pattern of the precipitable water is also consistent with that of the downward longwave radiation in the clear-sky. In addition, it is suggested that an increase in the CRF is due to that in the low-level clouds. It is also suggested that decreases in sea ice area and increases in net evaporation over the ice-retreated area may cause increases in the atmospheric water vapor and low-level clouds, but due to a problem of the JRA-55, further analysis is necessary.

# Climate memory of the Eurasian land process for the Arctic amplification

*Tetsu Nakamura[1], Koji Yamazaki[1], Tomonori Sato[1], Jinro Ukita[2]

1. Faculty of Environmental Earth Science, Hokkaido University, 2. Faculty of Science , Niigata University

Amplified warming over the Arctic region, so called Arctic amplification (AA), and its relevance to the mid-latitude cooling in winter have recently been intensively studied. Recognizing rapid decline of the Arctic sea ice as to coincide with AA, sea ice-climate impacts have been examined in both observational and modeling studies. However, there is a serious gap between diverged simulation results among models/studies and observational evidence showing strong relevance of sea ice variation to AA signals on the interannual to decadal timescales. To fill the gap, we assume the climate memory effect of the land process that achieves amplification and recurrence of the sea ice-climate impacts. Here we designed and performed a set of general circulation model experiments that is able to extract the memory effect of land process. The memory of the northern Eurasian cooling anomalies that originally induced by sea ice loss are stored as snow amount and soil temperature. Memorized anomalies could induce the atmospheric circulation resembling the negative Arctic oscillation and amplify the Arctic warming in the later years. Estimated atmospheric circulation change due to this memory effect is comparable with that directly induced by sea ice loss. Reducing uncertainty of the land process operated in the climate models, which is expected to have large model dependency, would be a major choice to achieve the robust simulation results to evaluate sea ice-induced AA.

# Interannual variation of summer precipitation and atmospheric water circulation over and around Alaska

*Shohei Morino[1], Tetsuya Hiyama[2], Hatsuki Fujinami[2], Hironari Kanamori[2], Masahito Ueyama[3]

1. Graduate School of Environmental Studies, Nagoya University, 2. Institute for Space-Earth Environmental Research, Nagoya University, 3. Graduate School of Life and Environmental Sciences, Osaka Prefecture University

Arctic warming is more apparent than global average. Water cycle in the region is also changing due to the climate warming. The variation of atmospheric water circulation influences terrestrial ecosystems through precipitation and soil water content. Hiyama et al. (2016) revealed the atmospheric circulation associated with the increase in summer precipitation from 2005 to 2008 in eastern Siberia. Ohta et al. (2014) indicated that increased precipitation in eastern Siberia caused waterlogging and damaged the larch forest. On the other hand, a recent observational research indicated that recent increased summer precipitation caused increase in methane emission from the black spruce forest in the interior of Alaska. Therefore, this study investigated interannual variability of summer precipitation and associated atmospheric water circulation in the interior of Alaska using ERA-Interim reanalysis data and rain gauge observation data in Fairbanks from 2003 to 2017. We extracted dry and wet years based on summer precipitation time series and then conducted composite analyses. Geopotential height and horizontal wind at 850 hPa and vertically integrated moisture flux were composited. We found that the change in low-level westerly wind and moisture flux blowing into the interior of Alaska was a primary factor to induce the interannual variation of summer precipitation in the region. This westerly moisture flux is associated with the atmospheric circulation pattern with cyclonic and anticyclonic anomalies around and over the Alaska. Moreover, the anomaly pattern is related to cyclone activity. More cyclones are detected in the region of the cyclonic anomaly, while less cyclones in the region of the anticyclonic anomaly. Sea surface temperature may partly contribute to the cyclone activity. A planetary wave might influence precipitation variability in the interior of Alaska through a teleconnection in these latitudes.

# Detection of a climatological short break in the polar night jet in early winter and its relation to cooling over Siberia

*Yuta Ando[1], Koji Yamazaki[2], Yoshihiro Tachibana[1], Masayo Ogi[3], Jinro Ukita[4]

1. Graduate School of Bioresources, Mie University, 2. Hokkaido University, 3. Centre for Earth Observation Science, University of Manitoba, 4. Faculty of Science, Niigata University

The polar night jet (PNJ) is a strong stratospheric westerly circumpolar wind in winter, and the strength of the climatological PNJ is widely recognized to increase from October through late December. We found the PNJ stops increasing temporarily during late November, when the upward propagation of Rossby waves from the troposphere increases. The upward propagation of Rossby waves, which is strongest over Siberia, is related to strengthening of the low pressure over Siberia. We suggest that longitudinally asymmetric forcing by land–sea heating contrasts caused by their different heat capacities might cause the strengthening of the low pressure.

# Recent breakdown of the seasonal linkage between the winter North Atlantic Oscillation/Northern Annular Mode and summer Northern Annular Mode

*Koji Yamazaki[1], Yoshihiro Tachibana[2], Masayo Ogi[1], Tetsu Nakamura[1], Kazuhiro Oshima[3]

1. Hokkaido University, 2. Mie University, 3. Institute of Environmental Sciences

The summer Northern Annular Mode (NAM) and the winter North Atlantic Oscillation (NAO)/winter NAM have a positive correlation from the mid-1960s to the 1980s. Namely, when the winter NAO/NAM is in a positive phase, the following summer NAM tended to be a positive phase. During the period from the mid-1960s to 1980s, the NAO/NAM signals extended to the stratosphere in winter. Also, lower tropospheric warm anomaly over northern Eurasia in winter associated with the positive phase of NAO/NAM continued to spring. In summer, the annular anomalies in the temperature and 500-hPa height fields appeared and high-latitude westerly was enhanced following the winter positive NAO/NAM. However, after circa 1990, the seasonal linkage was broken, i.e., the winter-to-summer correlation became insignificant. The stratospheric signal in the winter NAO/NAM became weak and summer signals associated with the winter NAO/NAM almost disappeared. Seasonal evolutions of atmospheric circulation and sea surface temperature (SST) anomalies associated with the winter NAO are examined for early good linkage period and recent poor linkage period. We discuss the possible causes of the linkage breakdown such as stratospheric ozone, North Atlantic SST, and Atlantic multidecadal oscillation, besides chaotic internal variability in the climate system. Simulations with the Community Earth System model suggest that the ocean and/or sea ice with inter-seasonal memories possibly cause the linkage, besides large internal variability through which the linkage can take place by chance.

# Did an Arctic sea-ice hole cause hemispheric extreme cold winter in 2017/18?

*Keisuke Ota[1], Yoshihiro Tachibana[1], Kensuke K. Komatsu[1], Alexeev A. Vladimir[2], Cai Lei[2], Yuta Ando[1]

1. Graduate School of Bioresources, Mie University, 2. International Arctic Research Center, University of Alaska Fairbanks

While unprecedented cold weather characterized the American and Asian winter of 2017/18, the Pacific side of the Arctic experienced largely ice-free ocean, referred to as a “sea-ice hole.” The jet stream dividing cold Arctic air from warm persistently meandered northward with intrusion into the sea-ice hole. Large southward streams over Asia and America were also persistent, allowing cold air to spread there. We hypothesise that the sea-ice hole and Pacific atmospheric rivers were responsible for the cold winter, using data analyses and numerical experiments. We argue that the presence of the sea-ice hole resulted in formation of atmospheric rivers that penetrated into the Arctic with anomalous south winds toward the sea-ice hole, which led to more warm water injected into the sea-ice hole by the wind-driven current through Bering Strait. Poleward propagation of the atmospheric rivers made upper air warm, leading to their upgliding, which further heated the overlying air, causing poleward jet meanders. As a part of the response the jet meandered southward over Asia and North America, resulting in cold intrusions. This winter may be the first year when the sea-ice hole shifted the dynamics of hemispheric climate to the new state, with potential for self-sustainability.

# Flood affects vegetation at plant species level to regional level: *Arctagrostis latifolia* increased one year after flooding in Indigirka lowland, northeastern Siberia

*Tomoki Morozumi[1,2], Shihong Zhong[1], Ryo Shingubara[5,1], Shunsuke Tei[2], Shinya Takano[1], Rong Fan[1,2], Yumiko Miyamoto[2], Ruslan Shakhmatov[1], Shin Nagai[3], Hideki Kobayashi[3], Rikie Suzuki[3], Trofim C Maximov[4,6], Atsuko Sugimoto[2,7]

Institute for Biological Problems of Cryolithozone SB RAS, 5. Graduate School of Environmental Studies, Nagoya University, 6. North Eastern Federal University, 7. Station for Arctic Research, Global Institution for Collaborative Research and Education, Hokkaido University

In June-July 2017, unusual extensive (~10000 $km^2$) and long-time (~2 months) river floods were observed at coastal lowlands in northeastern Siberia. We focused on vegetation covered with dwarf shrub, sparse larch and polygonal wetlands, which were affected by the extreme flooding. We investigated plant species composition and in-situ phenology at site, and clarify the vegetation change after the flood in Indigirka river lowland, eastern Siberia (70°N, 148°E) for 2009-2018 July summer. We also recorded timing of leaf opening (greening) after flooding by digital time-lapse camera (GardenWatchCam, Brinno), and visible-near-infrared band satellite images (Landsat 8 OLI, USGS). In the field, forbs and graminoids (e.g. *Arctagrostis latifolia* as indicator of disturbance in arctic tundra) were increased among plots after the flood. On the other hand, dwarf shrubs (i.e. *Vaccinium vitis-idaea*) and moss species (i.e. *Hylocomium splendens*) were declined. The timing of leaf opening was delayed in the field. Fraction of leaf coverage per plot surface area were estimated from photo images. Leaf coverage on shrub were significantly smaller in 2017 summer (5.6%) than those in 2012-2016 (37%) in the plots (n=3, $p < 0.005$). Satellite images also supported that the greening of vegetation was delayed, and vegetation cover was declined in the region in 2017. Damaged moss cover and organic layers were remained to be exposed mud / bare soil in August 2018 (1 year after flood). However, leaf covers were even increased in some sedge-wetland plots, because of the increased growth of graminoids (e.g. *Arctagrostis latifolia*), forbs and sedges. Replacing to more graminoid might affect carbon and energy balances, and even might triggering permafrost thaw in some parts. Therefore, process changing and recovering from flood should be monitored in temporary and spatially multiscale.

# Extent and cause of an extreme flooding occurred in spring - summer 2017 over the Indigirka River lowland in Northeastern Siberia

*Shunsuke Tei[1], Tomoki Morozumi[2], Shin Nagai[3], Shinya Takano[2], Atsuko Sugimoto[1], Ryo Shingubara[4], RONG FAN[2], Alexander Fedorov[5], Trofim Maximov[6]

Graduate School of Environmental studies, Nagoya University, 5. Melnikov Permafrost Institute, 6. North-Eastern Federal University

Flooding is one of the greatest disasters that produce strong effects on the ecosystem and livelihoods of local population. It is expected that the flood frequency will increase globally making its risk assessment an urgent issue. In spring - summer (June - July) 2017, an extreme flooding occurred in the Indigirka River lowland of Northeastern Siberia that covered a large area with water. In this study, the extent and cause of the flooding were determined using the results of field observations, satellite images, and climate re-analysis datasets, and its possible effects on the ecosystem were discussed. It was found that the flooding covered a significant lowland area equal to about 9530 $km^2$ and that the rise in the relative Indigirka River water level with respect to the average value determined for the period of nine years spanning from 2009 to 2017 amounted to about 350 cm. The largest annual maximum snow depth (snow water equivalent: SWE) in the lowland was observed in 2017 over the same period (2009-2017), and the surface of the lower reach of the lowland was partially covered with snow even in the end of June due to the extreme snowfall that occurred in fall - winter 2016. The climate re-analysis dataset obtained for temporal-spatial variations in SWE, snowmelt, and runoff over the lowland during 2015-2017 revealed that a large amount of snow-melted water had flown into the river system in June 2017, resulting in the extreme flooding. The latter also waterlogged most trees over the lowland, which caused serious ecosystem devastation and changes in the material cycling in the studied region.

# Monitoring of the light absorbing aerosols and the impact on radiation budget of atmosphere and snow

*Masahiro Hosaka[1], Hiroshi Ishimoto[1], Tomonori Tanikawa[1], Masashi Niwano[1], Kouji Adachi[1], Naga Oshima[1], Mizuo Kajino[1], Taichu Y Tanaka[1], Sumito Matoba[2]

1. Meteorological Research Institute, 2. Hokkaido University

The cryosphere is one of the most vulnerable regions to climate change. Snow/ice rapidly melts in the Arctic region under global warming. The light absorbing aerosols (black carbon and mineral dust) contribute to it by absorbing solar radiation and heating the atmosphere, and the deposition of these aerosols reduces the snow/ice surface albedo. In addition, snow grain size tends to increase in the warmer environment, which further reduces snow surface albedo. Therefore, we started the project, entitled "Monitoring of the light absorbing aerosols and the impact on radiation budget of atmosphere and snow ice (FY2017-2021)", which is supported by Ministry of the Environment.

In this research project, we will monitor the snow impurities originating from the light absorbing aerosols, the snow grain size, and the related surface albedo variations. These are to be accomplished by ground-based measurements and satellite remote sensing with special focuses on East Asia, one of the major sources of the light absorbing aerosols, and the Arctic region most affected by them. Field observation of weather, radiation and snowpack in Japan and the Arctic regions will be continued to create longer datasets while observation sites are added. We will implement new measurements and devices for analysis. The results of the observation measured in more detail will be utilized to improve the process models as well as the remote sensing algorithm. Such improvements should allow us to create longer-term datasets (i.e., shape advancement of snow particle and snow impurity particle) by remote sensing over the entire Northern Hemisphere.

The numerical models should allow us to assess the impact of physical processes described above on global warming. We will improve the MRI-ESM (Meteorological Research Institute - Earth System Model) and a new model NHM-Chem-SMAP which is a regional atmospheric model that incorporates chemical processes and snow physical processes. We will also investigate the dynamics and the radiation absorption of light absorbing aerosols and the influence of its deposition and snow grain size on albedo.

This research project is composed of three sub-projects. The results of them in FY 2017 are the followings:

(1) Monitoring by ground-based observation measurements: We continued observation of the weather, radiation and snowpack in winter at three stations in Japan. In addition to the continuous observation of weather and radiation by the automatic weather station (AWS; Automatic Weather Station), periodic snow pit observation with snow sampling was performed. Snow impurity concentration was measured by analysis of the snow samples. We visited Qaanaaq in northwest Greenland and Ny-Alesund in the Arctic Ocean. In addition to continuously obtaining valuable observation data with maintenance, we started the sampling of aerosol in the Arctic atmosphere and carried out the observation of sea ice albedo. By introducing a sublimation device, we developed a method to directly observe and analyze snow impurities in snow samples with a microscope without melting snow. The results will be used for the improvement of the remote sensing algorithm.

©2019. Japan Geoscience Union. All Right Reserved. 

(2) Monitoring by satellite remote sensing: Shape of real snow particles and their scattering characteristics were investigated. It was confirmed that they were consistent with those of virtual particles used for the algorithm. Using Himawari 8 with high temporal-spatial resolution, we developed an algorithm to improve the detection method of snow cover and sea ice. Therefore, high accuracy monitoring in the East Asian region including Japan became possible.

(3) Evaluation by numerical models: We improved the MRI-ESM results including the black carbon representation. The radiation effects were also investigated. We also improved the aerosol expression of NHM-Chem and investigated its effect. We also succeeded in coupling NHM-Chem with SMAP, so that we can now proceed with our research using this coupled model.

# Mass concertation and particle number of black carbon on glaciers in the eastern Alaskan Range, Alaska USA

*Keiko Konya[1], Takuma Miyakawa[1], Masayuki Takigawa[1], Masahiro Yamaguchi[1], Shad O'neel[2], Martin Truffer[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. USGS, 3. University of Alaska, Fairbanks

Black Carbon (BC) on snow reduces albedo lower and accelerates ablation. The Arctic demonstrates susceptibility to albedo feedbacks from non-local sources. We have estimated BC mass concentrations in snow from glacier surfaces (0-2 cm depth) and at subsurface (2-10 cm depth) in the Alaska range.
During April 2017, snow sampling was conducted on Gulkana, Black Rapids and Jarvis glaciers, which are all located within 50 km of each other. Between one and four sampling sites were selected at each glacier, at approximately 1500 m elevations. BC mass concentrations and particle size distributions was measured with a Single Particle Soot Photometer (SP2).
Measured BC mass concentrations are similar but less than previous studies. The mean value was about 6 $\mu$g/L and size distribution shows two modes around 0.3 and 0.7 $\mu$m. We have also measured the number of all aerosols by coulter counter and revealed that BC particles are about 1% of all aerosols.
We compared our measurements results to simulated BC deposition using the Weather Research and Forecasting model coupled to Chemistry (WRF-Chem). The simulated BC mass concentration agreed well with observed. We also reveaed by model result that contribution rate of biomass burning in Siberia was about 25 %. We will also estimate increase of surface melt rate caused by BC deposition.

# Remote estimation of phenological shifts in phytoplankton community in the Pacific Arctic Region

*Hisatomo Waga[1], Toru Hirawake[1]

1. Hokkaido University

Phytoplankton blooms in the Pacific Arctic Region (PAR) has been characterized as a huge single bloom in spring when light availability is high, the mixed layer is shallow and nutrients are abundant due to winter deep mixing. However, several studies have reported that recent increases in occurrence of a relatively small but evident second bloom in fall when light availability is still relatively high and storm-driven mixing replenishes nutrients in the upper well-lit layer. Here we explored interannual variations in phytoplankton phenology in PAR by focusing on biomass and size structure of phytoplankton community based on satellite data. In this study, phenology of phytoplankton community was divided into three types based on time-series chlorophyll-*a* (chl*a*) variations using a nonlinear least squares optimization function: fall bloom (FB), flat high (FH), and flat low (FL). The simple model for FH and FL was a straight line with slope 0, and FH and FL are divided by the chl*a* threshold of 2.5 mg $m^{-3}$. The complex parameterization of the time-series chl*a* variation for FB was a Gaussian model superimposed over a background concentration of phytoplankton. During our study period of 2003–2017, FB was dominant in the middle (65–67 ˚N) and southern PAR (62–65 ˚N), and accounted for 49.1 and 66.8%, respectively. On the other hand, FL was dominant and accounted for 45.9% in the northern PAR (67–70 ˚N). The proportions of FB and FL showed significant ($p < 0.05$) increasing and decreasing trends in northern PAR (67–70 ˚N), whereas both middle and southern PAR didn’ t show any significant trend for temporal variations in these proportions. In addition, the amplitudes of FB in northern and southern PAR exhibited increasing and decreasing trends, respectively. When we compared the phytoplankton size structure during each phenology, the largest phytoplankton size structure was found in FH, followed by FB and then FL. Moreover, higher amplitude was consisted by larger phytoplankton size structure, suggesting the phytoplankton size structure during the bloom period directly influenced on the amplitude of FB. Since the phytoplankton size structure determines the sinking rate of phytoplankton, these results indicate that benthic organisms in northern and southern PAR would receive more and less fresh phytoplankton during fall. Our findings suggest that the spatiotemporal monitoring of phytoplankton community not only in spring bloom period but also after the period is important for understanding of variations in PAR, because even small changes in the phytoplankton community would have cascading effects on the higher trophic levels via the short and efficient energy pathways in this region. Overall, satellite monitoring of phytoplankton community could improve our understanding about processes of marine ecosystem variations which occurred and/or would occur in PAR.

# Seasonality of diatom and silicoflagellate assemblages observed in settling particles of the western Arctic Ocean

*Jonaotaro Onodera[1,2], EIJI WATANABE[2], Naomi Harada[1,2]

1. Research and Development Center for Global Change, JAMSTEC, 2. Institute of Arctic Climate and Environment Change Research, JAMSTEC

Under the changing hydrographic condition of Arctic Ocean, production, species composition and the phenology of phytoplankton and ice-algae assemblages has been influenced. In order to observe the relationship between changing environmental condition and siliceous phytoplankton (diatoms and silicoflagellates), settling particle samples obtained by bottom tethered moorings with sediment trap were studied in the southern Chukchi Borderland and the southwestern Canada Basin from October 2010 to September 2014 and from September 2015 to September 2017, respectively. Settling flux of diatom valves increased in summer and occasional events of shelf matter advection. Settling flux of ice algae was relatively abundant around late July-early August probably reflecting seasonal sea-ice retreat. However, ice algae and planktic diatoms did not increase in summer 2012 when oligotrophic sea-surface water covered around the mooring station. Settling fluxes of silicoflagellate skeleton increased in July (with high dominance of Stephanocha speculum commonly observed in cold waters) and November-January (with S. medianoctisol which is relatively abundant in polar ocean with sea-ice).

# Iron and macronutrient distributions near the fronts of marine-terminating glaciers in Inglefield Gulf, northwestern Greenland

*NAOYA KANNA[1], Shin Sugiyama[2], Takuto Ando[1], Izumi Asaji[3,2], Yoshiki Fujishi[3,2], Jun Nishioka[2]

1. Arctic Research Center, Hokkaido University, 2. Institute of Low Temperature Science, Hokkaido University, 3. Graduate School of Environmental Science, Hokkaido University

The Greenland Ice Sheet drains freshwater into the ocean through land- and marine-terminating glaciers. Runoff from land-terminating glaciers is assumed to be iron (Fe) and silicate source to the ocean. However, influence of discharge from marine-terminating glaciers on Fe or macronutrient enrichment is poorly understood due to the difficulty of oceanographic observations in a proglacial fjord. Here we present Fe and macronutrient dataset obtained in Inglefield Gulf region of northwestern Greenland, which is fed by ~10 marine-terminating glaciers.

In the summers of 2016-18, we collected meltwater samples on Bowdoin Glacier, one of marine-terminating glaciers feeding Inglefield Gulf. Seawater was sampled in Inglefield Gulf with acid-cleaned Teflon-coated Niskin-X samplers and a Teflon coating messenger suspended on a Kevlar wire. Dissolved Fe (DFe, passes 0.2 $\mu$m acid-cleaned filters) in the seawater samplers was pre-concentrated using NOBIAS Chelate PA-1 resin (Hitachi High-Tech. Corp.). The DFe in the seawater and the glacial meltwater were analyzed with and without pre-concentration on a Graphite Furnace Atomic Absorption Spectrometer (Hitachi High-Tech. Corp.). Macronutrient in these water samplers was analyzed using an auto-analyzer (QuAAtro, BL TEC Inc.) with a continuous flow system.
Near the terminus of three marine-terminating glaciers (Melvill, Sharp, and Hart Glaciers), relatively cold (1~2°C) and fresh (as low as 28) waters were distributed in the upper 50 m. We deduce that the water masses in the upper 50 m have been modified by interaction with these glaciers, as previously reported. The DFe in the glacially modified waters ranged from 1.5 to 4.3 nmol/kg. On the Bowdoin Glacier, DFe in the meltwater ranged from 15.6 to 636 nmol/kg, with an average of 197 ±179 nmol/kg (n = 13). The glacial meltwater was significantly enriched in DFe, and thus discharge from marine-terminating glaciers is a potentially important DFe source of the glacially modified waters. The DFe:nitrate ($NO_3^-$) ratios in the glacially modified waters varied from 0.7 to 147 mmol/mol, which were notably higher than phytoplankton cellular Fe:N ratios (~0.02 mmol/mol, Sunda and Huntsman, 1995). This suggests that phytoplankton in the glacially modified waters were under Fe replete conditions in Inglefield Gulf.

# Paleoenvironmental reconstruction from sediments of Bowdoin fjord, northwestern Greenland

*Takuto Ando[1], NAOYA KANNA[1], Izumi Asaji[2,3], Yoshiki Fujishi[2,3], Shin Sugiyama[1,2,3]

1. Arctic Research Center, Hokkaido University, 2. Institute of Low Temperature Science, Hokkaido University, 3. Graduate School of Environmental Science, Hokkaido University

Evaluating impact of Arctic amplification on sea ice extent and the Greenland ice sheet is seriously important for predicting future environmental change. Calving glaciers that flow directly into the ocean are widely distributed in the north Greenland. In the ocean nearby calving glaciers, obvious seasonal variation results sea ice cover in winter and upwelling of deep water associated with the glacial meltwater in summer. Especially, freshwater plumes in summer season enhance primary production due to entrainment of nutrient-rich deep water and distribute glacial sediments in front of the glacier terminus. The present conditions of marine environment near the glacier terminus has been investigated in recent studies. However, it is necessary to reconstruct the variations in marine and depositional environments near the glacial terminus in the past for more accurate prediction of future environmental changes. In the Arctic regions, only a few researches have been performed on paleoclimate reconstruction from fjord sediments, while ice cores and lake sediment cores have often been used for the same purpose. We collected surface sediments and sediment cores from Bowdoin fjord in northwestern Greenland, which is in front of the carving glacier, in July 2018. In this presentation, we show preliminary results about sedimentation process and marine ecosystem in Bowdoin fjord, which are reconstructed from the sediments.

# A large-eddy simulation of upwelling meltwater plume at marine-terminating glacier fronts

*Yoshimasa Matsumura[1], Naoya Kanna[2], Shin Sugiyama[3,2]

1. Atmosphere and Ocean Research Institute, University of Tokyo, 2. Arctic Research Center, Hokkaido University, 3. Institute of Low Temperature Science, Hokkaido University

To investigate the behavior of subglacier discharge of meltwater and its impact on the oceanic environment in Greenland fjords, large-eddy simulations of upwelling meltwater plume were performed using a three-dimensional non-hydrostatic ocean model.

The model setup was idealized based on in-situ measurements at the glacier front in the Bowdoin fjold, northwestern Greenland. The model resolution was 2.0 m horizontally and vertically and the time step interval was less than 0.1 second, which were sufficiently fine to capture the turbulent nature of upwelling plume and its high frequency disturbance recorded in the in-situ data.

The buoyancy supply caused by the underwater discharge of fresh meltwater induced immediate and strong upwelling, then the plume reached the surface with vertical momentum that radially pushed out the surface water and clearly formed semicircular structure of ~200 m adjoined to the glacier front, which was visualized by high turbidity in reality.
Since the turbulent plume entrains the saline and nutrient-rich water of Atlantic origin below thermocline, the underwater meltwater discharge acts as a pump for providing nutrients to the photic layer, that may support primary production and ecosystem in the fjold.

In the presentation, we will introduce results of sensitivity experiments with different shapes of glacier front cavity and discharge conduit, and quantitative comparison with in-situ observations will be discussed.

Keywords: meltwater discharge, large-eddy simulation

# Impact of observation-based snow/ice albedo with starting temperature of −2˚C for surface melting effect on a global ocean simulation

*Takahiro Toyoda[1], Teruo Aoki[1,2], Masashi Niwano[1], Tomonori Tanikawa[1], Shogo Urakawa[1], Hiroyuki Tsujino[1], Hideyuki Nakano[1], Kei Sakamoto[1], Nariaki Hirose[1], Goro Yamanaka[1]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Graduate School of Natural Science and Technology, Okayama University

Based on detailed field observations, we conducted global ocean simulation experiments with modification of starting temperature for surface melting effect from −1˚C to −2˚C in the snow/ice albedo parameterization. An ensemble mean field of five experiments with the modified parameterization starting from December 1989–January 1990 were compared with the original experiment. Significance of the impact of the modification was evaluated by using the ensemble spread, which measures the internal variability.

In the Arctic Ocean, the mean albedo was reduced by up to 0.015 in June–July by the modification of the parameterization (i.e. lower albedo in the ensemble mean of the modified experiements than in the original experiment), which resulted comparably from both direct effect of the modification and indirect effect via changes of the snow and ice distributions by the albedo reduction. Snow thickness on the sea ice was reduced by up to 1.5 cm in June–July but afterward impact of the modification was diminished as the snow mostly melted away. Impact of the modification on the sea ice firstly appeared in the rim regions of the snow cover with the bare ice fraction extended and, in August–September, ice thickness decreases by 1.5 cm were achieved over most of the Arctic Ocean. On the other hand, ice thickness increases were seen in some marginal ice zones, which were attributed to reduced ocean surface circulation, such as in the Beaufort Gyre, resulting from reduced surface stresses with reduced ice cover.

In the Southern Ocean, the albedo reduction by up to 0.015 in December–January resulted from comparable contributions of the direct effect of the modification of the parameterization and the indirect effect via the snow thickness decrease, as in the Arctic Ocean. In contrast to the Arctic Ocean, the decrease impact of the snow thickness by up to 2.5 cm in the Weddell Sea partly remained through year. In addition, increases of the ice thickness were widely distributed in December–January. A detailed analysis revealed that the warming effect of the albedo reduction by the modification enhanced the reduction of the sea ice concentration, in particular that of thinner ice, which weakened the ice pressure and enhanced thicker ice formation via the rheology, leading to the increases of the ice thickness. Note that thicker ice is less affected by thermodynamical melting effect than thinner ice. This thickening impact of the sea ice remained through year in the Weddell Sea. These changes by the modification of the parameterization were robust compared with the ensemble spread.

Although the above experiments and results might be rather preliminary, we believe that our demonstration of the potential impact of the new observational insight on ocean general circulation model simulations would be of value for further enhancing both observation and modelling/prediction activities and their collaborative study.

## [A-CG37] Science in the Arctic Region

convener:NAOYA KANNA(Arctic Research Center, Hokkaido University), Masashi Niwano(Meteorological Research Institute), Tetsu Nakamura(Faculty of Environmental Earth Science, Hokkaido University), Shunsuke Tei(Arctic Research Center, Hokkaido University), Chairperson:Naoya Kanna(Arctic Research Center, Hokkaido University)

The Arctic and circumpolar region is the key area for the study of global change because the anthropogenic impact is projected to be the largest in this area due to the complicated feedback processes of the nature. A number of international and interdisciplinary research projects have been conducted for the studies on the land-atmosphere-ocean system. In order to understand the feedback processes occurring in the Arctic and to project the global warming in the future, we need to establish the intense observational network and to exchange the knowledge and information by combining the different scientific communities under the common interest of the Arctic. The objectives of this session are 1) to exchange our knowledge on the observational facts and integrated modelling and 2) to deepen our understanding on wide range of natural sciences related to the Arctic and the circumpolar region. Studies on humanities, social sciences, and interdisciplinary fields are also welcomed.

# Introduction of the IASC project "T-MOSAiC"

Masaki Uchida[1], *Tetsuo Sueyoshi[1]

1. National Institute of Polar Research

Terrestrial Multidisciplinary distributed Observatories for the Study of Arctic Connections (T-MOSAiC) is one of the IASC (International Arctic Science Committee) projects. T-MOSAiC has been formulated as a research and synthesis project to provide an integrated, cross-disciplinary evaluation of how the changing Arctic Ocean affects terrestrial environments, from the coastal zone to the continental interior. The project will focus on connecting studies which take place throughout the Arctic and across disciplines in order to generate new findings into Arctic geosystems, ecosystems and human systems. There are key aspects to be addressed include connectivity, gradients, discontinuities, thresholds, extreme events and emergent properties, with specific questions that bridge sites and disciplines. Data sets will be available via open access repositories. T-MOSAiC will run in parallel to the ocean-based project Multidisciplinary drifting Observatory for the Study of Arctic Climate (MOSAiC), with temporal overlap in 2019-2020 and exchange of data sets such as climate observations from land and ocean stations.

Participating in T-MOSAiC has several advantages to your research. Join an international project across disciplines that targets key physical, ecological and societal issues affecting the Arctic and the world, at this critical time of rapid change and international decision-making. Contribute to fill key observational data in gaps identified by the T-MOSAiC Science Plan. Assure laboratory and project visibility at the international level. Benefit from T-MOSAiC and IASC grants for early career researchers for networking. Link with large T-MOSAiC partners such as MOSAiC (https://www.mosaic-expedition.org/), INTERACT (https://eu-interact.org/), Sentinel North (https://sentinelnorth.ulaval.ca/en), Nunataryuk (https://nunataryuk.org/) and others. Develop new collaborations, including across disciplines. Please visit the T-MOSAiC web site and get more information (https://www.t-mosaic.com/).

# Estimation of ice thickness and volume in the Sea of Okhotsk using ICESat and CryoSat-2 data

*Sohey Nihashi[1], Nathan T. Kurtz[2], Takenobu Toyota[3]

1. National Institute of Technology, Tomakomai College, 2. NASA GSFC, 3. Institute of Low Temperature Science, Hokkaido University

Sea-ice thickness in the Sea of Okhotsk is estimated from freeboard derived from satellite altimeter data. Ice thickness is estimated by assuming densities of sea ice, snow, and seawater based on in-situ observations (Toyota et al., 2007; Ohshima et al., 2001). Snow depth is assumed 10% of ice thickness by referring to in-situ observation (Toyota et al., 2007). Ice freeboard (thickness) derived from a laser altimeter GLAS on ICESat is used for 2004-08 (Nihashi et al., 2018). After 2011 to 2018, data from radar altimeter SIRAL-2 on CryoSat-2 is used. CryoSat-2 freeboard is obtained by a method of Kurtz et al. (2014). Comparison with ice thickness observed hourly aboard icebreaker Soya by visual observation suggests that ice thickness derived from ICESat and CryoSat-2 are almost consistent. Total ice thickness (ice thickness including snow depth) in February and March, when the sea-ice area is maximum, averaged over the entire sea-ice zone ranges from 77.5 cm (2008) to 123.0 cm (2017). The mode of total ice thickness ranges from 50-60 cm (2007; 2008; 2017) to 90-100 cm (2013). Ice volume in the Sea of Okhotsk is estimated from the total ice thickness and ice concentration derived from AMSR-E (2004-11), SSMI (2012), and AMSR2 (2013-18). Ice volume is estimated by interpolating these sea-ice datasets onto an NSIDC polar stereographic grid at a spatial resolution of about 12 km. The maximum ice volume is $8.3\times10^{11}$ $m^3$ (2016), while the minimum is $5.4\times10^{11}$ $m^3$ (2015). The interannual variability is shown to be mainly determined by the sea-ice area, although ice thickness seemed to be effective in 2008. It has been shown that the maximum sea-ice area and ice production in the Sea of Okhotsk can be explained from atmospheric and oceanographic conditions (e.g., Ohshima et al., 2006; Nakanowatari et al., 2010; Kashiwase et al., 2014). Based on these studies, we compare the ice volume with the atmospheric and oceanographic data. And then we find that the ice volume can be explained to some extent by the air temperature in the northwest and north of the sea just before the freezing season (November-December), the air temperature in the northwest of the sea during active freezing period (February-March), and the wind toward the offshore during the ice advance season (January-March). Multiple regression analysis is performed on the ice volume using these atmospheric conditions. And we try to reproduce the ice volume in the Sea of Okhotsk since the 1950s when the satellite data does not exist from the atmospheric data by using the regression line.

# Arctic Sea Ice Changes in the DAMIP experiments using the MRI Earth System Model

*Takuro Aizawa[1], Masayoshi Ishii[2], Naga Oshima[2], Seiji Yukimoto[2], Hiroyasu Hasumi[1]

1. Atmosphere and Ocean Reseaerch Institute, The University of Tokyo, 2. Meteorological Reseaerch Institute

Arctic sea ice decreases rapidly with a temperature rise by Arctic amplification which is caused by an increase of the greenhouse gases. According to some studies, the Arctic Ocean is projected to become ice-free Ocean in the nature future. As sea ice melts due to the effect of sensible heat, it has a close relationship with air temperature. Although the historical temperature in the Arctic is well known by the previous observational studies, the historical sea ice variability hasn’ t still understood sufficiently because of the lack of observations in pre-satellite era. Therefore, the modeling study will greatly contribute to the understanding of the Arctic climate change.

Meteorological Research Institute (MRI) has developed a new version of MRI Earth System Model (MRI-ESM2) for participating in the various Model Intercomparison Project (MIP), especially CMIP6 (Coupled Model Intercomparison Project Phase 6). We conducted the CMIP6 historical experiment (1850-2014) and the DAMIP (Detection and Attribution MIP) experiments by MRI-ESM2. The DAMIP experiments consist of hist-GHG (Well-mixed greenhouse-gas-only historical simulations), hist-aer (Anthropogenic-aerosol-only historical simulations) and hist-nat (Natural-only historical simulations). The DAMIP experiments make it possible to the clarify the impacts of anthropogenic and natural forcing on the global warming. And the experiment will be able to estimate how the sea ice variability was influenced by the external anthropogenic and the natural forcing. The decadal to multi-decadal variability of the Arctic sea ice is seen in all experiments, but each experiment indicates some characteristic changes. The hist-GHG experiment shows a strongly decrease in the sea ice extent due to the rapid increase of the greenhouse gases. The hist-aer experiment indicates an expansion in the summer sea ice extent over the period to 1980 when the concentration of sulphate aerosols is peak out, which lead to the global and Arctic cooling. But over the period from 1980 to now, the summer sea ice extent shows a decrease. The hist-nat experiment shows a weakly decrease in the summer sea ice extent over the period from 1880 to 1940, since then the summer sea ice extent remains at the same level. Thus, our simulations show the historical summer Arctic sea ice extent and the contributions of the external anthropogenic and the natural forcing to the sea ice changes.

# Oceanographic Observation in the Refreezing Warm Chukchi Sea during 2018 Mirai Cruise

*Tsubasa Kodaira[1], Takehiko Nose[1], Takuji Waseda[1], Jun Inoue[2]

1. The University of Tokyo, 2. National Institute of Polar Research

In November 2018, R/V Mirai entered Chukchi Sea to conduct observations with special attention to the Marginal Ice Zone (MIZ). Based on satellite SST measurements over Chukchi Sea, it is found that Chukchi Sea has a clear warming trend in the last decade. The warm Chukchi Sea enabled R/V Mirai to conduct rare observations in November to measure the refreezing ocean. The preliminary results of the hydrographic and velocity observation are presented. The repeated measurements along an observation line toward MIZ north of Hana Shoal showed temperature and salinity changes largely over the Chukchi slope compared to the shallow shelf.

# Observed Waves in the refreezing eastern Chukchi Sea during 2018 Mirai Cruise

*Takuji Waseda[1], Takehiko Nose[1], Tsubasa Kodaira[1], Alison Kohout[2], Johannes Gemmrich[3], Hui Shen[4], Jun Inoue[5]

1. The University of Tokyo, 2. National Institute of Water and Atmospheric Research, 3. University of Victoria, 4. Bedford Institute of Oceanography, 5. National Institute for Polar Research

The sea ice in the Pacific side of the Arctic Ocean starts to melt in August, retreats the most in September, and advances again in October. In November, in typical years, most of the Chukchi Sea is covered by ice. Waves generated in the open waters is largest in October. During the R/V Mirai (JAMSTEC) expedition in November 2018 (MR18–05C, PI J. Inoue), anomalously warm surface waters delayed freezing of Chukchi Sea providing a unique opportunity to observe ocean waves in the freezing period. A drifting wave buoy, ship-borne wave gauge, and satellite synthetic aperture radar data were analyzed to characterize the waves during that period. The drifting wave buoy was deployed at the edge of the Marginal Ice Zone, gradually migrated to the west, and eventually got trapped in the sea ice. During this period, the largest significant wave height observed by a buoy was 2.6 m. Once trapped in ice, the buoy-detected wave energy significantly reduced from the open water wave height detected by ship-borne wave gauge. The possible generation, decay, and propagation of waves in the ice-covered sea for on-ice and off-ice conditions will be discussed in conjunction with the obtained satellite SAR images.

# Mooring measurement near a marine-terminating glacier in Bowdoin Fjord in northwestern Greenland

*Yoshiki Fujishi[1,2], Yasushi Fukamachi[1,3], NAOYA KANNA[3], Shin Sugiyama[1,3]

1. Institute of Low Temperature Science, Hokkaido University, 2. Graduate School of Environmental Science, Hokkaido University , 3. Arctic Research Center, Hokkaido University

Submarine melting of calving glaciers is considered as an important process in the mass loss of the Greenland ice sheet (Straneo et al., 2013). Moreover, freshwater runoff has been increasing in recent years and its impact on marine ecosystem is recognized. Bowdoin Glacier, a marine-terminating outlet glacier in northwestern Greenland, has experienced rapid retreat since 2008 (Sakakibara et al., 2018). However, oceanographic observations are sparse in Greenlandic fjords, especially near the calving front of glaciers. The lack of a long-term in-situ data makes it difficult to quantify submarine melting. To better understand seasonal variability in current, temperature, and salinity in this proglacial fjord, mooring measurement was performed in Bowdoin Fjord, a 20-km-long fjord in front of Bowdoin Glacier.
Two moorings were deployed in Bowdoin Fjord, one at 17 km from the glacier front (BF17) and another at approximately 1 km from the glacier front (BF01), respectively. The ocean depth was 540 m at BF17 and 186 m at BF01. The moorings were equipped with a pressure sensor (DEFI2-D50HG, JFE Advantech), thermistors (NWT-SN, Nichiyu Giken and SBE56, Seabird), current meters (INFINITY-EM, JFE Advantech) and conductivity-temperature sensors (SBE-37SM, Seabird). At BF17, a current meter and a conductivity-temperature sensor were at the depths 527 m and 530 m, respectively. A pressure sensor and seven thermistors were at 220 m and 222, 246, 268, 318, 368, 418, and 468 m, respectively. At BF01, a current meter and a conductivity-temperature sensor were at the depths of 167 m and 170 m, respectively. The instruments were operated from August 2016 to July 2018 at BF17 and from July 2017 to July 2018 at BF01.
At BF17, temperature near the bottom was lower during northward current (towards the glacier). Temperature variations corresponded well with that of salinity throughout the year, i.e. temperature increased when salinity decreased. From August to October, we observed fortnightly temperature variations suggesting the influence of tide on water exchange in the fjord. In early August, water near the bottom at BF01 flowed towards the glacier and temperature near the bottom rapidly decreased. This event occurred when the daily mean air temperature measured at Qaanaaq Airport exceeded 0 ˚C, indicating the initiation of subglacial discharge. Temperature variations near the bottom at BF01 correlated with salinity, i.e. temperature and salinity increased at similar timings. Both at BF17 and BF01, temperature variations were small in winter and spring, which we attribute to sea ice cover usually observed in Bowdoin Fjord from November to June. Our data suggested that tide plays a key role in water exchange in the fjord, whereas water property near the glacier front was strongly influenced by meltwater discharge. In the presentation, water property variations and fjord circulation are discussed with weather conditions, and the data obtained at BF17 are compared with those at BF01.

ACKNOWLEDGEMENTS

*Tomio INAZAKI[1], Takanori Ogahara[1]

1. Public Works Research Institute, Tsukuba Central Institute

We reanalyzed the comprehensive geoscientific investigation data obtained at a site where outstanding liquefaction took place just after the 2011 off the Pacific coast of Tohoku earthquake. The studied site, Makuhari-Kaihin Park, Chiba Prefecture, faces the Tokyo Bay and is situated on a reclaimed land constructed through 1973 to 1987. The field surveys were composed of high-resolution seismic surveys along two short lines, core boring at 4 points, suspension PS logging, CPTs at 7 points, and dynamic cone penetration tests. Core descriptions and detailed grain size analyses were quite helpful to discriminate man-made strata from natural layers and classify them into wet deposits, dry soils and surface cover soils. A time series of aerial photos of the site was interpreted to reconstruct the reclamation process of the site. Our interpretation is as follows; 1) Northern block was first reclaimed since 1973 and the southern block was followed since 1976. Reclamation was completed till 1987 and then the surface was covered with improved soils to form a loan park surrounded by a planted zone. The boundary between the reclamation blocks was buried in the northern part of the park. Aerial photos clearly recorded dendritic sand dunes in the southern block spread by using aligned sand pipes. Wet deposits were overlain with 1 to 2 m thick dry soils toward the offshore.
Based on the time and spatial history of the reclamation process at the site, we implemented a geoscientific interpretation of liquefaction process of the site. 1) The cover soils acted as a cap layer which controlled the mode of occurrence of the surface fissures and sand boil chains caused by liquefaction. 2) Sand dominant parts in the wet deposits first liquefied during the earthquake, and it caused segmentation of man-made strata into several fragments and differential oscillations during the earthquake. Liquefaction resulted in fluidization of fine-grained parts in the wet deposits. No trace of liquefaction was recognized in the underlying natural layers. In contrast, characteristic structure associated with liquefaction and fluidization was obvious in the wet deposits in the whole points of the site. It means that the surface fissures and sand boil chains were inappropriate to explain liquefaction process because liquefaction inherently takes place in the subsurface.

# Distribution morphology of deformed reclaimed valley associated with the 2018 Hokkaido Eastern Iburi Earthquake

*Takayuki Nakano[1], Satoshi Fujiwara[1], Hiroshi Une[1]

1. GSI of Japan

## 1. Introduction

In the 2018 Hokkaido Eastern Iburi Earthquake (M6.7) that occurred on September 6, 2018 (Japan Society of Erosion Control Engineering, 2018 etc.), the fluidization phenomenon of filled land caused by liquefaction etc. in reclaimed valley on Kiyota Ward, Sapporo City seriously damaged residential land and social infrastructures (Japanese Geotechnical Society and Japan Society of Civil Engineers, 2018 etc.). In order to discuss this fluidization phenomenon of reclaimed valley, it is necessary to know the reclaimed valley distribution morphology. Therefore, we disclosed the distribution morphology of the reclaimed valley created by the difference between the pseudo DEM generated from aerial photos using the SfM-MVS technique and the post-construction DEM. Also, we extracted the surface deformation in this area from SAR interferogram and compared it with reclaimed valley distribution.

## 2. Target area and study method

Reclaimed valley distribution maps were created in Kiyota Ward, Sapporo City (Kiyota site) and Atsuma Town (Atsuma site). Pre-construction DSMs were generated from 44 aerial photos of the 1960s and 1970s taken by the GSI of Japan, respectively. The DSMs were generated by using the SfM-MVS technique and the DSMs were converted to a pseudo DEM by filtering (Nakano, 2017). On the SfM analysis, we established 35 and 20 ground control points (GCPs) respectively. A 5-m grid DEM of the fundamental geospatial data was used for the post-construction DEM. The used SAR interferogram is an image by a pair of August 23, 2018 and September 6, 2018 analyzed by the GSI of Japan using the ALOS-2 data of JAXA.

## 3. Result & Discussion

We acquired the reclaimed valley distribution map more detail than the past distribution map in the Kiyota site. The reclaimed thickness at the Satozuka district where ground damage was serious in the Kiyota site was ca. 15 m at the maximum. Since the RMSE of vertical residual of GCPs on the SfM analysis was ca. 1.2 m, the value of reclaimed thickness has an error equivalent to that. Comparing this reclaimed valley distribution map with the SAR interferogram, we could identify surface deformations moving away from the satellite or non-interference areas in the reclaimed valley area. This non-interference areas correspond the serious damage areas and the surface deformations area has the potential to show the subsidence or sliding-like deformation of reclaimed valley.

In the Atsuma site, we confirmed small reclaimed valley which the thickness is less than 10 m. The RMSE of vertical residual of GCPs on the SfM analysis was ca. 0.8 m. Surface fissures in this site were discovered on site (Iiba and Nagai, 2018 etc.), and it is estimated that the sliding-like deformation of reclaimed valley occurred.

## 4. Challenges

We identified the reclaimed valley distribution morphology easily and quickly by using SfM-MVS and filtering analysis with aerial photo. Also, InSAR indicated the possibility of quickly detecting the surface deformation immediately after the disaster. However, we should be careful since the pseudo DEM created from DSM generated by the SfM analysis will have large errors when the area was forest land before construction. It is necessary to examine a more effective and prompt filtering method. Finally, I would like

©2019. Japan Geoscience Union. All Right Reserved. 

to offer my sincere sympathy to the people living in the damaged regions by the earthquake.

# Liquefaction risk evaluation using relative height data of natural levee

*Mamoru Koarai[1], Kouta Uchiyama[1], Takayuki Nakano[2]

1. Earth Science course, College of Science, Ibaraki University, 2. Geospatial Information Authority of Japan

The liquefaction risk evaluation of the natural levee has been divided in two by a border of relative height 5m in the liquefaction evaluation standard of Nakano et.al. (2015).But it is necessary to reconsider evaluation division, because almost no natural levee with over 5m relative height exists in the Naka River low land and the Tone River downstream.
In this study, land condition map, 5m grid DEM and liquefaction occurrence area by The 2011 off the Pacific coast of Tohoku Earthquake in downstream of the Tone River were overlaid by GIS. The relative height of natural levee was calculated from an elevation of the natural levee liquefaction generated and an elevation of other neighbor landform such as back marsh, coastal plain and delta.
After the liquefaction occurrence rate of the natural levee was calculated every relative height difference of the 0.5m unit, the liquefaction occurrence rate decreased suddenly between 1.5 m-2.5 m of relative height or the liquefaction occurrence rate gradually decreased over 1.5 m-2.5m of relative height. It is appropriate to establish a border of relative elevation of a natural levee by 2m or 3m.

# Spatial Analysis of Social Vulnerability to large-scale flood: a case study on the Katsushika Ward, Tokyo

*LIAN XIAO[1]

1. University of Tsukuba

Due to global climate change, the scalability and frequency of flooding is increasing. On the other hand, population aging and family structural changes, as well as the lack of adaptation measures, accelerate vulnerability to flooding. It is necessary to reduce the vulnerability to floods and to accelerate adaptive capacity. Therefore, assessing social vulnerability to flooding disasters is an important step in reducing flooding vulnerability and accelerating resilience.

In this study, we refer to the MOVE framework (a disaster vulnerability assessment framework) and analyze social vulnerability from three perspectives: exposure to a flood, susceptibility, and resilience. We subsequently develop an index system to evaluate the social vulnerability using 14 indicators. Spatial distribution of the social vulnerability of floods in the Katsushika Ward, Tokyo, is revealed based on the collected data using the information entropy method and geographic information system (GIS).

Keywords: GIS, large-scale flood, Social Vulnerability

# Importance and method of visualization of future occurrence possibilities of giant earthquakes along the Nankai trough

*Yo Fukushima[1]

1. International Research Institute of Disaster Science, Tohoku University

Earthquakes occur in a diverse fashon and we can only make probabilistic forecasts on their occurrence. In a future, we might be able to make deterministic forecasts for certain earthquakes, but at the current status we do not foresee a realization of such a type of forecast.

Currently, discussion on how to take countermeasures on the anticipated giant Nankai trough earthquakes based on forecast information is going on in Japan, led by a Japanese governmental working group. On the giant Nankai trough earthquakes, it has been known mainly from historic documents and seismological observations that 1) the mean recurrence interval of giant Nankai trough earthquakes is 100–150 years, 2) there are two segments, west and east of the Kii peninsula, and they tend to generate earthquakes one after another with a short time interval (within a few years) or rupture simultaneously, 3) normally there are few interplate earthquakes along the Nankai subduction.

Based on such current knowledge, the report by the governmental working group issued in December 2018 emphasizes on the case where a magnitude ~8 earthquake rupturing only one side (west or east) and another earthquake is strongly anticipated on the other side. The report also mentions the cases where a smaller earthquake (magnitude ~7) or an unusual slow slip occur, but with conservative descriptions on the countermeasures for such cases. In short, the report focuses on relatively certain and presumably impending case of what to do in case of the “half-rupture”.

While, at the standpoint of the national government, the framework of the report is appropriate, there seems to be potential motivation on local government, public organizations and private companies to make own flexible decisions depending on their circumstances. There may be cases where some anomalous geophysical phenomenon, even without an eventual occurrence of a giant earthquake, would lead to social reactions and the organizations should take some countermeasures. It seems thus useful for the organizations to understand the possibilities of anomalous natural phenomena that might lead to an earthquake (and social phenomena that follows). Event tree diagrams used in volcanology and other fields can be useful for that purpose. It would be important that experts collaborate with the stakeholders (potential users) and know their needs and opinions in developing them.

# Investigation of efficient tsunami evacuation using real-time disaster information

*Yusuke Oishi[1,2,3], Takashi Furumura[2], Fumihiko Imamura[3], Yoshiteru Mihara[4], Fumiyasu Makinoshima[3], Yamashita Kei[3], Takao Higashiyama[5], Tomonori Goto[5], Makoto Oomura[4], Mitsuyuki Nagayama[4]

1. Fujitsu Laboratories Ltd., 2. Earthquake Research Institute, the University of Tokyo, 3. IRIDeS, Tohoku University, 4. Kawasaki City, 5. Fujitsu Ltd.

## 1. Introduction

In recent years, due to the expansion of the offshore tsunami observation network in Japan and the development of high-speed analysis techniques to utilize the observed data, it is becoming possible to transmit more detailed real-time disaster prediction information. Just after the 2011 Tohoku-Oki Earthquake occurred, while the majority of voice calls were regulated, packet communication continued to be relatively connected and smartphones played an important role in information sharing. Therefore, it is expected that real-time disaster information obtained through smartphones can realize safer evacuation in the near future. In this study, in order to evaluate the effect and the challenge of providing real-time disaster information through smartphone in tsunami evacuation, a demonstration experiment was carried out.

## 2. Tsunami evacuation demonstration experiment

In the demonstration experiment conducted in the opportunity of the Kawasaki city’ s annual tsunami evacuation drill on December 9, 2018, we set up points where passing through was not permitted due to assumed damages caused by strong shake of earthquake, e.g., building collapse, fire, liquefaction, etc., and staff members were located with panels that said “impassable”. When participants of the demonstration experiment encountered the impassable points, they posted the location of these points through a smartphone application, and the posted information was shared in real time on the application screen of other participants. The smartphone application was developed for this experiment and was distributed before the experiment. The number of participants who used the provided smartphone application was 84.

Evacuation behaviors were measured as time series data of position information by the position measurement function of smartphones. In the experiment, in order to evaluate the effect of real-time disaster information about the locations of above-mentioned impassable points on evacuation behaviors, 24 participants from the organizations conducting the demonstration experiment were divided into two groups. One of the two groups were not provided the posted information. As a result, in the group with disaster information, multiple evacuees succeeded in choosing an efficient evacuation route by reducing the number of encounters to the impassable points, and the effectiveness of the real-time disaster information was confirmed. However, when comparing the average value for each group, although the evacuation distance was slightly shorten in the group with the information, it did not lead to reduction in evacuation time, because the average walking speed was slower than the group without the information. The average walking speed that takes the standstill time into account was 4.9 km/h for the group without the real-time disaster information and was 4.7 km/h for the group with the information.

©2019. Japan Geoscience Union. All Right Reserved. 

One of the estimated factors that lower the average walking speed is the standstill time to consider evacuation routes using the smartphone application at the branching points and at the places near the impassable points, or the action to post the impossible points. In the group with the real-time disaster information, among twelve people, nine people stopped for more than 10 seconds during the evacuation action.

### 3. Future work

One of the reasons why the average evacuation speed was decreased in the group with the real-time information is that the accuracy of the posted information was rather low and the standstill time to consider evacuation route was prolonged. In the questionnaire conducted after the evacuation drill, there were multiple opinions such as "With the wrong information, there were no passible road leading to the evacuation site". Among the 74 postings about the impassable points, 40 posts (54.8% of the whole) were accurate with an error of 20 m or less. In order to realize evacuation effectively utilizing real-time disaster information, it is important to evaluate the quality of information and consider information providing means that are easy-to-understand and lead to immediate determination of the next action.

# Validity Verification in Typhoon Disaster Prevention Model for Typhoon Damage Reduction –GUST Wind Speed, Maximum Wind Speed -

*Woo-Sik JUNG[1], Hana Na[1]

1. Department of Atmospheric Environment Information Engineering, Atmospheric Environment Information Research Center, Inje University, Gimhae 50834, Korea

In recent years, as the intensity of typhoons affecting the Korean peninsula has become stronger due to global warming resulting from climate change, studies on typhoons attacking the Korean peninsula are being increasingly carried out. Many previous studies have constructed typhoon disaster prevention models for estimating the maximum wind speed of the 3-second gust that can occur during a typhoon. In addition, such studies have enabled the establishment of foundational materials for the typhoon disaster prevention system. However, there have been few studies on the validity of the maximum possible wind speed of the 3-second gust, as estimated by the typhoon disaster prevention model. Therefore, in this study, validity analysis was carried out via verification using the observed 3-second gust values. For the verification, the GUST wind speed data from marine meteorological buoys (which serves as the basis of maximum wind speed) monitored by the Korea Meteorological Administration, and maximum instantaneous wind speed data from lighthouse observation, were used. In addition, this study compared and analyzed the 3-second gust values observed at points located within the radius of the maximum wind speed, and at points located outside the radius of the maximum wind speed during the typhoon season. The points within the radius of the maximum wind speed showed a more similar trend to the observed values than the points outside the radius. In addition, the points within the radius better simulated the maximum wind speed. Moreover, the 3-second gust values calculated by the typhoon disaster prevention model were slightly greater than the observed values at almost all points. From the viewpoint that the calculated value is the maximum possible wind speed, it is considered to provide useful information in terms of pre-disaster prevention regarding typhoon damage. As a result of comparing the wind speeds at the 10 m altitude (which were obtained from the typhoon prevention model by categorizing the Korean peninsula into inland, coastal, and island regions), with the observed values, the island region, showed the best results (due to the presence of fewest obstacles on the ground), followed by the coastal, and inland regions. This study suggests that the 3-second gust is a justified parameter to be used in the typhoon disaster prevention model. Therefore, the typhoon disaster prevention model can be efficiently applied to the typhoon disaster prevention system.

# A Study on the Assimilation of Meteorological Data and Sea Surface Temperature Data for Improving the Accuracy of WRF Prediction during Typhoon periods on the Korean Peninsula

*Woo-Sik JUNG[1], Hana Na[1]

1. Department of Atmospheric Environment Information Engineering, Atmospheric Environment Information Research Center, Inje University, Gimhae 50834, Korea

Typhoons affecting the Korean peninsula and the surrounding regions originate in the Western Pacific Ocean. The SST around Korean peninsula are increasing at a more rapid rate than the rate of global SST. Consequently, the intensity of typhoons affecting the Korean peninsula will become stronger. Therefore, studies on the implementation of the typhoon disaster prevention system, to minimize the damage by predicting the maximum possible wind speed at the time of the influence of the typhoon, were carried out. In addition, recent studies have used the WRF model, which is useful for work-site operation and research. It is suitable for work-site operation as well as research to emulate the high-resolution data of the typhoon disaster prevention model. In this study, SST data and FDDA data were assimilated to produce the optimal WRF results. The results obtained were used as input data to the typhoon disaster prevention model, which is part of the typhoon disaster prevention system. This study selected Typhoon Bolaven (that moved north to the Yellow Sea and greatly damaged the metropolitan area in the Korean peninsula), and used WRF 3.5.1 version for data evaluation. The RDAPS numerical model data of the Korea Meteorological Administration were used as the model input data, and the OSTIA data were used as the SST data. For the FDDA data assimilation (OBS nudging), the sensitivity test was performed using the wind speed and temperature data of vertical and synoptic observations in the Korean peninsula region. As a results of time series analysis and statistical analysis, the maximum wind speed difference was about 5 m/s when the input data were applied differently. High-resolution sea surface temperature data assimilation yielded better results than the meteorological data assimilation. When the meteorological data assimilation and high-resolution sea surface temperature data assimilation were applied simultaneously, better results were obtained than under individual data assimilation cases. If the maximum possible wind speed of the 3-second gust that can occur during a typhoon is estimated using the optimal high-resolution results, the damage due to the typhoon will be effectively reduced through accurate prediction.

# Validation and application of a finite element approach on field mechanically stabilized earth walls with secondary reinforcement

*BING-RU WU[1], CHIH-HSUAN LIU[1], CHING HUNG[1]

1. National Cheng Kung University

Mechanically stabilized earth (MSE) walls have been used widely to prevent slopes from natural disasters around the world. The typical vertical spacing of geosynthetic reinforcement used in the practical MSE wall may cause high reinforcement connection strength and lead to wall-facing bulging. Previous studies show that installing short (secondary) reinforcement layers in-between primary reinforcement layers could mitigate these problems by reducing wall facing deflection and primary reinforcement strains, increasing the wall internal stability, alleviating down-drag forces behind the wall facing, and so on. Although the performance of the secondary reinforcement has been widely examined, its controlling factors (i.e., length, spacing, distribution) on the behavior of MSE wall are scarcely studied. In this study, a finite element approach was validated via a benchmark field case and was applied to understand the effect of the controlling factors on the behavior of MSE wall as well as giving a guidance on the design of MSE wall with secondary reinforcement.

# EXPERIMENTAL STUDY ON POLYUREA-COATED RC SLAB SUBJECTED TO CONTACT EXPLOSIONS

*Minghsien Wu[1], Yingkuan Tsai[1], Chien-Hsien Liu[1], Pang-Ting Pai[1], Feng-Cheng Yang[1], Chun-Chia Huang[1]

1. Chung Cheng Institute of Technology National Defense University

Global terrorism is on the rise as the number of attacks soared, puts the world under the threat of car bomb, suicide bomb and so forth, and causes a huge amount of loss of life and property. Current buildings and infrastructures are mostly constructed using reinforced concrete, due to the brittleness of concrete material, when a structure subjected to blast loadings, the phenomena such as cracking and spalling at the proximal face of the target, and the ejection of fragments from the distal face of the loaded surface can be observed. These types of damage or failure could severely harm to the structural stability and the safety of people and equipment inside the building. Thus, the blast resistance of buildings has become an important issue in structural design and evaluation. Considering the high tensile strength and excellent impact resistance of polyurea materials, it is expected that the blast performance of a reinforced concrete element can be enhanced by coating this material onto its surface.

The purpose of this study is to investigate the blast performance of the polyurea coating on reinforced concrete slabs by conducting a series of filed explosion tests. The size of the specimen is 50cm×50cm×15cm. Four pieces of RC slabs were tested: RC slab without coating, RC slabs with coating on the front face, coating on the back face, and coating on the both faces. The thickness of coating is 3 mm. The specimens were fixed on a steel frame and detonated at the center of the test surface with a size of 5cm×5cm×2.5cm of 100g C4 rectangular explosive. The size and depth of the damage area on the front and back of the RC slabs were measured and evaluated by developing 3D models with point clouds from photographs.

The results show that when the unreinforced RC slabs is subjected to contact explosion, cratering will occur on the front side of the specimen and spalling will occur on the back side of the specimen; and when the RC slabs is coated on the front side of the specimen, the polyurea reinforcing layer at the contact explosion site is destroyed, but the damage degree were reduced; and in the case of the back-explosive surface reinforcement, the damage range of the cratering is also reduced, and the polyurea coated with the back-explosive surface has no crack, damage and blow-through. When the coating layer is removed, the back surface of the test piece is observed, and only cracks are generated but no obvious spalling. It is obvious that polyurea produces good adhesion due to its material properties and tightly constrains the fragments. Therefore, it has been shown by experiments that the use of polyurea elastic coatings to reinforce the explosion surface or the back explosion surface of the RC slabs can enhance the explosion-proof capability and reduce or protect from spalling, thereby achieving the purpose of protecting the internal life and property of the building. It is known from this test that the polyurea coating with a thickness of 3 mm can effectively and significantly reduce or avoid the occurrence of spalling when applied to the back surface of RC slabs.

# Simulation and field investigation of scour and sediment transport after Dam removal in the mountainous creek in Central Taiwan

*Chunhung WU[1]

1. Feng Chia University

The research focuses on using the flume experiments to observe the head-erosion phenomena caused by dam removal and simulate the channel evolution in the upstream and downstream of dam after dam removal by using CCHE2D model. The research area is in the Landaw river watershed in Huisun National Forest Area in the Central Taiwan. Two silts of silt dam build in the Landaw river had been lowered down 2.5 m height to release the deposited sediment to transport to downstream in 2013, and the research proceeded long term observation of the head-erosion in the upstream of the silt dam by using UAV and field investigation.
The research proceeded the flume experiments to simulate the sediment transport from the upstream of the dam and simulate the channel evolution in the upstream and downstream of dam by using CCHE2D model after dam removal. The control factors in the flume experiments are the sediment size, the discharge, the channel slope, and the removal area of check dams. The sediment size settings in this research include totally 0.9 mm, half 0.9 mm and half 0.5 mm, and totally 0.5mm, while the discharge settings include 3.4, 83.0, and 102.6 cubic centimeter per second. The channel slope settings include 4.4, 8.7 and 13 degree. The research records the sediment yield volume, the geomorphologic changes and the knickpoints evolution in the longitudinal sections after removing different area of dams in 27 flume experiments. Based on the dominant factors for the bank erosion scouring, 27 flume experiments can be classified into 3 types, including infiltration-dominated bank erosion experiments, surface runoff-dominated bank erosion experiments, and infiltration and surface runoff co-exist bank erosion experiments.
Furthermore, the research also uses CCHE2D model to simulate the sediment transport after the dam removal process of the silt dam in the upstream of Landaw river watershed. The research uses the river discharge in the day with the maximum 24 hours accumulated rainfall from 2015 to 2018, and the original DSMs in 2010, 2016, 2018 as the topographic models to simulate the scouring process in the upstream of the silt dam after dam removal. The research also proceeded the field investigation to verify the simulation result.
The accumulated rainfall setting for the simulation of CCHE2D model is 585 mm in 24 hours, and this is the accumulated rainfall with return period years of 50 year in the Landaw river watershed. Based on the simulation result by using CCHE2D model with the accumulated rainfall of 585 mm in 24 hours, the elevation of main river has been lowered down 5.4 m, and the maximum width of the head-erosion in the upstream od the silt dam is around 5.24 m. The total erosion sediment volume is estimated as 1370 cubic meter. The slope in the longitudinal profile along the main river can be classified into two sections. The slope from the silt dam to 23 m upward in the upstream is estimated as 0.31, while that from the 23 m upward in the upstream to the 200 m upward in the upstream is estimated as 0.151. This means that the knickpoint is in the 23 m upward in the upstream of the silt dam. The result will be the basis for developing the assessment model for assess the feasibility of dam removal in the rivers.

# Examination and systematization of predispositions to floods in the Heavy Rain in July 2018

*Kanako Kimura[1], Toshihiko Sugai[2]

1. The University of Tokyo, 2. Graduate School of Frontier Sciences, the University of Tokyo

## Introduction

Though predispositions to floods have been mentioned in the studies of river engineering, geography and geomorphology, the relationship between flood and topography / geology is dealt with as self-evident in most of them. Hence, this study focuses on the predispositions to floods.
The floods in the Heavy Rain in July 2018, especially those of the Oda River (the Takahashi River System) are the subjects of this study. The purposes of this study are (1) to create a database on the floods, (2) to examine predispositions for each space scale, taking into account the influence of artificiality, (3) to acquire knowledge contributing to high accuracy of flood risk assessment.

## Fields & Methods

In the Chugoku district, 3 denudation surfaces are seen. And, the plains on the Setouchi side have been formed by the rivers flowing down from the Chugoku mountains. These rivers are characterized by weathering granitoids distributed upstream.
The Oda River is a first-class river which joins the Takahashi River in Kurashiki city. Since the Oda River has a gentler river bed than that of the Takahashi River, it is affected by the backwater from the Takahashi River.
The Association of Japanese Geographers has released the map of the flood points caused by the heavy rain on the Web (http://ajg-disaster.blogspot.com/). The characteristics of the river channels on the flood points on this map (mainly those of the Oda River) were investigated and compiled into a matrix.
On 9 dike break points of 4 rivers, the aerial photos were interpreted, and the classification maps of flood landforms were created.
Besides, the downstream change graph of the river bed height, the bed slope…etc. of the Oda River were created.

## Results

Many dike break points lie in the administrative sections of the prefectures, and raised beds are seen on 9 of the 10 points in the tributaries to the Oda River. There are sluice gates on 2 dike break points and 5 slope failure points reported in the Council for Social Infrastructure (2018). At the outer bank of the large river curve in Fukuhara, where the overflows and the slope failures were occurred this time, dike breaks were also occurred in the past.
Although alluvial ridges have been regarded as safe against floods, the largest dike breaks occurred on the alluvial ridge.
The downstream change graphs show that floods didn’ t occur in a downstream section of a weir with a relatively steep river bed but occur in a further downstream section where a river bed becomes gentle.

## Discussion

On the point scale, a sluice gates and a raised bed section is one of the predispositions to floods. From comparing dike break points and non-dike break points, it is suggested that steep slope gradient affects dike break, too. And it is necessary to update the flood risk assessment on alluvial ridges.
On the section scale, compared the downstream section of a weir with a steep river bed, the further

©2019. Japan Geoscience Union. All Right Reserved. 

downstream section with a gentle bed is dangerous.
On the regional scale, it is considered that the bed slope difference of the Oda River and the Takahashi River is affected by the denudation surfaces. It is also one of the predispositions that granitoids is widely distributed in Chugoku district.
Regarding artificiality, it turned out that the river maintenance has not kept up. However, there is the more serious issue that the Mabi-cho area, where many floods occurred this time, has become a bedroom town. Therefore, it is necessary to reconsider how to use land.

1. GSI of Japan

I. Introduction
In June 2006, it was necessary to prepare the portal site about hazard maps which anyone can search on the internet, according to the policy established by Ministry of Land, Infrastructure Transport and Tourism. Geospatial Information Authority of Japan, in cooperation with Water and Disaster Management Bureau and so on, began to operate Hazard Map Portal Site since April 2007. This latest site has two main contents. One is Layered Hazard Map which enables users to layer various maps and disaster risks, and another is Published Hazard Map showing links to hazard maps made by each local government.

II. Questionnaire about Hazard Map Portal Site
A questionnaire was conducted in 2015 for 18 local governments and about 1,000 residents to figure out these things: how much they recognize and use it, needs, and to know the problems of this site. Various needs and requests were made clear, for example, the addition of the function displaying all disaster risk information by clicking map, implementation of browsing feature by mobile device, preparation of download page published data on this site, expanding the data about disaster risk information and evacuation facilities, making the data open for public on the Internet and machine-readable (hereinafter referred to “Open Data”) and so on.

III. Three activities
Three activities were carried out based on this questionnaire.
1. Improvement of function
Three functions were mainly added on this site. One is the function displaying multiple risks, which were inundation, landslide, sediment disaster and so on, at arbitrary point on Layered Hazard Map, another is the compatibility with smartphones which enable to access this site away from home, and the other is function of downloading list files of URL linking to Published Hazard Map.
2. Expanding Data
Designated Emergency Evacuation Area (flood from river, storm surges, tsunami, debris flow, steep slope failure / landslide, fire disasters), expected inundation areas of ministry-controlled river due to statistical heaviest rainfall, expected inundation areas of tsunami, and landform classification of Fundamental Land Classification Survey were released.
3. Open Data
Raster tiles of expected inundation areas of ministry-controlled river due to statistical heaviest rainfall, Landslide Prone Areas and dangerous site by sediment and landslide disaster was added to Open Data list. Furthermore, these raster tiles data started to be converted to vector tiles data and will be distributed as Open Data by June 2019.

IV. Future perspective
We carried out improvement of this site system, expansion data of disaster risk information and Open Date of raster tiles covered on Layered Hazard Map. Due to this effort, tasks revealed in 2015 questionnaire survey were solved and this site became more useful. This result led to further publicize

©2019. Japan Geoscience Union. All Right Reserved. 

disaster risk and contributed to raise awareness of disaster prevention.
In order to expand data and make the site more useful, various information including expected inundation area maps classified by duration time and expected inundation areas by reservoir break will be disclosed and more functions, for example 3D page of Layered Hazard Map, will be added.

Keywords: disaster risk, hazard map, web map, open data

# A study on evaluation formulae of the principal fault in PFDHA- In consideration of a relevance to known active faults-

*Tsuyoshi Kanda[1], Makoto Takao[1], Toshimichi Kaneto[1], Takehisa Arakawa[1]

1. Tokyo Electoric Power Company Holdings, Inc

Takao et al. (2013) proposed some evaluation formulae for probabilistic fault displacement hazard analysis (PFDHA) based on data on surface earthquake faults in Japan.

As for the formulae in terms of the principal fault, Takao et al. (2013) did not discriminate between (1) an earthquake that occurred in an area where an active fault exists, and (2) an earthquake that occurred in an area where no cumulative deformation or active fault exists, in the same way as Youngs et al. (2003).

In this study, we re-examined the aforementioned evaluation formulae by discriminating between (1) and (2) for the 107 hypocenters described in Takao et al. (2003).

The results show that the differences in the P1p between (1) and (2) are distinct and that the P1p is closely correlated to the distance between the active fault and the hypocenter, so discrimination between (1) and (2) is useful for these evaluation formulae.

Therefore, it is suggested that the results of this study can be a powerful tool for applying the idea of diffuse seismicity in the probabilistic seismic hazard analysis (PSHA) to the PFDHA.

There are some differences in the evaluation formula for the fault displacement between (1) and (2), whereas it was confirmed that there is no clear correlation between the threshold value (boundary between (1) and (2)) and the predicted displacement using the regression equation.

We strongly recommend that these evaluation formulae should be examined in future by gathering more data on surface earthquake faults because the present data may be insufficient to consider the correlation between threshold value and fault displacement.

Keywords: PFDHA, probability of surface rupture of the principal fault, fault displacement, a relevance to an active fault

# Characteristics of sediment deposition distribution in debris flow disasters in caused by heavy rain in August 2014 Hiroshima, Japan

*Shoichiro Uchiyama[1], Toshihiko Sugai[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. The University of Tokyo

1. Background
Post-war sediment disaster countermeasures have been promoted mainly by the development of structural measures. However, disaster prone areas are expanding annually owing to the development of residential areas. Owing to the difficulty involved in preventing sediment disasters by taking structural measures alone, nonstructural measures are being promoted. However, many of the victims of the sediment damage caused by the Heavy Rain Event of July 2018 were located in sediment disaster-prone areas. From these facts, we can see that the preliminary evacuation is inadequately performed.

2. Purpose and significance
For autonomous evacuation to be conducted when the risk of the disaster is identified, it is necessary to anticipate the extent of damage possible in the inhabited areas. For example, the damage owing to debris flow can be predicted using knowledge of the behavior of debris flow and the relationship between debris flow and buildings or vegetation in the flow path. Therefore, in this study, the volume of sediment deposition by debris flow was measured, and its distribution characteristics were analyzed in six districts of Asaminami-ku, Hiroshima, which was damaged by the debris flow on August 20, 2014.

3. Method
There were 23 digital aerial photographs (Geospatial Information Authority of Japan) taken on May 21, 2008. Further, approximately four days after the disaster, unmanned aerial vehicles were used to capture aerial photographs, which comprised 700 vertical images. 30 points were measured by conducting a GNSS survey; 10 ground reference and 14 accuracy verification points were used. The spatial resolution of DSM and orthoimage created by SfM photogrammetry were 20.0 cm and 3.5 cm before and after the disaster, respectively. As a result of the accuracy verification of the DSM, the three-dimensional RMSEs at the accuracy verification point that employed 14 points were 26.2 cm (2008 DSM value) and 11.5 cm (2014 DSM value). The change in the height of the ground was obtained by subtracting the 2008 DSM elevation from the 2014 DSM value calculated using GIS. Next, the sediment deposition areas were interpreted from the orthoimage after the disaster, and polygon data were created using GIS.
In the surface height change data, a mesh having a positive value corresponds to sediment deposition inside the sediment deposition area polygon. At this time, we considered the error of the DSM at 2 periods as follows: the square root of the sum of the squares (28.6 cm) of RMSE values (26.2 cm before disaster, 11.5 cm after disaster) at each time were obtained as mentioned above, and only the mesh with a height change larger than this value was targeted.

4. Result
Of the results obtained, Yagi 3 districts were figured. There were two blue falling water lines near the center, and the main flow path widened to approximately 25 m. Within the range 70 m above and below the flow path, seven buildings were lost, resulting in 20 casualties (A). In the housing at the most downstream part of this row, a portion of the building moved downward while remaining intact, resulting in two casualties. In addition, the apartment that was in the center of this row of houses was lost in the debris flow; however, because it was a vacant lot in the pre-disaster aerial photograph, the apparent

©2019. Japan Geoscience Union. All Right Reserved. 

change in the DSM appears to be sedimentary (B). In the public housing building located on the falling water line, sediment flowed, resulting in one casualty (C). Among the vegetation growing adjacent to the main flow path, the side close to the flow path was eroded (D). There was an area in which the sediment deposition thickness was in the main flow path thin (E). A sediment layer exceeding 2 m in thickness accumulated in the parking lot at the end of the main flow path. In the orthorectified images, the sediments exhibited a mud-like texture (F).

# Land use change after tsunami and its problems in Kii peninsula

*Kenta Okidate[1], Tatsuto Aoki[2]

1. School of Humanities, Kanazawa University, 2. School of Regional Development Studies, Kanazawa University

Disaster prevention against tsunami is paid attention socially. In Japan, many cities are located in the coast and have a possibilities of damage by tsunami. This paper presents the results of quantitative analyzing land use changes in region have few researches and clarifying its regional characteristics and problem.

Three study areas, Shirahama area, Kushimoto area, Nachiwan surrounding area, were damaged by tsunami in 1944 and 1946. After the disaster, these regions were restored disorderly.

By analyzing Geographic Information System (GIS) data with QGIS, Interview, and field survey, land use changes in study areas were clarified.

Housing/Building increased greatly by converting Wasteland/Farmland and Forest. Especially, from 1947 to 1965, converting flooded vacant lot by tsunami into Housing/Building was prominent. Increasing of Housing/Building, Wasteland/Farmland and port facilities by reclamation were seen. Also, building lot increased in tsunami inundated areas and these areas for itself increased by reclamation in all study areas. Large buildings are increased in the coast with the passing of the years.

As a result of analysis, expanding building lot, building port facilities and so on were clarified as regional characteristics. These are geomorphological limitation, tourism development, increasing demand of building lot and economic structure as its factors. 3 problems, crowded building lot in the coast, increasing building lot and port facilities by reclamation, large buildings in the coast, were also clarified. These problems may disturb refuge from tsunami. A long-term plan for safe land use is necessary to solve problems.

# Reconstruction of the building damages caused by the Typhoon Kathleen and analyses of their land conditions at the southern foot of the Akagi Volcano using U.S. military aerial photographs

*Masafumi Aoyama[1], Yoshiki Saito[2]

1. Faculty of Education, Gunma University, 2. Graduate Student, Gunma University

We reconstructed building damages caused by the Typhoon Kathleen and analyses of their land conditions at the southern foot of the Akagi Volcano using U.S. military aerial photographs and GIS. Flood inundation area were identified based on the building damages and flood deposits by using U.S. military aerial photos. Building damages due to the flood concentrated in the former river channel and valley bottom plain. Several schools (25%) in the study area located in the inundation area of the Typhoon Kathleen.

[J] Poster | H (Human Geosciences )：H-DS Disaster geosciences

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_15

## [H-DS15] Human environment and disaster risk

convener:Tatsuto Aoki(School of Regional Development Studies, Kanazawa University), Hisao Kondo(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology)

This session discusses disaster risks being inherent in the natural and human environment, which sometimes happen to appear at a disaster, from the viewpoint of not only natural sciences but also social and human sciences. Examples of discussion subjects are as follows: uncertainty of forecasting disaster and problems of huge disaster with low frequency that raised from the 2011 Tohoku earthquake, the methodology for improving hazard maps, national recovery plans considering probable changes or sustainability of the society, international cooperation for disaster mitigation, problems of active faults or liquefaction, adjusting disaster mitigation plan to the regional characteristics, technical development for supporting disaster prevention, education for the disaster mitigation.

# Validity Verification in Typhoon Disaster Prevention Model for Typhoon Damage Reduction –GUST Wind Speed, Maximum Wind Speed -

*Woo-Sik JUNG[1], Hana Na[1]

1. Department of Atmospheric Environment Information Engineering, Atmospheric Environment Information Research Center, Inje University, Gimhae 50834, Korea

In recent years, as the intensity of typhoons affecting the Korean peninsula has become stronger due to global warming resulting from climate change, studies on typhoons attacking the Korean peninsula are being increasingly carried out. Many previous studies have constructed typhoon disaster prevention models for estimating the maximum wind speed of the 3-second gust that can occur during a typhoon. In addition, such studies have enabled the establishment of foundational materials for the typhoon disaster prevention system. However, there have been few studies on the validity of the maximum possible wind speed of the 3-second gust, as estimated by the typhoon disaster prevention model. Therefore, in this study, validity analysis was carried out via verification using the observed 3-second gust values. For the verification, the GUST wind speed data from marine meteorological buoys (which serves as the basis of maximum wind speed) monitored by the Korea Meteorological Administration, and maximum instantaneous wind speed data from lighthouse observation, were used. In addition, this study compared and analyzed the 3-second gust values observed at points located within the radius of the maximum wind speed, and at points located outside the radius of the maximum wind speed during the typhoon season. The points within the radius of the maximum wind speed showed a more similar trend to the observed values than the points outside the radius. In addition, the points within the radius better simulated the maximum wind speed. Moreover, the 3-second gust values calculated by the typhoon disaster prevention model were slightly greater than the observed values at almost all points. From the viewpoint that the calculated value is the maximum possible wind speed, it is considered to provide useful information in terms of pre-disaster prevention regarding typhoon damage. As a result of comparing the wind speeds at the 10 m altitude (which were obtained from the typhoon prevention model by categorizing the Korean peninsula into inland, coastal, and island regions), with the observed values, the island region, showed the best results (due to the presence of fewest obstacles on the ground), followed by the coastal, and inland regions. This study suggests that the 3-second gust is a justified parameter to be used in the typhoon disaster prevention model. Therefore, the typhoon disaster prevention model can be efficiently applied to the typhoon disaster prevention system.

# A Study on the Assimilation of Meteorological Data and Sea Surface Temperature Data for Improving the Accuracy of WRF Prediction during Typhoon periods on the Korean Peninsula

*Woo-Sik JUNG[1], Hana Na[1]

1. Department of Atmospheric Environment Information Engineering, Atmospheric Environment Information Research Center, Inje University, Gimhae 50834, Korea

Typhoons affecting the Korean peninsula and the surrounding regions originate in the Western Pacific Ocean. The SST around Korean peninsula are increasing at a more rapid rate than the rate of global SST. Consequently, the intensity of typhoons affecting the Korean peninsula will become stronger. Therefore, studies on the implementation of the typhoon disaster prevention system, to minimize the damage by predicting the maximum possible wind speed at the time of the influence of the typhoon, were carried out. In addition, recent studies have used the WRF model, which is useful for work-site operation and research. It is suitable for work-site operation as well as research to emulate the high-resolution data of the typhoon disaster prevention model. In this study, SST data and FDDA data were assimilated to produce the optimal WRF results. The results obtained were used as input data to the typhoon disaster prevention model, which is part of the typhoon disaster prevention system. This study selected Typhoon Bolaven (that moved north to the Yellow Sea and greatly damaged the metropolitan area in the Korean peninsula), and used WRF 3.5.1 version for data evaluation. The RDAPS numerical model data of the Korea Meteorological Administration were used as the model input data, and the OSTIA data were used as the SST data. For the FDDA data assimilation (OBS nudging), the sensitivity test was performed using the wind speed and temperature data of vertical and synoptic observations in the Korean peninsula region. As a results of time series analysis and statistical analysis, the maximum wind speed difference was about 5 m/s when the input data were applied differently. High-resolution sea surface temperature data assimilation yielded better results than the meteorological data assimilation. When the meteorological data assimilation and high-resolution sea surface temperature data assimilation were applied simultaneously, better results were obtained than under individual data assimilation cases. If the maximum possible wind speed of the 3-second gust that can occur during a typhoon is estimated using the optimal high-resolution results, the damage due to the typhoon will be effectively reduced through accurate prediction.

# Validation and application of a finite element approach on field mechanically stabilized earth walls with secondary reinforcement

*BING-RU WU[1], CHIH-HSUAN LIU[1], CHING HUNG[1]

1. National Cheng Kung University

Mechanically stabilized earth (MSE) walls have been used widely to prevent slopes from natural disasters around the world. The typical vertical spacing of geosynthetic reinforcement used in the practical MSE wall may cause high reinforcement connection strength and lead to wall-facing bulging. Previous studies show that installing short (secondary) reinforcement layers in-between primary reinforcement layers could mitigate these problems by reducing wall facing deflection and primary reinforcement strains, increasing the wall internal stability, alleviating down-drag forces behind the wall facing, and so on. Although the performance of the secondary reinforcement has been widely examined, its controlling factors (i.e., length, spacing, distribution) on the behavior of MSE wall are scarcely studied. In this study, a finite element approach was validated via a benchmark field case and was applied to understand the effect of the controlling factors on the behavior of MSE wall as well as giving a guidance on the design of MSE wall with secondary reinforcement.

Keywords: retaining structure, MSE wall, controlling factors, secondary reinforcement, finite element

# EXPERIMENTAL STUDY ON POLYUREA-COATED RC SLAB SUBJECTED TO CONTACT EXPLOSIONS

*Minghsien Wu[1], Yingkuan Tsai[1], Chien-Hsien Liu[1], Pang-Ting Pai[1], Feng-Cheng Yang[1], Chun-Chia Huang[1]

1. Chung Cheng Institute of Technology National Defense University

Global terrorism is on the rise as the number of attacks soared, puts the world under the threat of car bomb, suicide bomb and so forth, and causes a huge amount of loss of life and property. Current buildings and infrastructures are mostly constructed using reinforced concrete, due to the brittleness of concrete material, when a structure subjected to blast loadings, the phenomena such as cracking and spalling at the proximal face of the target, and the ejection of fragments from the distal face of the loaded surface can be observed. These types of damage or failure could severely harm to the structural stability and the safety of people and equipment inside the building. Thus, the blast resistance of buildings has become an important issue in structural design and evaluation. Considering the high tensile strength and excellent impact resistance of polyurea materials, it is expected that the blast performance of a reinforced concrete element can be enhanced by coating this material onto its surface.

The purpose of this study is to investigate the blast performance of the polyurea coating on reinforced concrete slabs by conducting a series of filed explosion tests. The size of the specimen is 50cm×50cm×15cm. Four pieces of RC slabs were tested: RC slab without coating, RC slabs with coating on the front face, coating on the back face, and coating on the both faces. The thickness of coating is 3 mm. The specimens were fixed on a steel frame and detonated at the center of the test surface with a size of 5cm×5cm×2.5cm of 100g C4 rectangular explosive. The size and depth of the damage area on the front and back of the RC slabs were measured and evaluated by developing 3D models with point clouds from photographs.

The results show that when the unreinforced RC slabs is subjected to contact explosion, cratering will occur on the front side of the specimen and spalling will occur on the back side of the specimen; and when the RC slabs is coated on the front side of the specimen, the polyurea reinforcing layer at the contact explosion site is destroyed, but the damage degree were reduced; and in the case of the back-explosive surface reinforcement, the damage range of the cratering is also reduced, and the polyurea coated with the back-explosive surface has no crack, damage and blow-through. When the coating layer is removed, the back surface of the test piece is observed, and only cracks are generated but no obvious spalling. It is obvious that polyurea produces good adhesion due to its material properties and tightly constrains the fragments. Therefore, it has been shown by experiments that the use of polyurea elastic coatings to reinforce the explosion surface or the back explosion surface of the RC slabs can enhance the explosion-proof capability and reduce or protect from spalling, thereby achieving the purpose of protecting the internal life and property of the building. It is known from this test that the polyurea coating with a thickness of 3 mm can effectively and significantly reduce or avoid the occurrence of spalling when applied to the back surface of RC slabs.

Keywords: polyurea coatings, contact explosions, cratering, spalling

# Simulation and field investigation of scour and sediment transport after Dam removal in the mountainous creek in Central Taiwan

*Chunhung WU[1]

1. Feng Chia University

The research focuses on using the flume experiments to observe the head-erosion phenomena caused by dam removal and simulate the channel evolution in the upstream and downstream of dam after dam removal by using CCHE2D model. The research area is in the Landaw river watershed in Huisun National Forest Area in the Central Taiwan. Two silts of silt dam build in the Landaw river had been lowered down 2.5 m height to release the deposited sediment to transport to downstream in 2013, and the research proceeded long term observation of the head-erosion in the upstream of the silt dam by using UAV and field investigation.
The research proceeded the flume experiments to simulate the sediment transport from the upstream of the dam and simulate the channel evolution in the upstream and downstream of dam by using CCHE2D model after dam removal. The control factors in the flume experiments are the sediment size, the discharge, the channel slope, and the removal area of check dams. The sediment size settings in this research include totally 0.9 mm, half 0.9 mm and half 0.5 mm, and totally 0.5mm, while the discharge settings include 3.4, 83.0, and 102.6 cubic centimeter per second. The channel slope settings include 4.4, 8.7 and 13 degree. The research records the sediment yield volume, the geomorphologic changes and the knickpoints evolution in the longitudinal sections after removing different area of dams in 27 flume experiments. Based on the dominant factors for the bank erosion scouring, 27 flume experiments can be classified into 3 types, including infiltration-dominated bank erosion experiments, surface runoff-dominated bank erosion experiments, and infiltration and surface runoff co-exist bank erosion experiments.
Furthermore, the research also uses CCHE2D model to simulate the sediment transport after the dam removal process of the silt dam in the upstream of Landaw river watershed. The research uses the river discharge in the day with the maximum 24 hours accumulated rainfall from 2015 to 2018, and the original DSMs in 2010, 2016, 2018 as the topographic models to simulate the scouring process in the upstream of the silt dam after dam removal. The research also proceeded the field investigation to verify the simulation result.
The accumulated rainfall setting for the simulation of CCHE2D model is 585 mm in 24 hours, and this is the accumulated rainfall with return period years of 50 year in the Landaw river watershed. Based on the simulation result by using CCHE2D model with the accumulated rainfall of 585 mm in 24 hours, the elevation of main river has been lowered down 5.4 m, and the maximum width of the head-erosion in the upstream od the silt dam is around 5.24 m. The total erosion sediment volume is estimated as 1370 cubic meter. The slope in the longitudinal profile along the main river can be classified into two sections. The slope from the silt dam to 23 m upward in the upstream is estimated as 0.31, while that from the 23 m upward in the upstream to the 200 m upward in the upstream is estimated as 0.151. This means that the knickpoint is in the 23 m upward in the upstream of the silt dam. The result will be the basis for developing the assessment model for assess the feasibility of dam removal in the rivers.

# Examination and systematization of predispositions to floods in the Heavy Rain in July 2018

*Kanako Kimura[1], Toshihiko Sugai[2]

1. The University of Tokyo, 2. Graduate School of Frontier Sciences, the University of Tokyo

## Introduction

Though predispositions to floods have been mentioned in the studies of river engineering, geography and geomorphology, the relationship between flood and topography / geology is dealt with as self-evident in most of them. Hence, this study focuses on the predispositions to floods.
The floods in the Heavy Rain in July 2018, especially those of the Oda River (the Takahashi River System) are the subjects of this study. The purposes of this study are (1) to create a database on the floods, (2) to examine predispositions for each space scale, taking into account the influence of artificiality, (3) to acquire knowledge contributing to high accuracy of flood risk assessment.

## Fields & Methods

In the Chugoku district, 3 denudation surfaces are seen. And, the plains on the Setouchi side have been formed by the rivers flowing down from the Chugoku mountains. These rivers are characterized by weathering granitoids distributed upstream.
The Oda River is a first-class river which joins the Takahashi River in Kurashiki city. Since the Oda River has a gentler river bed than that of the Takahashi River, it is affected by the backwater from the Takahashi River.
The Association of Japanese Geographers has released the map of the flood points caused by the heavy rain on the Web (http://ajg-disaster.blogspot.com/). The characteristics of the river channels on the flood points on this map (mainly those of the Oda River) were investigated and compiled into a matrix.
On 9 dike break points of 4 rivers, the aerial photos were interpreted, and the classification maps of flood landforms were created.
Besides, the downstream change graph of the river bed height, the bed slope…etc. of the Oda River were created.

## Results

Many dike break points lie in the administrative sections of the prefectures, and raised beds are seen on 9 of the 10 points in the tributaries to the Oda River. There are sluice gates on 2 dike break points and 5 slope failure points reported in the Council for Social Infrastructure (2018). At the outer bank of the large river curve in Fukuhara, where the overflows and the slope failures were occurred this time, dike breaks were also occurred in the past.
Although alluvial ridges have been regarded as safe against floods, the largest dike breaks occurred on the alluvial ridge.
The downstream change graphs show that floods didn’ t occur in a downstream section of a weir with a relatively steep river bed but occur in a further downstream section where a river bed becomes gentle.

## Discussion

On the point scale, a sluice gates and a raised bed section is one of the predispositions to floods. From comparing dike break points and non-dike break points, it is suggested that steep slope gradient affects dike break, too. And it is necessary to update the flood risk assessment on alluvial ridges.
On the section scale, compared the downstream section of a weir with a steep river bed, the further

©2019. Japan Geoscience Union. All Right Reserved. 

downstream section with a gentle bed is dangerous.
On the regional scale, it is considered that the bed slope difference of the Oda River and the Takahashi River is affected by the denudation surfaces. It is also one of the predispositions that granitoids is widely distributed in Chugoku district.
Regarding artificiality, it turned out that the river maintenance has not kept up. However, there is the more serious issue that the Mabi-cho area, where many floods occurred this time, has become a bedroom town. Therefore, it is necessary to reconsider how to use land.

# Expand various disaster risk information and sophisticate methods to disseminate on the Hazard Map Portal Site

*Takuya Ueshiba[1], Yumeka Fujii[1], Naoki Yoshimatsu[1], Noriyuki Takakuwa[1], Wataru Yamasaki[1], Jun Suwabe[1]

1. GSI of Japan

I. Introduction
In June 2006, it was necessary to prepare the portal site about hazard maps which anyone can search on the internet, according to the policy established by Ministry of Land, Infrastructure Transport and Tourism. Geospatial Information Authority of Japan, in cooperation with Water and Disaster Management Bureau and so on, began to operate Hazard Map Portal Site since April 2007. This latest site has two main contents. One is Layered Hazard Map which enables users to layer various maps and disaster risks, and another is Published Hazard Map showing links to hazard maps made by each local government.

II. Questionnaire about Hazard Map Portal Site
A questionnaire was conducted in 2015 for 18 local governments and about 1,000 residents to figure out these things: how much they recognize and use it, needs, and to know the problems of this site. Various needs and requests were made clear, for example, the addition of the function displaying all disaster risk information by clicking map, implementation of browsing feature by mobile device, preparation of download page published data on this site, expanding the data about disaster risk information and evacuation facilities, making the data open for public on the Internet and machine-readable (hereinafter referred to “Open Data”) and so on.

III. Three activities
Three activities were carried out based on this questionnaire.
1. Improvement of function
Three functions were mainly added on this site. One is the function displaying multiple risks, which were inundation, landslide, sediment disaster and so on, at arbitrary point on Layered Hazard Map, another is the compatibility with smartphones which enable to access this site away from home, and the other is function of downloading list files of URL linking to Published Hazard Map.
2. Expanding Data
Designated Emergency Evacuation Area (flood from river, storm surges, tsunami, debris flow, steep slope failure / landslide, fire disasters), expected inundation areas of ministry-controlled river due to statistical heaviest rainfall, expected inundation areas of tsunami, and landform classification of Fundamental Land Classification Survey were released.
3. Open Data
Raster tiles of expected inundation areas of ministry-controlled river due to statistical heaviest rainfall, Landslide Prone Areas and dangerous site by sediment and landslide disaster was added to Open Data list. Furthermore, these raster tiles data started to be converted to vector tiles data and will be distributed as Open Data by June 2019.

IV. Future perspective
We carried out improvement of this site system, expansion data of disaster risk information and Open Date of raster tiles covered on Layered Hazard Map. Due to this effort, tasks revealed in 2015 questionnaire survey were solved and this site became more useful. This result led to further publicize

©2019. Japan Geoscience Union. All Right Reserved. 

disaster risk and contributed to raise awareness of disaster prevention.
In order to expand data and make the site more useful, various information including expected inundation area maps classified by duration time and expected inundation areas by reservoir break will be disclosed and more functions, for example 3D page of Layered Hazard Map, will be added.

Keywords: disaster risk, hazard map, web map, open data

# A study on evaluation formulae of the principal fault in PFDHA- In consideration of a relevance to known active faults-

*Tsuyoshi Kanda[1], Makoto Takao[1], Toshimichi Kaneto[1], Takehisa Arakawa[1]

1. Tokyo Electoric Power Company Holdings, Inc

Takao et al. (2013) proposed some evaluation formulae for probabilistic fault displacement hazard analysis (PFDHA) based on data on surface earthquake faults in Japan.

As for the formulae in terms of the principal fault, Takao et al. (2013) did not discriminate between (1) an earthquake that occurred in an area where an active fault exists, and (2) an earthquake that occurred in an area where no cumulative deformation or active fault exists, in the same way as Youngs et al. (2003).

In this study, we re-examined the aforementioned evaluation formulae by discriminating between (1) and (2) for the 107 hypocenters described in Takao et al. (2003).

The results show that the differences in the P1p between (1) and (2) are distinct and that the P1p is closely correlated to the distance between the active fault and the hypocenter, so discrimination between (1) and (2) is useful for these evaluation formulae.

Therefore, it is suggested that the results of this study can be a powerful tool for applying the idea of diffuse seismicity in the probabilistic seismic hazard analysis (PSHA) to the PFDHA.

There are some differences in the evaluation formula for the fault displacement between (1) and (2), whereas it was confirmed that there is no clear correlation between the threshold value (boundary between (1) and (2)) and the predicted displacement using the regression equation.

We strongly recommend that these evaluation formulae should be examined in future by gathering more data on surface earthquake faults because the present data may be insufficient to consider the correlation between threshold value and fault displacement.

Keywords: PFDHA, probability of surface rupture of the principal fault, fault displacement, a relevance to an active fault

# Characteristics of sediment deposition distribution in debris flow disasters in caused by heavy rain in August 2014 Hiroshima, Japan

*Shoichiro Uchiyama[1], Toshihiko Sugai[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. The University of Tokyo

1. Background
Post-war sediment disaster countermeasures have been promoted mainly by the development of structural measures. However, disaster prone areas are expanding annually owing to the development of residential areas. Owing to the difficulty involved in preventing sediment disasters by taking structural measures alone, nonstructural measures are being promoted. However, many of the victims of the sediment damage caused by the Heavy Rain Event of July 2018 were located in sediment disaster-prone areas. From these facts, we can see that the preliminary evacuation is inadequately performed.

2. Purpose and significance
For autonomous evacuation to be conducted when the risk of the disaster is identified, it is necessary to anticipate the extent of damage possible in the inhabited areas. For example, the damage owing to debris flow can be predicted using knowledge of the behavior of debris flow and the relationship between debris flow and buildings or vegetation in the flow path. Therefore, in this study, the volume of sediment deposition by debris flow was measured, and its distribution characteristics were analyzed in six districts of Asaminami-ku, Hiroshima, which was damaged by the debris flow on August 20, 2014.

3. Method
There were 23 digital aerial photographs (Geospatial Information Authority of Japan) taken on May 21, 2008. Further, approximately four days after the disaster, unmanned aerial vehicles were used to capture aerial photographs, which comprised 700 vertical images. 30 points were measured by conducting a GNSS survey; 10 ground reference and 14 accuracy verification points were used. The spatial resolution of DSM and orthoimage created by SfM photogrammetry were 20.0 cm and 3.5 cm before and after the disaster, respectively. As a result of the accuracy verification of the DSM, the three-dimensional RMSEs at the accuracy verification point that employed 14 points were 26.2 cm (2008 DSM value) and 11.5 cm (2014 DSM value). The change in the height of the ground was obtained by subtracting the 2008 DSM elevation from the 2014 DSM value calculated using GIS. Next, the sediment deposition areas were interpreted from the orthoimage after the disaster, and polygon data were created using GIS.
In the surface height change data, a mesh having a positive value corresponds to sediment deposition inside the sediment deposition area polygon. At this time, we considered the error of the DSM at 2 periods as follows: the square root of the sum of the squares (28.6 cm) of RMSE values (26.2 cm before disaster, 11.5 cm after disaster) at each time were obtained as mentioned above, and only the mesh with a height change larger than this value was targeted.

4. Result
Of the results obtained, Yagi 3 districts were figured. There were two blue falling water lines near the center, and the main flow path widened to approximately 25 m. Within the range 70 m above and below the flow path, seven buildings were lost, resulting in 20 casualties (A). In the housing at the most downstream part of this row, a portion of the building moved downward while remaining intact, resulting in two casualties. In addition, the apartment that was in the center of this row of houses was lost in the debris flow; however, because it was a vacant lot in the pre-disaster aerial photograph, the apparent

©2019. Japan Geoscience Union. All Right Reserved. 

change in the DSM appears to be sedimentary (B). In the public housing building located on the falling water line, sediment flowed, resulting in one casualty (C). Among the vegetation growing adjacent to the main flow path, the side close to the flow path was eroded (D). There was an area in which the sediment deposition thickness was in the main flow path thin (E). A sediment layer exceeding 2 m in thickness accumulated in the parking lot at the end of the main flow path. In the orthorectified images, the sediments exhibited a mud-like texture (F).

# Land use change after tsunami and its problems in Kii peninsula

*Kenta Okidate[1], Tatsuto Aoki[2]

1. School of Humanities, Kanazawa University, 2. School of Regional Development Studies, Kanazawa University

Disaster prevention against tsunami is paid attention socially. In Japan, many cities are located in the coast and have a possibilities of damage by tsunami. This paper presents the results of quantitative analyzing land use changes in region have few researches and clarifying its regional characteristics and problem.

Three study areas, Shirahama area, Kushimoto area, Nachiwan surrounding area, were damaged by tsunami in 1944 and 1946. After the disaster, these regions were restored disorderly.

By analyzing Geographic Information System (GIS) data with QGIS, Interview, and field survey, land use changes in study areas were clarified.

Housing/Building increased greatly by converting Wasteland/Farmland and Forest. Especially, from 1947 to 1965, converting flooded vacant lot by tsunami into Housing/Building was prominent. Increasing of Housing/Building, Wasteland/Farmland and port facilities by reclamation were seen. Also, building lot increased in tsunami inundated areas and these areas for itself increased by reclamation in all study areas. Large buildings are increased in the coast with the passing of the years.

As a result of analysis, expanding building lot, building port facilities and so on were clarified as regional characteristics. These are geomorphological limitation, tourism development, increasing demand of building lot and economic structure as its factors. 3 problems, crowded building lot in the coast, increasing building lot and port facilities by reclamation, large buildings in the coast, were also clarified. These problems may disturb refuge from tsunami. A long-term plan for safe land use is necessary to solve problems.

# Reconstruction of the building damages caused by the Typhoon Kathleen and analyses of their land conditions at the southern foot of the Akagi Volcano using U.S. military aerial photographs

*Masafumi Aoyama[1], Yoshiki Saito[2]

1. Faculty of Education, Gunma University, 2. Graduate Student, Gunma University

We reconstructed building damages caused by the Typhoon Kathleen and analyses of their land conditions at the southern foot of the Akagi Volcano using U.S. military aerial photographs and GIS. Flood inundation area were identified based on the building damages and flood deposits by using U.S. military aerial photos. Building damages due to the flood concentrated in the former river channel and valley bottom plain. Several schools (25%) in the study area located in the inundation area of the Typhoon Kathleen.

# Monitoring and Simulating Land Use/Cover Changes and its Impact on Land Surface Temperature in Sapporo City, Japan

*RUCI WANG[1], YUJI MURAYAMA[1]

1. University of Tsukuba

In recent years, urban heat island phenomenon (UHI) which prevails in many cities worldwide has caused broad public concern. UHI phenomenon impairs healthy urban development and causes excessive energy consumption, climatic and environmental deterioration. Land use/cover changes are one of the most crucial variables influencing on UHI. Therefore, monitoring and simulating land use/cover changes and analyzing its effects on LST are essential for healthy urban development. This study aims to capture the impact of land use/cover on LST and simulate the LST under various land use/cover scenarios in Sapporo city, Japan. At first, we monitored the land use/cover changes from 1985 to 2015 and detect the change of LST concerning land use/cover distribution. Then, we predicted the future conditions of LST based on various land use/cover scenarios. The results show that the LST differs according to land use/cover types, and the proportion of land use/cover types is the most significant factor affecting LST. The findings also indicate that the built-up area and paddy field have the highest average LST, while the green space and water area help cool the city. In the future, the green area such as urban green parks and grassland should be planned in the city to mitigate the UHI phenomenon. It reveals the spatial characterization of LST which provides significant insights for government and city planners.

# Spatiotemporal Variations of Land Cover/Use and Sustainable Urban Heat Island (UHI) Mitigation Strategies: A Case Study of Chinese Bay Megacities

*Fei LIU[1], Yuji MURAYAMA[1]

1. University of Tsukuba

Rapid urbanization significantly affects the urban thermal environment in the context of global climate change. The assessment of surface urban heat island (SUHI) and development of mitigation strategies in megacities have become frontier issues on human health and urban sustainability. In this study, taking of the three Chinese bay megacities, we attempt to 1) disclose the relationship between land surface temperature (LST) and land cover using remote sensing quantified analysis, 2) to clarify the mechanism and characteristics of SUHI formation based on bi-temporal patterns and variations of land cover, and 3) to sustainably regulate and optimize the urban environment and further create urban planning and policies for relieving urban thermal effect. The study target is Guangzhou metropolitan area (GMA), Hangzhou metropolitan area (HMA) and Shanghai Metropolitan area (SMA) in China. The result of this study indicated remarkably different characteristics, arrangement, and variations among different bay thermal environments. Overall, spatial layouts and changes in the thermal environment of these three megacities were substantially identical with their land cover pattern and tendency. Although land covers significantly influenced the LST as a whole, the different areas had different magnitudes of SUHI coming from different land cover compositions and differentials. The results would provide a valuable reference to disentangle spatiotemporal variation of the bay urban thermal environments, and the urbanization-induced land covers temperature dynamics. This study would contribute to the development of future SUHI mitigation solutions.

# A LST Study of the Seoul Metropolitan City, South Korea, Based on Landsat Data (1996 –2017)

*Prabath Priyankara[1,3], Manjula Ranagalage[1,4], DMSLB Dissanayake[1,4], Takehiro Morimoto[1,2], Yuji Murayama[1,2]

1. Graduate School of Life and Environmental Sciences, University of Tsukuba, Japan, 2. Faculty of Life and Environmental Sciences, University of Tsukuba, Japan, 3. Faculty of Agriculture, University of Ruhuna, Sri Lanka, 4. Faculty of Social Sciences and Humanities, Rajarata University of Sri Lanka, Sri Lanka

Rapid urban growth often replaced urban vegetation with impervious surfaces which leads to increase land surface temperature (LST) periodically and tends to form urban heat islands (UHI). This is a serious issue of urbanized cities and the increase of LST badly affects the well-being of the life and environments of the cities. The Seoul Metropolitan City (SMC), South Korea, is one of the developed and rapidly urbanizing metropolitan city in Asia. The aim of this study was to examine the spatiotemporal variations of LST in the SMC and surroundings in the context of the UHI using Landsat data. The study examined the relationship of LST with the normalized difference vegetation index (NDVI) and the normalized difference built-up index (NDBI) at three time periods 1996, 2006, and 2017. Also, the study was investigated the environmentally critical areas based on LST and NDVI by modeling environmental criticality index (ECI). According to the results of the study, there is a negative correlation between LST with NDVI and positive correlation of LST with NDBI across all three time periods. In SMC, most of the environmentally critical areas are located in the central business district (CBD), near the harbor, and along the main transportation network. According to the results of the study, it is recommended that the identified environmentally critical areas to be considered in the urban planning of the city. Green spaces of the city will help to improve the life and environmental well-being of the SMC.

# Improvement of GIS exercise classes using the GIS open educational resources based on questionnaire surveys

*Hiroyuki Yamauchi[1], Takashi Oguchi[1], Yuichi S. Hayakawa[2,1], Kotaro Iizuka[1]

1. Center for Spatial Information Science, The University of Tokyo, 2. Environmental Geography, Faculty of Environmental Earth Science, Hokkaido University

Free and open source GIS software has been utilized for GIS education all over the world. However, as far as we recognize, GIS education in many Japanese universities underutilize such software packages. Therefore, we developed GIS exercise materials explaining spatial data analyses using free and open-source GIS. We have been providing these materials for higher education and designated them as the GIS Open Educational Resources. We used the materials in a university exercise class, which was held as an intensive course for three days at The University of Tokyo. During the exercise, we have conducted questionnaire surveys to clarify the three criteria: difficulty, understanding and satisfactory levels of the students. The results showed that the students felt difficulty in some situations such as the utilization of GIS for the first time and complex operations using different types of data. The contents of the exercise syllabus and materials were improved based on the feedback. We conducted another GIS exercise class at the university to verify the utility of improvements. In this presentation, we show the improvements in the exercise syllabus and the comparison of educational effects on students before and after the improvements.

# The Development of COP for Tzu Chi Disaster Prevention System by Using QGIS-Taking 2018 Hualien Earthquake as an Example

*kuan-wen tseng[1], Ming-Ta Tsai[1], Yun-Ching Wang[1], Ming-Chih Wang[1], Chien-Hsien Liu[1]

1. 03-3809093

The Hualien earthquake occurred at 23:50 and 41.6 seconds on February 6, 2018. The epicenter was located in the coastal area of Hualien County. The earthquake scale was 6.2 and the Seismic source depth was 6.3 kilometers. The earthquake disaster along the Milun fault was mainly concentrated in Hualien City, and collapsed the first and second floors of the “Tongshuai” building. The “Yunmen Cuidi” Building showed a 45-degree tilt. The lower floors of the residential community building "Baijin Shuangxing" and “Wuzhu Wusu” at Guosheng Sixth Street were destroyed. This study mainly uses the powerful geospatial analysis capabilities of Geographic Information System (GIS) to provide Tzu Chi's plans for disaster mitigation. The projects include: (1) humanitarian cares; (2) visiting and reporting of damage situations around main disaster areas and (3) “Reassuring Homes Visits” in order to provide assistance to Tzu Chi people for operations of disaster mitigation.

# Comparative study on shape and distribution of landslides caused by the 2012 Northern Kyushu heavy rainfall and the 2016 Kumamoto earthquake in the Aso region, Kumamoto, Japan

*Yasutaka Haneda[1], Takashi Oguchi[2], Kotaro Iizuka[2], Hitoshi SAITO[3,2], Yuichi S. Hayakawa[4,2], Shoichiro Uchiyama[5]

1. Graduate School of Frontier Science, The University of Tokyo, 2. Center for Spatial Information Science, The University of Tokyo, 3. College of Economics, Kanto Gakuin University, 4. Faculty of Environmental Earth Science, Hokkaido University, 5. National Research Institute for Earth Science and Disaster Resilience

The 2016 Kumamoto earthquake triggered many landslides in the Aso region, southwestern Japan. Previous studies have revealed the processes of some large representative landslides in the western Aso region, but they have not comprehensively dealt with lots of small landslides. Other studies have discussed landslide distribution and relationships with that of the heavy rainfall events in July 2012 in the northern part of the Central Cones of the Aso volcano. However, they have not been investigated the western part of the Aso region which has various topographical and geological characteristics. Therefore, this study compares the formation and distribution of landslides caused by the heavy rainfall and earthquake events in both the central and western part of the Aso region.

The study areas are the western part of the Aso region and the Sensuikyo region at the northern part of the Central Cones (Fig. 1). The western part was divided into three sites: site P (caldera walls and the outer rim), Q (western part of Central Cones), and R (river terrace and talus) based on geomorphological and geological characteristics. The Sensuikyo region is referred to as site S. This study utilized multi-temporal datasets derived from airborne lidar and photogrammetry using UAV photographs: (i) before the heavy rainfall, (ii) between the heavy rainfall and the earthquake, and (iii) after the earthquake. By using digital elevation data and a sediment transportation map, elevation lowering spots caused by the landslides were identified. Then terrain information and the indexes of shape and spatial distribution were analyzed at the elevation lowering spots.

From the analysis, it was found that the heavy rainfall induced 374 landslides and the earthquake triggered 440 landslides. Landslides affected by the two different events were recognized in sites P and S. In site S, the indexes of spatial distribution showed that the earthquake caused the displacement of regolith remained on the upper convex part of the slope. In site P, the shape indexes indicated that the former event led to removal of topsoil, whereas the latter event induced the failure of lava and pyroclastic rocks. In site Q, failed slopes are not as steep as locations where landslides occurred due to past heavy rainfall events, and remained thick unconsolidated topsoil is composed of volcanic ash. It slipped deeply in 2016 due to strong seismic shaking strengthened by topographic site effects on the convex part of the slope. In site R, landslide shapes and comparison with those in site P suggest that collapsed soil directly fell into rivers without erosion of topsoil.

This study has revealed that the distribution of landslides due to the earthquake is related to that by the heavy rainfall in the Sensuikyo region. On the other hand, in the western part of the Aso region, differences in shape and distribution are found between landslides caused by the two events. Moreover, there are differences in the formation of earthquake-induced landslides among the different study sites.

# Using GIS and remote sensing to assess relationships between landslides and land cover changes in the Sanbagawa and Mikabu Belts, Shikoku, Japan

*Roxanne Lai[1], Takashi Oguchi[1]

1. University of Tokyo

The Sanbagawa and Mikabu Belts are metamorphic belts that run across Southwest Japan, and are home to numerous large crystalline schist landslides, including the widely-studied slow but continuously moving Zentoku landslide. Villages and communities have been built on these landslide areas due to historical and cultural factors, as well as the fertility of the soil. With changing human needs and social trends, however, changing land uses is becoming an increasingly important issue. In Japan, movement of the population from rural to urban areas have resulted in much land and agricultural land abandonment. As vegetation cover changes after land abandonment, this temporal and spatial effect may have important effects on geomorphic processes such as landslide susceptibility and landslide kinematics.

Here we track long-term land cover changes over vegetated landslide areas of the Sanbagawa and Mikabu Belts of Shikoku Island, Japan, and conduct spatio-temporal analyses to assess relationships between landslides and land cover changes. Given changing land uses, including land abandonment in these landslide areas over time, we use long-term high-resolution land cover vegetation datasets to examine first the long-term land use changes, and then use statistical methods to explore their relationships with landslide susceptibility and kinematics. Mapping of spatial data and their analysis using GIS constitute a core part of the research. The results suggest interconnections between land use changes and land movement.

# Analysis of Morphometric Parameters for Mountains Ranges and Landslides due to the July 2018 Heavy Rain in Western Japan Using GIS Data

*Toshikazu Fukuba[1], Takashi Oguchi[2]

1. Department of Earth and Planetary Environmental Science, The University of Tokyo, 2. Center for Spatial Information Science, The University of Tokyo

Morphometric parameters for mountains ranges have been analyzed in many studies. These studies in recent years used Digital Elevation Models (DEMs) to calculate values of morphometric parameters within mountains and provided consideration on landform evolution. In addition, morphometric parameters calculated by DEMs have been used for producing landslide hazard maps. This study investigates geomorphometric parameters within the Chugoku and Shikoku Mountains, Japan, and the relationships among the parameters. In addition, landslides caused by the July 2018 heavy rain in western Japan is also investigated and the relationships between the landforms of the mountains and the landslides are discussed. Altitude, slope angle, slope aspect and slope curvature are chosen for morphometric parameters to be investigated.

Morphometric parameters for the Chugoku and in Shikoku Mountains computed using DEMs and GIS have some characteristics common to the Japanese Alps. For example, for wide altitudinal zones, slope angle tends to be constant around 30 to 40 degrees even if altitude changes. However, the values of the constant slope angle are not the same, which may be due to geological differences or the difference in the formation age of mountains. Although the frequency distribution of slope aspect is similar to the Chugoku and Shikoku Mountains, anisotropy of slope aspect is different between the two mountains. This may be caused by differences in the formation age, formation mechanism, or geology of the mountains.

Analysis of landslides caused by the July 2018 heavy rain in Hiroshima using landslide data and DEMs revealed that landslides mostly occurred around 300 m in altitude, at 15 to 30 degrees in slope angle, and on concave slopes. Although the characteristics slope angles higher than 30 degrees point to frequent slope failures at high and steep mountain slopes in the Chugoku and Shikoku Mountains, landslides corresponding to one rainfall event do not necessarily follow this, because they depend on the distribution of rainfall during the event. Therefore, possibility of landslides in low and gentle mountains close to populated areas needs to be considered seriously for mitigating landslide disasters.

# Analyzing short-term topographic change in coastal sand dunes using UAS-SfM photogrammetry: A case study in Northern Kujukuri, Japan

*Seulgi Lee[1], Yasutaka Nakata[2], Kotaro Iizuka[3], Takashi Oguchi[3]

1. Graduate School of Frontier Sciences, The University of Tokyo, 2. Forest Research Department, Forestry Research Institute, Hokkaido Research Organization, 3. Center for Spatial Information Science, The University of Tokyo

Collection of spatial data is critical for the identification of coastlines and coastal zones and related studies in coastal geomorphology. It is particularly important to obtain high-resolution elevation data in order to observe topographical changes of coastal sand dunes with frequent dynamic movements during a short period of time. Unmanned Aerial System (UAS) photogrammetry combined with Structure from Motion (SfM) offers an effective solution to the acquisition of such data. Kujukuri, facing the Pacific Ocean in Chiba Prefecture, Japan, is a region with a long coastal zone of about 60 km. Although the development of this area since the 1960s has destroyed many natural landscapes, they are relatively preserved in Northern Kujukuri. This study focuses on short-term topographic changes in coastal sand dunes there and discusses the effects of vegetation and wind.
UAV-SfM surveys were conducted seven times from September 2016 to December 2018, and the obtained topographic data were analyzed using GIS software (ArcGIS Pro) to evaluate changes in terrain conditions by season and year. We also analyzed the wind direction data provided by the Japan Meteorological Agency. Vegetation data were obtained from the field surveys and the green-red vegetation index extracted from the UAS images. The following three characteristics were identified: 1) Short-term topographic changes tend to be influenced by specific events such as storm events, and therefore terrain conditions in the same season may be different from year to year. 2) General wind conditions represented by the meteorological data corresponding to the overall change of sand dune topography, especially at seasonal or longer scales. 3) Formation of small sand dunes is affected by vegetation distribution. This study has suggested factors affecting short-term topographic changes of coastal sand dunes based on frequent data acquisition in the field and geospatial technologies.

# Responses of suspended sediment yield to precipitation, topography and dam control in the Yellow River Basin, China

*Ruiqi Zhang[1], Takashi Oguchi[2]

1. Department of Natural Environmental Studies, Graduate School of Frontier Sciences, The University of Tokyo, 2. Center for Spatial Information Science, The University of Tokyo

Soil erosion has long been a serious problem in the Yellow River Basin in China. The high sediment load carried by the Yellow River results in deposition along its path, raising the riverbed and increasing the flood risk in the lower reaches. To mitigate this situation, large-scale soil conservation measures have been put into practice such as the construction of dams to effectively trap fluvial sediments. Previous studies on this topic focused on the interannual fluctuation of sediment yield caused by dams and reservoirs. However, few studies focused on their effects on the seasonal variation of sediment yield. In 2002, the Yellow River Conservancy Committee began to implement the water-sediment regulation (WSR) scheme to regulate the river water, which further strengthen the impact of dam control on the seasonality of sediment yield. Therefore, this research aims to integrate natural contributing factors such as topography and precipitation with the WSR-based dam control to analyze the seasonal and spatial variations of sediment yield in the Yellow River, for the years 2008 to 2012. Data of daily suspended sediment concentration, water discharge, and precipitation were downloaded from the Chinese Data Sharing Infrastructure of Earth System Science, and the ASTER GLOBAL DEMs with a resolution of 1 arc-second were downloaded from the U.S. Geological Survey web site. ArcGIS and R software packages are used to analyze the obtained data. Inspection of data quality revealed that consecutive sediment yield and precipitation data for 97 watersheds are usable.

Data analysis indicated the following four basic hydrological characteristics of the watersheds. 1) Water discharge within each watershed is not stable both interannually and seasonally, because it has been affected by the implementation of dam regulation as well as low discharge conditions mostly in spring and winter especially in some small watersheds. 2) The variation of sediment yield in some natural watersheds reflects change in precipitation, leading to sediment yield peaks in summer. 3) In other watersheds, the variation of sediment yield tends to be independent of precipitation. Instead, some artificial conservation measures such as dam control effectively intercept sediments from the upstream area. 4) The correlation between suspended sediment yield and water discharge varies among watersheds, and the correlation coefficient can be used as a parameter representing hydrological characteristics. The DEMs have been also analyzed to relate hydrology and climate with geomorphology. The obtained results may help the policy makers better understand the erosion situations in the Yellow River Basin and regulate the soil conservation measures.

[E] Poster | H (Human Geosciences )：H-TT Technology & Techniques

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_16

## [H-TT19] Geographic Information Systems and Cartography

convener:Takashi Oguchi(Center for Spatial Information Science, The University of Tokyo), Yuji Murayama(Graduate School of Life and Environmental Sciences), Yoshiki Wakabayashi(Graduate School of Urban Environmental Sciences, Tokyo Metropolitan University)

This session discusses various methods which acquire, store, analyze and visualize geospatial data, and presents the outcomes of empirical studies using GIS or mapping methods. The session also deals with applications of digital data, and GIS, and mapping to various fields of earth and planetary science and human society. All presentations and discussion of this session are made in English.

# Monitoring and Simulating Land Use/Cover Changes and its Impact on Land Surface Temperature in Sapporo City, Japan

*RUCI WANG[1], YUJI MURAYAMA[1]

1. University of Tsukuba

In recent years, urban heat island phenomenon (UHI) which prevails in many cities worldwide has caused broad public concern. UHI phenomenon impairs healthy urban development and causes excessive energy consumption, climatic and environmental deterioration. Land use/cover changes are one of the most crucial variables influencing on UHI. Therefore, monitoring and simulating land use/cover changes and analyzing its effects on LST are essential for healthy urban development. This study aims to capture the impact of land use/cover on LST and simulate the LST under various land use/cover scenarios in Sapporo city, Japan. At first, we monitored the land use/cover changes from 1985 to 2015 and detect the change of LST concerning land use/cover distribution. Then, we predicted the future conditions of LST based on various land use/cover scenarios. The results show that the LST differs according to land use/cover types, and the proportion of land use/cover types is the most significant factor affecting LST. The findings also indicate that the built-up area and paddy field have the highest average LST, while the green space and water area help cool the city. In the future, the green area such as urban green parks and grassland should be planned in the city to mitigate the UHI phenomenon. It reveals the spatial characterization of LST which provides significant insights for government and city planners.

# Spatiotemporal Variations of Land Cover/Use and Sustainable Urban Heat Island (UHI) Mitigation Strategies: A Case Study of Chinese Bay Megacities

*Fei LIU[1], Yuji MURAYAMA[1]

1. University of Tsukuba

Rapid urbanization significantly affects the urban thermal environment in the context of global climate change. The assessment of surface urban heat island (SUHI) and development of mitigation strategies in megacities have become frontier issues on human health and urban sustainability. In this study, taking of the three Chinese bay megacities, we attempt to 1) disclose the relationship between land surface temperature (LST) and land cover using remote sensing quantified analysis, 2) to clarify the mechanism and characteristics of SUHI formation based on bi-temporal patterns and variations of land cover, and 3) to sustainably regulate and optimize the urban environment and further create urban planning and policies for relieving urban thermal effect. The study target is Guangzhou metropolitan area (GMA), Hangzhou metropolitan area (HMA) and Shanghai Metropolitan area (SMA) in China. The result of this study indicated remarkably different characteristics, arrangement, and variations among different bay thermal environments. Overall, spatial layouts and changes in the thermal environment of these three megacities were substantially identical with their land cover pattern and tendency. Although land covers significantly influenced the LST as a whole, the different areas had different magnitudes of SUHI coming from different land cover compositions and differentials. The results would provide a valuable reference to disentangle spatiotemporal variation of the bay urban thermal environments, and the urbanization-induced land covers temperature dynamics. This study would contribute to the development of future SUHI mitigation solutions.

# Comparative study on shape and distribution of landslides caused by the 2012 Northern Kyushu heavy rainfall and the 2016 Kumamoto earthquake in the Aso region, Kumamoto, Japan

*Yasutaka Haneda[1], Takashi Oguchi[2], Kotaro Iizuka[2], Hitoshi SAITO[3,2], Yuichi S. Hayakawa[4,2], Shoichiro Uchiyama[5]

1. Graduate School of Frontier Science, The University of Tokyo, 2. Center for Spatial Information Science, The University of Tokyo, 3. College of Economics, Kanto Gakuin University, 4. Faculty of Environmental Earth Science, Hokkaido University, 5. National Research Institute for Earth Science and Disaster Resilience

The 2016 Kumamoto earthquake triggered many landslides in the Aso region, southwestern Japan. Previous studies have revealed the processes of some large representative landslides in the western Aso region, but they have not comprehensively dealt with lots of small landslides. Other studies have discussed landslide distribution and relationships with that of the heavy rainfall events in July 2012 in the northern part of the Central Cones of the Aso volcano. However, they have not been investigated the western part of the Aso region which has various topographical and geological characteristics. Therefore, this study compares the formation and distribution of landslides caused by the heavy rainfall and earthquake events in both the central and western part of the Aso region.

The study areas are the western part of the Aso region and the Sensuikyo region at the northern part of the Central Cones (Fig. 1). The western part was divided into three sites: site P (caldera walls and the outer rim), Q (western part of Central Cones), and R (river terrace and talus) based on geomorphological and geological characteristics. The Sensuikyo region is referred to as site S. This study utilized multi-temporal datasets derived from airborne lidar and photogrammetry using UAV photographs: (i) before the heavy rainfall, (ii) between the heavy rainfall and the earthquake, and (iii) after the earthquake. By using digital elevation data and a sediment transportation map, elevation lowering spots caused by the landslides were identified. Then terrain information and the indexes of shape and spatial distribution were analyzed at the elevation lowering spots.

From the analysis, it was found that the heavy rainfall induced 374 landslides and the earthquake triggered 440 landslides. Landslides affected by the two different events were recognized in sites P and S. In site S, the indexes of spatial distribution showed that the earthquake caused the displacement of regolith remained on the upper convex part of the slope. In site P, the shape indexes indicated that the former event led to removal of topsoil, whereas the latter event induced the failure of lava and pyroclastic rocks. In site Q, failed slopes are not as steep as locations where landslides occurred due to past heavy rainfall events, and remained thick unconsolidated topsoil is composed of volcanic ash. It slipped deeply in 2016 due to strong seismic shaking strengthened by topographic site effects on the convex part of the slope. In site R, landslide shapes and comparison with those in site P suggest that collapsed soil directly fell into rivers without erosion of topsoil.

This study has revealed that the distribution of landslides due to the earthquake is related to that by the heavy rainfall in the Sensuikyo region. On the other hand, in the western part of the Aso region, differences in shape and distribution are found between landslides caused by the two events. Moreover, there are differences in the formation of earthquake-induced landslides among the different study sites.

# Using GIS and remote sensing to assess relationships between landslides and land cover changes in the Sanbagawa and Mikabu Belts, Shikoku, Japan

*Roxanne Lai[1], Takashi Oguchi[1]

1. University of Tokyo

The Sanbagawa and Mikabu Belts are metamorphic belts that run across Southwest Japan, and are home to numerous large crystalline schist landslides, including the widely-studied slow but continuously moving Zentoku landslide. Villages and communities have been built on these landslide areas due to historical and cultural factors, as well as the fertility of the soil. With changing human needs and social trends, however, changing land uses is becoming an increasingly important issue. In Japan, movement of the population from rural to urban areas have resulted in much land and agricultural land abandonment. As vegetation cover changes after land abandonment, this temporal and spatial effect may have important effects on geomorphic processes such as landslide susceptibility and landslide kinematics.

Here we track long-term land cover changes over vegetated landslide areas of the Sanbagawa and Mikabu Belts of Shikoku Island, Japan, and conduct spatio-temporal analyses to assess relationships between landslides and land cover changes. Given changing land uses, including land abandonment in these landslide areas over time, we use long-term high-resolution land cover vegetation datasets to examine first the long-term land use changes, and then use statistical methods to explore their relationships with landslide susceptibility and kinematics. Mapping of spatial data and their analysis using GIS constitute a core part of the research. The results suggest interconnections between land use changes and land movement.

# Analysis of Morphometric Parameters for Mountains Ranges and Landslides due to the July 2018 Heavy Rain in Western Japan Using GIS Data

*Toshikazu Fukuba[1], Takashi Oguchi[2]

1. Department of Earth and Planetary Environmental Science, The University of Tokyo, 2. Center for Spatial Information Science, The University of Tokyo

Morphometric parameters for mountains ranges have been analyzed in many studies. These studies in recent years used Digital Elevation Models (DEMs) to calculate values of morphometric parameters within mountains and provided consideration on landform evolution. In addition, morphometric parameters calculated by DEMs have been used for producing landslide hazard maps. This study investigates geomorphometric parameters within the Chugoku and Shikoku Mountains, Japan, and the relationships among the parameters. In addition, landslides caused by the July 2018 heavy rain in western Japan is also investigated and the relationships between the landforms of the mountains and the landslides are discussed. Altitude, slope angle, slope aspect and slope curvature are chosen for morphometric parameters to be investigated.

Morphometric parameters for the Chugoku and in Shikoku Mountains computed using DEMs and GIS have some characteristics common to the Japanese Alps. For example, for wide altitudinal zones, slope angle tends to be constant around 30 to 40 degrees even if altitude changes. However, the values of the constant slope angle are not the same, which may be due to geological differences or the difference in the formation age of mountains. Although the frequency distribution of slope aspect is similar to the Chugoku and Shikoku Mountains, anisotropy of slope aspect is different between the two mountains. This may be caused by differences in the formation age, formation mechanism, or geology of the mountains.

Analysis of landslides caused by the July 2018 heavy rain in Hiroshima using landslide data and DEMs revealed that landslides mostly occurred around 300 m in altitude, at 15 to 30 degrees in slope angle, and on concave slopes. Although the characteristics slope angles higher than 30 degrees point to frequent slope failures at high and steep mountain slopes in the Chugoku and Shikoku Mountains, landslides corresponding to one rainfall event do not necessarily follow this, because they depend on the distribution of rainfall during the event. Therefore, possibility of landslides in low and gentle mountains close to populated areas needs to be considered seriously for mitigating landslide disasters.

# Analyzing short-term topographic change in coastal sand dunes using UAS-SfM photogrammetry: A case study in Northern Kujukuri, Japan

*Seulgi Lee[1], Yasutaka Nakata[2], Kotaro Iizuka[3], Takashi Oguchi[3]

1. Graduate School of Frontier Sciences, The University of Tokyo, 2. Forest Research Department, Forestry Research Institute, Hokkaido Research Organization, 3. Center for Spatial Information Science, The University of Tokyo

Collection of spatial data is critical for the identification of coastlines and coastal zones and related studies in coastal geomorphology. It is particularly important to obtain high-resolution elevation data in order to observe topographical changes of coastal sand dunes with frequent dynamic movements during a short period of time. Unmanned Aerial System (UAS) photogrammetry combined with Structure from Motion (SfM) offers an effective solution to the acquisition of such data. Kujukuri, facing the Pacific Ocean in Chiba Prefecture, Japan, is a region with a long coastal zone of about 60 km. Although the development of this area since the 1960s has destroyed many natural landscapes, they are relatively preserved in Northern Kujukuri. This study focuses on short-term topographic changes in coastal sand dunes there and discusses the effects of vegetation and wind.
UAV-SfM surveys were conducted seven times from September 2016 to December 2018, and the obtained topographic data were analyzed using GIS software (ArcGIS Pro) to evaluate changes in terrain conditions by season and year. We also analyzed the wind direction data provided by the Japan Meteorological Agency. Vegetation data were obtained from the field surveys and the green-red vegetation index extracted from the UAS images. The following three characteristics were identified: 1) Short-term topographic changes tend to be influenced by specific events such as storm events, and therefore terrain conditions in the same season may be different from year to year. 2) General wind conditions represented by the meteorological data corresponding to the overall change of sand dune topography, especially at seasonal or longer scales. 3) Formation of small sand dunes is affected by vegetation distribution. This study has suggested factors affecting short-term topographic changes of coastal sand dunes based on frequent data acquisition in the field and geospatial technologies.

# Responses of suspended sediment yield to precipitation, topography and dam control in the Yellow River Basin, China

*Ruiqi Zhang[1], Takashi Oguchi[2]

1. Department of Natural Environmental Studies, Graduate School of Frontier Sciences, The University of Tokyo, 2. Center for Spatial Information Science, The University of Tokyo

Soil erosion has long been a serious problem in the Yellow River Basin in China. The high sediment load carried by the Yellow River results in deposition along its path, raising the riverbed and increasing the flood risk in the lower reaches. To mitigate this situation, large-scale soil conservation measures have been put into practice such as the construction of dams to effectively trap fluvial sediments. Previous studies on this topic focused on the interannual fluctuation of sediment yield caused by dams and reservoirs. However, few studies focused on their effects on the seasonal variation of sediment yield. In 2002, the Yellow River Conservancy Committee began to implement the water-sediment regulation (WSR) scheme to regulate the river water, which further strengthen the impact of dam control on the seasonality of sediment yield. Therefore, this research aims to integrate natural contributing factors such as topography and precipitation with the WSR-based dam control to analyze the seasonal and spatial variations of sediment yield in the Yellow River, for the years 2008 to 2012. Data of daily suspended sediment concentration, water discharge, and precipitation were downloaded from the Chinese Data Sharing Infrastructure of Earth System Science, and the ASTER GLOBAL DEMs with a resolution of 1 arc-second were downloaded from the U.S. Geological Survey web site. ArcGIS and R software packages are used to analyze the obtained data. Inspection of data quality revealed that consecutive sediment yield and precipitation data for 97 watersheds are usable.

Data analysis indicated the following four basic hydrological characteristics of the watersheds. 1) Water discharge within each watershed is not stable both interannually and seasonally, because it has been affected by the implementation of dam regulation as well as low discharge conditions mostly in spring and winter especially in some small watersheds. 2) The variation of sediment yield in some natural watersheds reflects change in precipitation, leading to sediment yield peaks in summer. 3) In other watersheds, the variation of sediment yield tends to be independent of precipitation. Instead, some artificial conservation measures such as dam control effectively intercept sediments from the upstream area. 4) The correlation between suspended sediment yield and water discharge varies among watersheds, and the correlation coefficient can be used as a parameter representing hydrological characteristics. The DEMs have been also analyzed to relate hydrology and climate with geomorphology. The obtained results may help the policy makers better understand the erosion situations in the Yellow River Basin and regulate the soil conservation measures.

Keywords: Suspended sediment yield, the Yellow River basin, seasonality, precipitation, topography, dam control

# A study on geographical changes in main roads and coastlines in the 200 years in Japan

*Yuki IWAI[1], Yuji Murayama[1]

1. Graduate School of Life and Environmental Sciences, University of Tsukuba

This study analyzed the changes in the spatial distribution of main roads and coastlines and its determining factors between 1818 and 2018. These changes are important social and natural foundations for the Japanese national land formation, and the knowledge of the spatial changes is useful for promoting the sustainable society. Previous studies have focused on the regional transformation using aerial photographs, drilling surveys, and some old paper maps. They used the geographical data after modernization and targeted the specific region. In our study, an attempt is made to compare the long term of 200 years on the national scale by using INŌ's digital map.
Digital data of main roads and coastlines on the INŌ's map are included in the “Digital INŌ's Map, Professional Edition”. This is digitized by using the INŌ's large paper map which is the largest scale in the INŌ's map. In the analysis of the changes in main roads, we used the attribute information of Digital INŌ's Map. The changes in coastlines were derived by overlay analysis with coastlines of Digital INŌ's Map and the present national land. In the overlay analysis, each section of coastlines which did not overlap with the present national land was defined as the section changed by the backward movement of the coastline. On the other hand, each section of coastlines which overlapped with the present national land contained both the section changed by the reclamation and the section almost unchanged. In analyzing the determining factors, land use data (100m gridded area) and coastal ocean data (1km gridded area) were mainly used.
As a result, it was found that the route changes in main roads were 18.3% of the total (Fig.1), and the changes in coastlines were 28.9% of the whole length. In the changed coastlines, the changed section by the backward movement was 66.3% (Fig.2A), and the changed section due to the reclamation was 33.7% (Fig.2B). Main roads drawn on the INŌ's large map had different density depending on the region, because only main roads surveyed by INŌ's team were drawn on the INŌ's large map. Therefore, the distance of the changed section was summarized at the regional level. The rate of the change was the largest in Kyushu region (27.8%), and the smallest in Shikoku region (2.8%). On the other hand, coastlines drawn on the INŌ's large map distribute uniformly at the national scale. The rate of the change was the largest in the eastern Japan (Fig.2A) and the industrial areas (Fig.2B). Details on determining factors of changes will be discussed on the day of the presentation.

# Comparative analysis of foreign tourists' spatial behavior in Tokyo using locational data from the photo-sharing service of Flickr

*Bochra Bettaieb[1], Yoshiki Wakabayashi[1]

1. Tokyo Metropolitan University

These new sources of geospatial data, such as smartphones, global positioning systems, and travel cards, provide the possibility of analyzing high-resolution big data to capture patterns of human spatial behavior across space and time. This study analyzes the geocoded photos from a photo-sharing service to make a comparison of the tourist behavior in Tokyo between countries of foreign visitors.

We selected three places (Shinjuku, Asakusa, and Ginza) as study districts. The data were downloaded from Flickr, one of the most popular online platforms for people to share their travel experiences by uploading photos. We used the data of geocoded photos from 2014, taken within 1.5 km from Shinjuku, Ginza, and Asakusa stations. Information on the nationality of contributors recorded in the Flickr data was used to compare the tourist spots of foreign visitors. To summarize the distribution of the points of photos, we aggregated the point features into a rectangular polygon feature with 100 meter grid square, then we made dot maps and mesh maps to capture the overall distribution of the photos.

The obtained results showed that some tourist spots common to foreign visitors in three study areas, namely, places close to railroad stations. However, spatial patterns of tourist spots varied with the study district in question. In Shinjuku and Ginza, there are differences in tourist spots between Asians and Europeans. Particularly, European tourists' hot spots tend to be more scattered than Asians. However, such differences are not observed in Asakusa, where tourists' hot spots are concentrated around Sensoji Temple and Tokyo Sky Tree. The reason for this is that tourist attractions are concentrated in and around specific facilities in the Asakusa district. Hence, the variations of tourist spots obtained by analyzing the geotagged photographs on Flickr can be explained by the difference in behavior and interest of foreign tourists between countries, as well as the spatial distribution of tourist attractions.

# Neighborhood Walkability and its Potential Associations with Residents' Walking Habits

*Ikuho Yamada[1], Keiichiro Sanada[2]

1. Faculty of Science and Engineering, Chuo University, 2. Graduate School of Science and Engineering, Chuo University

Walkability is a concept that embraces various aspects of physical neighborhood environments that may support and promote walking in a neighborhood. Walkable neighborhoods are expected to improve residents' physical activity level and thus health because such environments may be able to implicitly encourage residents to choose walking over driving as a daily transportation mode. While research on walkability originated in western countries, where obesity and lifestyle-related illnesses has been a longstanding public health problem, such research in Japan is also useful and necessary because improving healthy life expectancy among the elderly in an undemanding way is critical in our super-aging society. The concept of walkability is also closely related to that of the compact city, which is considered to be a promising form of sustainable cities in the field of urban planning, as walking is expected to be a major transportation mode in such cities.

This research therefore aims to investigate potential associations between neighborhood walkability and residents' walking habits with specific consideration to characteristics of Japanese cities. Here, we consider two types of walking, namely walking for transportation and walking for leisure, separately because they may relate to neighborhood walkability in different ways. Moreover, we assess neighborhood walkability both subjectively and objectively so as to capture the neighborhood situations in a more comprehensive manner.

An Internet-based questionnaire survey was conducted in January 2018 in order to collect information about residents' walking habits, subjective evaluations of neighborhood environments, and health in selected 49 municipalities in Tokyo. The survey was implemented via an Internet research company, and about 4000 individuals who had registered as a panel of the ompany responded. Questions related to the residents' subjective evaluations of neighborhoods were based on an internationally used standard questionnaire named ANEWS (Abbreviated Neighborhood Environment Walkability Scale). In addition, objective measures of neighborhood walkability were computed using various GIS datasets such as the small area statistics of 2015 Population Census, road network data, and facility location data. Then, statistical analysis was conducted to assess potential associations between residents' walking habits and both subjectively and objectively measured neighborhood walkability.
Results indicated that the two types of walking habits related to different aspects of neighborhood walkability. For example, neighborhood community was found to have positive association with walking for leisure, but no such association was found with walking for transportation. Further, it was suggested that the associations between residents' walking habits and neighborhood walkability would potentially vary depending on neighborhood settings such as urban and suburban regions. Our results also suggested that subjective and objective measures of walkability might have different associations with the two types of walking even when they were assumed to measure the same aspect of neighborhood environments.

# THE STUDY OF USING PARTICLE FILTER METHOD COMBINED INDOOR MAGNETIC MAP AND PEDESTRIAN DEAD RECKONING FOR INDOOR POSITIONING.

*Yu-Chun Chen[1]

1. Department of Land Economics, National Chengchi University

In the past, we often needed a map to find out the destination in an unfamiliar environment. With the appearance of Global Positioning System, the outdoor positioning performance has approached perfection. However, due to the environment obstruction, the indoor signal will reduce the positioning accuracy. Therefore, indoor positioning technology has become the focus of research and development in recent years.
In the history of indoor positioning technology, target positions were detected by sensors, radio signals and image or Pedestrian Dead Reckoning (PDR). All the technologies above have their own advantages and disadvantages, like costly or low accuracy. It is necessary to combine the different technologies to achieve a comprehensive consideration of cost, efficiency and accuracy. This study used the built-in magnetometer of the smart phones to build the magnetic field maps of the floor and also accelerometer as an aid to achieve indoor positioning. This study effectively improved the accuracy and efficiency of indoor positioning by using the particle filter method combine PDR with the magnetic positioning.

# Assessing the Agriculture Sustainability based on Geospatial Technique in a Tropical Mountain Area : A Case Study in Kotmale Catchment in Sri Lanka.

*DM Sanjeewa Lasantha Bandara[1], Takehiro Morimoto [2]

1. Division of Spatial Information Science, Graduate School of Life and Environmental Sciences, University of Tsukuba,
2. Faculty of Life and Environmental Sciences, University of Tsukuba

Sustainable agricultural systems aim at developing new farming practices that do not degrade the environment. It should be catering to the future societal needs for food and feed, ecosystem services and human health, maximizing the net benefit for people, without compromising the ability of future generations to meet their own needs. The agricultural land where located in the tropical mountain area has been becoming a dilapidated situation due to the unplanned agricultural practices coupled with the physical properties of the area and socioeconomic factors. The Kotmale catchment area is located in the central highland of Sri Lanka and covers 572 $km^2$ with altitude ranges from 681 to 2,505 meters above mean sea level. It is extended from latitude 7˚6'32.80"N to 6˚47'33.12"N and from longitude 80˚ 50'21.26"E to 80˚34'31.34"E which encompasses in the south-central mountainous. The primary objective of this study is to assess the sustainability of agriculture based on the environmental and socioeconomic indicators in the Kotmale catchment using geospatial techniques. The Analytic Hierarchy Process (AHP) combined with Multi-Criteria Decision Making (MCDM) methods was used as data computation method, and both spatial and non-spatial data were used under the three main criteria, such as environment, social and economic. The results of the analysis show that soil erosion is one of the major issues and it is reported as mean erosion is 9.8 t $ha^{-1}$ $yr^{-1}$. The mean annual rainfall in this area has decreased over the study period (1986-2016) while temperature has increased up to 2-3 $^0$C. In view of socioeconomic factors, education level of the farmers, lack of labor force, fluctuation of the unit price of the agricultural production, insufficient income of the farmers was negatively affected to the current agricultural activities of the research area. The result would be an aid and sources for assessing the sustainability of agricultural land and decision makers will be able to use this result for future planning.

# Spatial Evaluation of Potential Tsunami Vertical Evacuation: A Case Study of the Western Coastal Belt in Sri Lanka

*Ranagalage Mahinda Manjula[1], Yuji Murayama[1]

1. Division of Spatial Science, Graduate School of Life and Environmental Sciences, University of Tsukuba, Japan

On December 26, 2004, a massive tsunami resulted to recode extensive damages in the Indian Ocean. The recorded death toll was more than 35,000, and approximately one million people were affected in Sri Lanka. Lack of awareness was the main reason for massive damage. After this tsunami incident, Sri Lanka was also categorized as a tsunami-vulnerable country. Several past studies have contributed to introducing proper mechanisms that would minimize the damages from the next tsunami incident. Most tsunami-vulnerable areas have been covered by horizontal tsunami evacuation after 2004, and people need to travel great distances to reach tsunami evacuation centers due to the lower elevation profile of the coastal area. The purpose of this study was to spatially evaluate the potential for tsunami vertical evacuation in the western coastal belt in Sri Lanka. The western coastal belt selected by considering the existing urban structure and tsunami vulnerability. Several criteria and assumptions have been computed to achieve the goal of the study. In this analysis, three tsunami scenarios 4 m, 8 m, and 12 m were used to identify potential vertical evacuation sites. According to the results of the inundation ratio, the category of critical buildings can be increased to 1.7% and 67.0% in 4 m and 12 m scenarios, respectively. It was indicated that the 12 m scenario consisted of more damage than the other two scenarios. Tsunami evacuation sites were selected based on the three tsunami scenarios and 220, 232 and 122 sites were selected for the 4 m, 8 m and 12 m tsunami scenarios, respectively. According to the calculations of the capacity of each site, the selected 220 sites will facilitate 17,594 people during the 4 m tsunami scenario. The selected 232 sites will accommodate 25,677 people during the 8 m scenarios. All selected sites are capable of accommodating the affected population in both the 4 m and the 8 m scenarios. However, the selected evacuation sites are not sufficient for accommodating the affected population in the 12 m scenario. In the 12 m scenario, 12,221 people are affected. However, the evacuation sites can only accommodate 10,165 people. The finding of vertical evacuation by considering the existing urban structure of the city is essential to save human lives during the next tsunami incident. The adopted methodology can be used as an example for other lowland coastal cities to select vertical evacuation to protect human life.

# A Framework for Assessing the Spatial Distribution of Vulnerability of Communities to Landslides in Tropical Mountainous Region: A Case study from Kegalle District –Sri Lanka.

*Nimala Chinthake Perera[1]

1. SANASA CAMPUS - SRI LANKA, IHRA - UNIVERSITY OF COLOMBO - SRI LANKA

Landslide vulnerability refers to the degree of loss to a given element at risk due to the occurrence of a landslide event. The concept of vulnerability is difficult to quantify due to the involvement of some social and physical indicators to determine vulnerability to a landslide in a given location. Therefore, limited research has been carried out to determine the spatial distribution of landslide vulnerability. This study attempt to map the spatial distribution of vulnerability to landslide using vulnerability index developed by entropy method abstracting information from fourteen indicators. The study was based on primary sources of data, obtained from 402 elements including associated human capital from Kegalle District-Sri Lanka. Then the Entropy method was used to estimate the level of vulnerability in sample locations (elements). Computed vulnerably vales were imported into Geodatabase which was used to evaluate element at vulnerability and map the spatial distribution of vulnerability. The spatial distribution of vulnerability was obtained from interpolating vulnerability values of sample locations (elements) by using Kriging interpolation method. Results were expressed on maps on which different spatial patterns of levels of vulnerability were found for the study area. According to the map, landslide vulnerabilities in the study area demonstrate notable regional specification. In general, vulnerability reflects expected degree of damage to the considered element or location by the adjacent to occurred landslides. Also, the spatial distribution of vulnerability has shown a close relationship with the rural-urban divide. According to landslide vulnerability analyses, 14.6% (247 sq Km) of the entire area is found to be the highest vulnerable zone for a landslide.

Further, 32% (544 sq Km) of the total land area categorized under very high or high vulnerable zones. Moderately vulnerable zones take part 13.4% (227 sq Km) of the total area. However, 26.4% (448 sq Km) of land area categorized as low or very low vulnerability, while 13.4% (227 sq Km) area categorize under the lowest zone it can be concluding that entropy method has a sufficient level of capacity to defined weigh for indicators which use for vulnerability assessment

# Applications of WebGIS to Educating Disaster Risk Reduction for Chinese and Japanese Students

*Jiali SONG[1], Takashi Oguchi[2], Hiroyuki Yamauchi[2], Takuro Ogura[1]

1. Graduate School of Frontier Sciences, The University of Tokyo, 2. Center for Spatial Information Science, The University of Tokyo

In this world of globalization and information explosion, WebGIS (Web Geographic Information Systems) can effectively support education in natural and social sciences. We should utilize this technology and for better human life. Research on mortality due to natural disasters has shown that nations with higher levels of education experience lower levels of mortality. This suggests that young students are knowledgeable and will contribute to future disaster risk reduction (DRR) if they are well educated. Hence, it is important to introduce DRR into high school education such as classes of geography. At present Chinese researchers are preparing disaster-related compulsory curricula for high school DDR education, and are designing special textbooks for this purpose. In Japan, some researchers have already constructed online WebGIS systems for DRR education using hazard maps available on the Internet. However, such DRR activities tend to be insufficient because of limited cognition of citizens about information related to hazards and risks. This study aims to construct an improved online DRR system for high school education using WebGIS technology along with hazard information including maps for China and Japan. In August 2018, Japanese students used the system in an event funded by the Japan Society for the Promotion of Science. After that, a similar educational event was held in a high school in China. During these activities, students compared paper hazard maps with electronic hazard maps and used both of them for consideration. At the end of each event, the feasibility and effectiveness of the system were surveyed by questionnaires to evaluate the understanding of students about WebGIS and relevant knowledge. The results indicate that students in both countries prefer teaching materials like the constructed DRR system for school classes. However, there are some differences between the two countries. For example, the Chinese students thought that analysis of dangerous areas using the layer of flooding areas was more difficult than the Japanese students, reflecting differences in DDR knowledge. To improve the applicability of the system, further educational activities will be conducted in the near future.

# Solar System Treks - GIS that provides interactive visualization and analysis for planetary science and exploration

*Emily Law[1], Brian Hamilton Day[2]

1. NASA Jet Propulsion Laboratory, 2. NASA Ames Research Center

Meeting the challenges of space exploration has resulted in new knowledge that has kept NASA and JPL world leaders in big data science and technology. We, NASA’s Solar System Treks Project (SSTP – https://trek.nasa.gov) development team at JPL, under the management of Solar System Exploration Virtual Research Institute (SSERVI, https://sservi.nasa.gov/), have developed a Geographic Information Sysetms (GIS) based system that includes a set of web-based portals that provide a suite of interactive visualization and analysis tools to enable mission planners, scientists, and engineers to access a large volume of cartographic products and models from a growing number of spacecraft. Currently, various web-based portals are available for discovering and exploring the Moon, Mars, Vesta, Ceres, Titan and Icy Moons of Saturn, and hydrology on Earth. This presentation will provide an overview of this GIS-based system highlighting its high level architecture, technologies and capabilities that was designed and developed specifically for exploration of any Solar System bodies. We will also describe its uses, features and capabilities, highlighting visualization and analysis innovations.

# Landslide Recognition using Remote Sensing Images and PCANet

*Yimei Wei[1], Takashi Oguchi[1]

1. Graduate School of Frontier Science, the University of Tokyo

Landslides are complex geological phenomena that can cause serious damage to the natural and social environments and may result in a significant loss of lives and properties. Consequently, landslide recognition, mapping, and monitoring are important for the prevention of secondary disasters and post-disaster relief. Since various remote sensing images have become more accessible in recent years, the use of satellite and aerial imagery for geological disasters has become a hot research topic. When remote sensing images are used to recognize landslides, image feature extraction is the main technical issue, and inefficiency in extracting ground object features has been a major challenge. This study explores the use of a simplified deep learning network structure, PCANet, to learn image features from post-disaster remote sensing images and train the classifier. This approach reduces the computation time of feature extraction and improves the efficiency of landslide recognition. The materials for training PCANet are image data sets for several areas in Japan including both landslide and non-landslide samples. They were collected from vertical aerial photographs and orthophotographs provided by the Geospatial Information Authority of Japan (GSI). In addition, post-disaster landslide distribution maps provided by the National Institute of Geosciences and Disaster Recovery (NIED) and GSI were utilized in the selection of sample images. As the analyzed remote sensing images were taken in a short time after a serious geological disaster, this research also contributes to future rapid responses to landslide hazards.

# Estimating the fractional vegetation cover using fixed-wing drone and multiple vegetation indices

*Kotaro Iizuka[1]

1. Center for Spatial Information Science, The University of Tokyo

Fractional vegetation cover (percentage of vegetation cover) plays a key role in characterizing the conditions of the terrestrial environment. To analyze the distribution of the vegetation conditions, several methods and models can be found for estimating its coverage. Remote sensing techniques, especially utilizing the satellite imagery is one of the major approaches due to its applicability in larger spatial extent and multiple channels observed from different electromagnetic spectra. Although, in cases of high frequent cloud covering regions such as the tropical regions, usually this is difficult to conduct. Thus, in this work, we seek in alternatively collecting a remotely sensed imagery from a fixed-wing drone and analyze to estimate the fractional vegetation cover of the study site. Normal RGB camera and multispectral sensors were carried onboard the fixed-wing drone, and multiple images were collected. The Structure from Motion method was implemented to develop an ortho image of the whole study site. The imageries were used to further develop a general land use/land cover (LULC) map of the site, and within the determined gridded area, the fraction of each LULC types were examined with different vegetation indices (VIs) computed from the multispectral data. Clear positive trend was found with increasing VIs and increasing fractional cover of healthy trees, and clear negative trend was found with decreasing VIs and increasing fractional cover of soils. This approach demonstrates that it is possible to analyze the coverage information through the utilization of drones, which can be also used as ground truthing, moreover, the findings would play an important role in further simulating such as the water cycles.

# Topographic surveys in Ny-Alesund, Svalbard, and improvement of mapping methods

*Jaeyong Lee[1], Takashi Oguchi[2]

1. Department of Environmental Studies, Graduate School of Frontier Sciences, The University of Tokyo, 2. Center for Spatial Information Science, The University of Tokyo

In Ny-Alesund, Svalbard in the Arctic, frozen layers with the active layer that melts only in the summer and the impermeable permanently frozen layer distribute widely. The vertical structure affects the distribution of groundwater as well as the surface environment and sediment movement. In addition, patterned-ground formed by repeated freezing and thawing and associated vegetation are the basis of polar ecosystems. Recent global warming alters the surface environments especially the expansion of the active layer and increased groundwater flow. In order to quantitatively understand such changes in the surface environment, we developed the technique of high-resolution mapping in Ny-Alesund. As field surveys in the polar regions have limitations in terms of site accessibility and duration, we utilized data from not only our fieldwork but also past fieldwork, along with satellite/aerial images and other geospatial data.
We analyzed altitude slope, aspect, curvature, and solar radiation for the area near the Ny-Alesund Science Village using DEMs produced by the Norwegian Polar Institute. We evaluated the reliability of the terrain analysis using TopoSvalbard satellite images and aerial photographs. We also utilized ground photographs and high-resolution ground mapping with the SfM-MVS method to produce a topographic map of the area. Since legal restrictions on the use of radio frequency in Ny-Alesund limit the use of UAVs, we made a pole camera with stabilizer function, which provides photographs with about 3 mm resolution. Such photographs are useful for very high-resolution mapping for small areas.

Keywords: Ny-Alesund, Permafrost, High-resolution mapping

# An analysis of the year-round distribution of $PM_{2.5}$ and Oxidant by (Web)GIS and R

*Junji Yamakawa[1]

1. Graduate School of Natural Science and Technology, Okayama University

The year-round concentration distribution of $PM_{2.5}$ and Oxidant in Okayama City, Okayama Prefecture, Japan were estimated by using the geostatistics method and expressed by the (Web)GIS.

The observed concentration data of those environmental substances were obtained from the Website of the National Institute for Environmental Studies. The target year of $PM_{2.5}$ was 2015, and the year of the oxidant was 2006. GNU R (R core team, 2018) was used for geostatistics analysis. The JPGIS (Geographical Survey Institute, 2018), which is government-based open data, was used for geostatistics analysis. The On-premise type GIS and the WebGIS were used in the research. The QGIS (QGIS Development Team, FOSS4G, 2018), and the jSTAT MAP (Statistics Bureau, Ministry of Internal Affairs and Communications, 2019) were used for the each type of the GIS.

First, the variogram of the observed concentration data of the environmental substances, were calculated for the estimation of the spatial dependence, then the prediction of the concentration distribution on the target area were carried out by using the Kriging method. The estimated concentration data were examined together with other geographic information data using (Web)GIS. The expression scheme of the accuracy of the estimation were investigated on the QGIS. Furthermore, transformation of the coordinates that was required on the using of the jSTAT MAP was also investigated.

The year-round mean concentration distribution of $PM_{2.5}$ and oxidant in Okayama city were estimated with certain accuracy. It was also possible to qualitative analysis of the coefficient of variation of estimated distributions of $PM_{2.5}$ and oxidant by GIS and WebGIS. The minor error on the conversion from the rectangular coordinate system to the regional mesh code requires further consideration.

GIS is effective for analysis and mapping of the global environmental data and geographic information data. WebGIS is also becoming capable of executing these analysis with only by the Web browser. Further utilization is expected in the study field of the Earth and planetary science.

Keywords: GIS, jSTAT MAP, Kriging, FOSS4G, PM2.5, Oxidant

# Development Process and Spatial Structure of Urban Villages in Shenzhen City China

*YARONG LUAN

During the 30 years of the reform and opening-up policy, economically developed cities and regions have expanded rapidly in China. Villages which originally surrounded the city before their expansion were rapidly submerged by the expanded city areas and surrounded by high-rise buildings. They are turned into the "urban villages". In the rapidly urbanized regions, urban villages are common phenomena. This problem becomes extremely serious in the Pearl River Delta region in China.

In the present study, Shenzhen City was selected as the research area. Field work was performed on the 18 sample urban villages selected from total 320 urban villages of Shenzhen City. Based on the changes in their internal spatial structures, the development of the urban villages is divided into three stages, e.g., embryonic stage, growth stage, reformed stage. After analyzing the spatial structures, different characteristic features were found in each stage. And the main factors of the spatial structural changes arising from different stages were summarized.

It was found that the traffic condition was the key factor for the embryonic stage; rental price was the key factor for the growth stage and the regulatory power of the government was the key factor for the reformed stage.

# An analysis on the location characteristic of alley spaces in Tokyo

*Ryo Taniguchi[1], Go Ishikawa[1], Mayumi Oka[2]

1. Tokyo Map Research Inc., 2. Research Organization of Information and Systems The Institute of Statistical Mathematics

The number of alley spaces in urban areas is rapidly decreasing due to road transportation plans centered on automobiles and large-scale development. In recent years, however, aspects of the alley as a common space are being reconsidered, and town planning with the alley was also promoted throughout the country. The alley is considered to be an important factor characterizing urban spaces, but it is difficult to grasp its location as special information. So than before, we devised "Alley Estimation Logic" which extracts block areas where the existence of allays is presumed by using GIS, and have checked the accuracy of logic through field survey in Tokyo and Tokushima prefectures.
In this study, we conducted "Alley Estimation Logic" for Tokyo and estimated the alley location. For the analysis, we used “Foundation Geographical Data” (scale level 2500) made by Geographical Survey Institute and “ArcGIS Pro 2.2” by Esri. Furthermore, we calculated "Alley Ratio" from the estimation result and considered the location characteristics of the alley through comparison with the number of wooden buildings and the use district etc. In addition, we estimate the "Alley Ratio" of municipalities in Mie prefecture as a whole, and we will verify regional differences due to differences in prefectures.

# On the Method to Evaluate Signboards based on the Relationship with the Surrounding Space

*Akihiro Kishikawa[1], Kazunari Tanaka[1]

1. Osaka Institute of Technology

The street space in the city is an important space to impress visitors with the image of the city.

However, in recent years, miscellaneous and townscapes are being formed due to the enlargement of buildings and the diversification of size, forms and colors of signboards.

The signboard design combines size, color, and letters together to create a signboard.

In this research, we aim at grasping the degree of group signs by checking the placement and colors appropriate to the characteristics of the place for Kyoto city.

Based on these relationships, we try to design a signboard suitable for the street.

# ON THE LANDSCAPES ELEMENTS FROM A BIRD’S-EYE VIEW SCAPE

*Nobuaki Tanaka[1], kazunari Tanaka[1]

1. Osaka Institute of Technology

When it comes to landscapes, beautiful landscapes are formed from local climates such as history and customs by elements such as varying nature and demographic structures. A feature that creates these beautiful landscapes is the linear landscape element. This linear element is characterized as being beautiful because landscape elements that can be continuously viewed form a beautiful landscape such as a building that looks continuous due to the shape and color, in addition to linear landscape elements such as rivers and roads. Hypotheses concerning continuity and image are present not only in urban landscapes, but also in the landscape of rural areas and mountainous regions. Therefore, in this research, focusing on a bird's eye view from high vantage points, we aim to examine urban landscapes by analyzing their elements, shape, view and area. As for the examination method, analyzed and expressed the continuity of streets, rivers, green roads etc, using image analysis and GIS. From the results, extract and consider the relationship between the position and shape of elements with regards to continuity and the beauty of urban landscapes.

Keywords: High-rise building, Bird's eye view Landscape , Continuity

# Experimental hazard map for accurate communication

*Ryo Endo[1], Takayuki Nakano[1]

1. GSI of Japan

Hazard maps have been prepared and published in each local government in order to utilize them for disaster prevention measures and evacuation in the event of a disaster. Color representation is often used for the map representation of the hazard map. However, there are some cases in which visibility deteriorates due to excessive information and mixed colors. In this report, we tried to create a hazard map considering the following matters, with the aim of improving the accuracy and understanding of hazard map information. The prototype is a paper hazard map of liquefaction.

1. Background map
A lot of kinds of maps are used as background maps of hazard maps. However, some background maps are difficult to read because of low-resolution. In order to ensure the legibility of the background diagram, we use vector data.

2. Information
Disaster related organizations (e.g. government offices, fire departments, police), evacuation routes / evacuation centers, hospitals, etc. are usually listed in hazard maps. but in order to prevent deterioration of visibility due to excessive information, we only list risk information of each hazard on the area and nformation on evacuation .

3. Color scheme
In the hazard map, many colors are used for map expression including disaster risk. However, there are individual differences in the characteristics of color vision, not everyone recognizes the color in the same way. For example, it has been pointed out that about 5% of men and about 0.2% of women have color vision characteristics that are difficult to distinguish between red and green (for example, Ito (2012)). Therefore, avoiding combinations of red and green, focusing on expressions of disaster risk degree, we tried to make a hazard map with attention to lightness and saturation etc. We confirmed whether people with color vision abnormality can properly read information of prototype hazard map using simulation images created with Adobe photoshop CC 2018.

Keywords: hazard map, universal design, color scheme

# Effectiveness of color hillshade with multiple light sources for geopark guide maps : A case of the North Ibaraki Geopark Project

*Keiko SUZUKI[1], Go ISHIKAWA[1], Mamoru KOARAI[2], Rika IMAIZUMI[3], Naoki TAKEDA[4]

1. Tokyo Map Research Inc., 2. Ibaraki University, 3. Aero Asahi Co., Ltd., 4. Association for Promotion of North Ibaraki Geopark Project

Until 2018, 44 geoparks were certified In Japan, and in each geopark, they use a large number of guide maps with geosite which to introduce the characteristic topography and geology of the area for education and sightseeing. For those guide maps topographic features and geological information that is easier for users to understand are emphasized. And there are also guide maps that use various topographic representation with high-precision elevation data and geographical analysis by GIS.

In the North Ibaraki Geopark Project of northern Ibaraki prefecture, they have created geosite maps, but the topography and geological representation were not necessarily sufficient. Therefore, we attempted to create a topographic representation that easy to understand topographic features and geological phenomena spatially for this new geosite guide maps in the project. Topographic representation is to express geo information practically and easily understand and for guide maps, we use color hillshade to make it artistic. According to the reduced scale, and regional features, three kinds of light source were examined, single light source, multiple light sources, multiple light sources with pseudo-shade. In this presentation, we describeits effectiveness, topographic representation and map representation.

*This research is supported by Ibaraki University Geological Information Utilizing Project and KAKENHI (16K01213).

# Estimation of three-dimensional structure of forest using LiDAR data in Abukuma mountainous region

Akane Narikiyo[1], *Mamoru Koarai[1], Wataru Murakami[2], Yasuhiro Ogawa[2]

1. Earth Science course, College of Science, Ibaraki University, 2. Forest Research Institute

Many shallow slope failure has occurred in granite area. The root of tree has effects of suppressing collapse. However, it is difficult to study using a method to dig roots. The tendency that root width is larger as stump diameter is larger as the results of field survey in southern part of Abukuma Mountains. In the meantime, Okatani et al., (2013) reports that it is possible to understand the 3D structure of forest by using LiDAR data. This study has two goals in Abukuma Mountains central area. The first is surveying the relationship with weathering layer of granite and root system development, the second is considering usefulness of LiDAR data for detection of the 3D structure of forest.

Research method for the first goal are field survey and data analysis. In 75 points in survey area, root system data (stump diameter, root width and root depth), weathered layer, slope topography (upper or under of slope, ridge or valley), slope orientation and inclination were surveyed. And the relationship of those data was analyzed using GIS. Investigation method for the second goal are every tree survey in two square zone and the forest zone, and analysis LiDAR data. Those data were superimposed, and number, tree height and total cross-sectional area sum was compared whether match or not using GIS.

In the first result, a positive correlation was found between stump diameter and root width, and between stump diameter and root depth. Also, the thinner soil layer thickness is the wider root width. In the second result, about the number, the estimated value by LiDAR data was significantly lower than the measured value in both square sections. But compared by two squares, the magnitude relation of the estimated value was the same as the measured value. In the forest zone, the actual measurement value of 7 out of 10 points didn’t differ the estimated tree height. Also, a positive correlation was found between stump diameter and tree height.

From there results, in a wide range, there is a possibility that the depth of the root can be estimated by the 3D structure of forest detected using LiDAR data.

Keywords: LiDAR data, three dimensional structure of forest, granite, Abukuma Mountainous region

# Disaster information sharing of welfare service workers based on knowledge from experience in a tsunami disaster area

*ARISA INOUE[1], Yoshiki Wakabayashi[1]

1. Graduate School of Urban Environmental Sciences, Tokyo Metropolitan University

In Great East Japan Earthquake occurred on March 11, 2011, welfare service facilities suffered great damage. Hence, improvement of evacuation plans for welfare service facilities having many elderly people who need assistance in the event of a disaster is an urgent issue. The aim of this study is to we can clarify what kind of information should be shared with their successors based on the disaster knowledge possessed by the staffs of the welfare service facilities.

To this end, I conducted the following research and analysis. First, I identified what kind of disaster knowledge acquired from the Great East Japan Earthquake. Second, I asked the responsible officials of the facilities about tsunami inundation area and evacuation dangerous area at the time of disaster. Third, I explored the current issues of disaster information sharing.

The study area is Oarai-machi, Higashi Ibaraki-gun, Ibaraki prefecture, that suffered the tsunami disaster at the time of the Great East Japan Earthquake. I chose five respondents from welfare facilities in Oarai-machi by employing a semi-structured interview.

The results of this study are summarized as follows. The evacuation behavior of the welfare service facility is not necessarily related to the location of the facility. The interview survey revealed that the staff did not trust the information of the tsunami hazard map issued by the administration nor the evacuation manual but they rely on the disaster knowledge. Concerning the tsunami inundation range considered by the responsible stuffs at the time of the disaster, the information varied with experience of the Great East Japan Great Earthquake.

In the evacuation dangerous area considered by the staff responsible for earthquake response, the dangerous places considered depend on the site of the facility location. Reasons for answering the dangerous area can be divided into two types: natural and artificial. The accuracy of disaster knowledge as for the tsunami inundation range depends on the experience of the Great East Japan Earthquake.

These findings suggest that the staff responsible for the disaster response is likely to take evacuation decision and evacuation behaviors based on their disaster knowledge in the future. Nevertheless, they do not share and make correction of disaster knowledge with staffs of other facilities. Hence transmission of knowledge from experience was not done. A cause of it can be the high turnover rate of welfare service staff; the staffs are too busy with, day-to-day correspondence, there is no time to think about the disaster. In addition, weak relationship between facilities can prevent information sharing. In the future, it is important to inherit knowledge from experience to staff who have no disaster experience and to share and modify knowledge among peers in welfare facilities.

# Spatial analysis of children's commuting space - a case study of Toyama city elementary school -

*Koji Ohnishi[1]

1. Department of Humanities, University of Toyama

Social attention to the safety and security of children has become high since the 1990s. Children use the outdoor space to move between school and home. Watching activities and urban maintenance have been done to protect children from crimes and traffic accidents. It is necessary to grasp the outdoor activities of children for these effective efforts. Currently, the progress of information and communication technology (ITC) makes it possible to research using child's location information with GNSS. In Toyama City, LPWA network covers 98% of the residential area as a Smart City infrastructure building project. So we used the location information from the LoRaWAN position information. This research was conducted in two school districts, Shibazono Elementary School District and the Hayahoshi Elementary School District. GPS position information (latitude / longitude) is transmitted at 1 minute intervals from the position information acquisition sensor device. The implementation period was from January 21 to February 15, 2019, 267 participants in Shibazono elementary school district and 550 participants in Hayahoshi elementary school district. Analysis was done from the viewpoint of distribution and density. As a result, it was found that a high-density point distribution can be seen along the set school road, and it was found that the school-established school road is prominently used. However, cases where unexpected small diameters are also used at high density from routes of movement to school childcare such as on routes not designated by the school were also collected. Also, the number of children going to school and returning to home is the same, but there was a big difference in density. It is due to the diversity of movement of children by afterschool activities. Looking at the point distribution by time, the time of passing through the danger points became clear. These information is effective for the local community. The differences in grade, the distribution has spread the lower grade than higher grade. It is due to autonomous movement and going out after returning home in higher grade, while lower grades move to various places depending on the guardian's car movement.

[J] Poster | H (Human Geosciences )：H-TT Technology & Techniques

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_17

## [H-TT23] Geographic Information System and Cartography

convener:Mamoru Koarai(Earth Science course, College of Science, Ibaraki University), Kazunari Tanka(Department of Civil Engineering and Urban Design, Faculty of Engineering, Osaka Institute of Technology), Kazuhiko Nakamura(The University of Tokyo)

This session discusses various methods which acquire, store, analyze and visualize geospatial data, and presents the outcomes of empirical studies using GIS or mapping methods. The session also deals with applications of digital data, GIS, and mapping to various fields of earth and planetary science and human society. All presentations and discussion of this session are made in Japanese.

# Development of 3D Web map making service, MyMap3D

*Yoshiharu Nishioka[1], Kaoru Kitao[2]

1. National Insititute of Advanced Industrial Science and Technology, 2. CubeWorks Inc.

We have developed MyMap3D as the service by which the user can make a 3D web map freely. The elevation data used for topography making, basically, using elevation tiles of the PNG format Geographical Survey Institute offers, when, everyone is without charge and it can be used. This service is designed in order to change most items of the indication setting, and it's designated using a query parameter of URL. A 3D rendering is performed using WebGL through three.js.

Keywords: 3D, map, WebGL, Elevation, PNG Elevation tile

# Experimental hazard map for accurate communication

*Ryo Endo[1], Takayuki Nakano[1]

1. GSI of Japan

Hazard maps have been prepared and published in each local government in order to utilize them for disaster prevention measures and evacuation in the event of a disaster. Color representation is often used for the map representation of the hazard map. However, there are some cases in which visibility deteriorates due to excessive information and mixed colors. In this report, we tried to create a hazard map considering the following matters, with the aim of improving the accuracy and understanding of hazard map information. The prototype is a paper hazard map of liquefaction.

1. Background map
A lot of kinds of maps are used as background maps of hazard maps. However, some background maps are difficult to read because of low-resolution. In order to ensure the legibility of the background diagram, we use vector data.

2. Information
Disaster related organizations (e.g. government offices, fire departments, police), evacuation routes / evacuation centers, hospitals, etc. are usually listed in hazard maps. but in order to prevent deterioration of visibility due to excessive information, we only list risk information of each hazard on the area and nformation on evacuation .

3. Color scheme
In the hazard map, many colors are used for map expression including disaster risk. However, there are individual differences in the characteristics of color vision, not everyone recognizes the color in the same way. For example, it has been pointed out that about 5% of men and about 0.2% of women have color vision characteristics that are difficult to distinguish between red and green (for example, Ito (2012)). Therefore, avoiding combinations of red and green, focusing on expressions of disaster risk degree, we tried to make a hazard map with attention to lightness and saturation etc. We confirmed whether people with color vision abnormality can properly read information of prototype hazard map using simulation images created with Adobe photoshop CC 2018.

Keywords: hazard map, universal design, color scheme

# Effectiveness of color hillshade with multiple light sources for geopark guide maps : A case of the North Ibaraki Geopark Project

*Keiko SUZUKI[1], Go ISHIKAWA[1], Mamoru KOARAI[2], Rika IMAIZUMI[3], Naoki TAKEDA[4]

1. Tokyo Map Research Inc., 2. Ibaraki University, 3. Aero Asahi Co., Ltd., 4. Association for Promotion of North Ibaraki Geopark Project

Until 2018, 44 geoparks were certified In Japan, and in each geopark, they use a large number of guide maps with geosite which to introduce the characteristic topography and geology of the area for education and sightseeing. For those guide maps topographic features and geological information that is easier for users to understand are emphasized. And there are also guide maps that use various topographic representation with high-precision elevation data and geographical analysis by GIS.

In the North Ibaraki Geopark Project of northern Ibaraki prefecture, they have created geosite maps, but the topography and geological representation were not necessarily sufficient. Therefore, we attempted to create a topographic representation that easy to understand topographic features and geological phenomena spatially for this new geosite guide maps in the project. Topographic representation is to express geo information practically and easily understand and for guide maps, we use color hillshade to make it artistic. According to the reduced scale, and regional features, three kinds of light source were examined, single light source, multiple light sources, multiple light sources with pseudo-shade. In this presentation, we describeits effectiveness, topographic representation and map representation.

*This research is supported by Ibaraki University Geological Information Utilizing Project and KAKENHI (16K01213).

# Estimation of three-dimensional structure of forest using LiDAR data in Abukuma mountainous region

Akane Narikiyo[1], *Mamoru Koarai[1], Wataru Murakami[2], Yasuhiro Ogawa[2]

1. Earth Science course, College of Science, Ibaraki University, 2. Forest Research Institute

Many shallow slope failure has occurred in granite area. The root of tree has effects of suppressing collapse. However, it is difficult to study using a method to dig roots. The tendency that root width is larger as stump diameter is larger as the results of field survey in southern part of Abukuma Mountains. In the meantime, Okatani et al., (2013) reports that it is possible to understand the 3D structure of forest by using LiDAR data. This study has two goals in Abukuma Mountains central area. The first is surveying the relationship with weathering layer of granite and root system development, the second is considering usefulness of LiDAR data for detection of the 3D structure of forest.

Research method for the first goal are field survey and data analysis. In 75 points in survey area, root system data (stump diameter, root width and root depth), weathered layer, slope topography (upper or under of slope, ridge or valley), slope orientation and inclination were surveyed. And the relationship of those data was analyzed using GIS. Investigation method for the second goal are every tree survey in two square zone and the forest zone, and analysis LiDAR data. Those data were superimposed, and number, tree height and total cross-sectional area sum was compared whether match or not using GIS.

In the first result, a positive correlation was found between stump diameter and root width, and between stump diameter and root depth. Also, the thinner soil layer thickness is the wider root width. In the second result, about the number, the estimated value by LiDAR data was significantly lower than the measured value in both square sections. But compared by two squares, the magnitude relation of the estimated value was the same as the measured value. In the forest zone, the actual measurement value of 7 out of 10 points didn’t differ the estimated tree height. Also, a positive correlation was found between stump diameter and tree height.

From there results, in a wide range, there is a possibility that the depth of the root can be estimated by the 3D structure of forest detected using LiDAR data.

# Disaster information sharing of welfare service workers based on knowledge from experience in a tsunami disaster area

*ARISA INOUE[1], Yoshiki Wakabayashi[1]

1. Graduate School of Urban Environmental Sciences, Tokyo Metropolitan University

In Great East Japan Earthquake occurred on March 11, 2011, welfare service facilities suffered great damage. Hence, improvement of evacuation plans for welfare service facilities having many elderly people who need assistance in the event of a disaster is an urgent issue. The aim of this study is to we can clarify what kind of information should be shared with their successors based on the disaster knowledge possessed by the staffs of the welfare service facilities.

To this end, I conducted the following research and analysis. First, I identified what kind of disaster knowledge acquired from the Great East Japan Earthquake. Second, I asked the responsible officials of the facilities about tsunami inundation area and evacuation dangerous area at the time of disaster. Third, I explored the current issues of disaster information sharing.

The study area is Oarai-machi, Higashi Ibaraki-gun, Ibaraki prefecture, that suffered the tsunami disaster at the time of the Great East Japan Earthquake. I chose five respondents from welfare facilities in Oarai-machi by employing a semi-structured interview.

The results of this study are summarized as follows. The evacuation behavior of the welfare service facility is not necessarily related to the location of the facility. The interview survey revealed that the staff did not trust the information of the tsunami hazard map issued by the administration nor the evacuation manual but they rely on the disaster knowledge. Concerning the tsunami inundation range considered by the responsible stuffs at the time of the disaster, the information varied with experience of the Great East Japan Great Earthquake.

In the evacuation dangerous area considered by the staff responsible for earthquake response, the dangerous places considered depend on the site of the facility location. Reasons for answering the dangerous area can be divided into two types: natural and artificial. The accuracy of disaster knowledge as for the tsunami inundation range depends on the experience of the Great East Japan Earthquake.

These findings suggest that the staff responsible for the disaster response is likely to take evacuation decision and evacuation behaviors based on their disaster knowledge in the future. Nevertheless, they do not share and make correction of disaster knowledge with staffs of other facilities. Hence transmission of knowledge from experience was not done. A cause of it can be the high turnover rate of welfare service staff; the staffs are too busy with, day-to-day correspondence, there is no time to think about the disaster. In addition, weak relationship between facilities can prevent information sharing. In the future, it is important to inherit knowledge from experience to staff who have no disaster experience and to share and modify knowledge among peers in welfare facilities.

## [H-CG31] Nuclear Energy and Geoscience

convener:Eiji Sasao(Tono Geoscience Center, Japan Atomic Energy Agency), Ryuta Hataya(Central Research Institute of Electric Power Industry), Shinji Takeuchi(Department of Earth and Environmental Sciences, College of Humanities & Sciences, Nihon University), Chairperson:Tadafumi Niizato

Handling of geological hazard assessments represent a major environmental concern in the modern society due to constructing nuclear facilities and their radioactive wastes, and also related to the management of contaminated biosphere after nuclear disasters of Fukushima-Daiichi Nuclear Power Plant. The session rational is to provide a forum to deal with various aspects of scientific and engineering aspects of nuclear power. The session in this year focuses on radioactive waste disposal and covers not only scientific aspect such as characterization of geological environment but also engineering aspects such as microbe-nuclide, mineral-water, and cement-water interactions. In addition to this, themes on seismic hazards at nuclear facilities, environmental behavior of radionuclides emitted from disabled nuclear plants, and volume reduction and reuse of cesium contaminated soils are welcomed. Through these presentations, we aim to promote intercultural communication and collaboration between science, engineering and social science.

# Uplift estimation in coastal sea area by extrapolation of the land area model and its uncertainty

*Ryuta Hataya[1], Takaomi Hamada[1], Yohei Shimizu[1]

1. Central Research Institute of Electric Power Industry

## 1. Introduction

The research meeting of the METI in 2015-2016 discussed research issues of geological disposal in the coastal area [1]. After that, we began this study in August 2016[2]. In this study, finally, we’ d like to estimate the downward erosion under the coastal seafloor.

## 2. Method

We use the conventional method considering the future preliminary investigation for geological disposal siting [2, 3, 4, 5 etc.]. We drew the distribution map of the late Pleistocene uplift in the land using these data. Then, we construct a model of uplift motion after late Pleistocene in three dimensions on the basis of the uplift distribution and extrapolate it to the sea. Next, we have verified the model by discussing the uplift history from the tertiary to the recent. Furthermore, we’ ve discussed uncertainty of the extrapolation of uplift late from the land to the sea by the sensitivity analysis.

## 3. Case study

We have conducted the case study on the Miyazaki plain, which is known to have terraces widely distributed and the amount of uplift after the late Pleistocene is relatively large.

### (1) Basic uplift model

Our basic model of the uplift in the case study area is a flat plate approximation model, which means monotonous tilting in one direction [2].

### (2) Verification of uplift model by discussing the uplift history

The geological structure of the Neogene system shows tilting movement in the ESE direction [6]. The geomorphology and geological distribution of Pleistocene suggest tilting movement in the ENE direction. In addition, it is now rotating counterclockwise in North Kyusu district [7]. From these, the tilting direction in the late Pleistocene is considered to be in the ENE direction.

### (3) Discussed uncertainty of the extrapolation of uplift late from the land to the sea

In addition to the basic data set, we have created multiple possible data sets reflecting the uncertainty of the survey. These are saved data of some areas from the basic data set, and some data are replaced based on working hypotheses of terrace chronology. We constructed models from each data set and compare the average uplift rate distribution models of the late Pleistocene of coastal sea area. In this examination, the difference in uplift estimation due to the amount of data was larger than the difference of terrace chronology.

## 4. Summary and future tasks

©2019. Japan Geoscience Union. All Right Reserved. 

Needless to say, the uplift model in the land depends on the data set of the uplift, and discussion on geological history is useful for verification of the model. Also, in this presentation, we showed how to evaluate the effect of uncertainty deriving from data set and models (working hypothesis). We would like to continue case studies.

**Acknowledgments:**
This study was conducted as a project of the Ministry of Economy, Trade and Industry. Tono Geoscience Centre of Japan Atomic Energy Agency, DIA Consultant and Kawasaki Geological Engineering greatly helped us. For the survey of the sea area, we used the sea acoustic wave exploration records disclosed by the National Institute of Advanced Industrial Science and Technology. We express our deep thanks to their participants.

# Deep groundwater mobility at costal area estimated by groundwater dating

*Takuma HASEGAWA[1], Kotaro NAKATA[1], Yuichi Tomioka[1], Tomoko Ota[1], Atsunao Marui[2], Isao Machida[2], Reo Ikawa[2], Masahiko Ono[2], Shinji Matsumoto[2]

1. Central Research Institute of Electric Power Industry, 2. The National Institute of Advanced Industrial Science and Technology

On high-level radioactive waste disposal, “Nationwide map of Scientific Features for Geological Disposal” was published and costal area is the favorable from transportation point of view. To evaluate deep groundwater mobility at coastal area, groundwater was sampled from deep borehole at the order of 1000 m in depth. Major ions, tritium, carbon-14, chorine-36 were measured. Based on these results, the groundwaters were categorized into four groups, which are modern meteoric water, modern seawater, glacial meteoric water, fossil sea water. Meteoric water and seawater was divided by 1900 mg/l of Cl concentration. Modern and old groundwater was divided by 10 pMC of $^{14}C$ concentration. The type of seawaters was well categorized into modern seawater and fossil seawater by $^{14}C$ concentration because residence times of modern seawater and fossil seawater are quite different. $^{36}Cl/Cl$ of Modern sea water is equivalent to that of present seawater ($\fallingdotseq 0.7\times10^{-15}$), and that of fossil sea water is higher than that of present seawater. It indicates that $^{36}C/Cl$ of fossil seawater influenced by in-situ production, which takes at least a few ten thousand years. Thus, the category of modern seawater and fossil seawater was validated by not only $^{14}C$ but also $^{36}Cl$. Due to the lack of information, which are shallow groundwater and surface investigation, it could not be confirmed that modern meteoric water and glacial meteoric water was categorized by water isotopes and noble gas temperature. However, it is deduced the origin of Cl of meteoric water is from modern seawater and that of glacial meteoric water is from fossil sea water. It is though that the age of mixing water reflects the groundwater age.

As a result, the deep groundwaters at costal area were categorized into modern meteoric water and modern seawater about 40%, glacial and fossil seawater about 60%.

This study was performed under contracts “Development and Improvement on waste disposal system at coastal area” awarded by the Japanese Ministry of Economy, Trade and Industry.

# Attempt to Estimate permeability of rock mass based on elasticity and resistivity measurement in underground tunnel

*Sota Kawaguchi[1], Tada-nori Goto[1], Koki Kashiwaya[1]

1. Graduate School of Engineering, Kyoto University

Fracture distribution in the rock has a great influence on the groundwater flow. So, it is necessary to grasp its characteristics for resource exploration and geological disposal of radioactive waste. Previous studies have been attempting to grasp the hydraulic characteristics on a local scale using boreholes and the like, but it is considered difficult to grasp the hydraulic characteristics in undrilled areas. In this study, we tried to estimate the permeability of rocks in deep underground from physical property values like resistivity and Young's modulus in order to grasp macroscopic hydraulic characteristics of rock including fracture. The validity of the present estimation method was examined, by comparing this estimated value with the measured value.

The survey area is the research tunnel exposed bedrock (depth 300 m, 500 m) of the Mizunami underground research labolatory of the Japan Atomic Energy Agency, located in Mizunami-city, Gifu Prefecture. In this area, a lot of logging data is published and the fracture distribution in the gallery is also examined in detail.(eg. Ishibashi et al.,2016) Furthermore, permeability of the same rock is measured in 2015 (Sato, 2015). In this study, we measured resistivity using a small electric surveying device (4 pole method with electrode interval of about 10 cm) in addition to these. Young's modulus was measured using a Schmidt-lock hammer.

In this study, the permeability was estimated using a rock physics model. The resistivity was expressed as follows using modified archie’ s law (Katsube and Hume,1983)(1).

$\sigma_{eff}=a\,\sigma_w\,\Phi^m+\sigma_c c$(1)

Where $\sigma_{eff}$ is electrical conductivity of rock, $a$is toriosity, $\sigma_w$ is relectrical conductivity of pore water, $\Phi$is porosity, m is cementation factor, $\sigma_c$ is clay reistivity.The elasticity of rock, was expressed as follows using Gassmann’ s Relation (Gassmann, 1951) added clay effect (2).

$1/K=1/K_m+\Phi/K_w+c/K_c$(2)

Where K is bulk module of rock, $K_m$ is bulk module of mineral, $\Phi$is porosity, $K_w$ is bulk module of pore water, $c$ is clay content, $K_c$ is bulk module of clay. Where K is bulk module of rock, Km is bulk module of mineral, $\Phi$is porosity, $Kw$ is bulk module of pore water, $c$ is clay content, $Kc$ is bulk module of clay. The porosity and the clay content rate were two unknown parameter, and these were determined from the measured values of resistivity and bulk modulus by Nelder-Mead method. Permeability was estimated from Kozeny-Carman's equation (Carman, 1961) for plane crack (3).

$k=\Phi t^2/8\,\tau^2$

k is permeability, $\Phi$is porosity, t is opening width, $\tau$ is tortuosity.

Estimated value of pemeability and measured value are consistent with estimated value and error of about one digit in many rock parts.

We will use other rock physics models like unsaturated pore and data obtained from laboratory experiments and loggingdate to further improve the estimation accuracy of permeability.

# Study on relationship between pathway of groundwater and mass transport, and cooling process of granitic rock

*Eiji Sasao[1], Takashi Yuguchi[2], Masayuki Ishibashi[1]

1. Tono Geoscience Center, Japan Atomic Energy Agency, 2. Faculty of Science, Yamagata University

Fractures in the crystalline rock (e.g. granite) can act as the pathways for groundwater flow and mass transport. Therefore, understanding of the fracture distribution is an important subject for the disposal of high-level nuclear waste. The authors studied the relation between the formation of fracture and infilling mineral, and geological history from the emplacement to present in the Toki granite, Tono district, central Japan (Sasao et al., 2015). Ishibashi et al. (2016a) found that the micropores are selectively formed in plagioclases due to deuteric alteration and that those have the potential of acting as matrix diffusion paths. These results suggest that the magma cooling process played a significant role for the formation and development of the pathways for groundwater flow and mass transport.

The authors studied cooling process of granitic magma in the Toki granite, distributed in the southwestern part of Gifu Prefecture, central Japan, based on petrological, mineralogical and themochronological methodologies. We also discussed the relationship between magma cooling process, and fracture distribution and alteration of biotite and plagioclase (Yuguchi et al., 2019a, 2019b, 2015, 2012, Ishibashi et al., 2016a, 2016b, 2014). In this study, We present the relationship between formation of the pathway of groundwater and mass transport, and cooling process of granitic rock.

# Fracture characterization in the accretionary complex from the view point of mass transfer

*Shinji Takeuchi[1], Chikara Kurata[1], Masakazu Niwa[2], Tadamasa Ueki[2]

1. Department of Earth and Environmental Sciences, College of Humanities & Sciences, Nihon University, 2. Japan Atomic Energy Agency

Introduction
As most of the basement rock of Japan is thought to be composed of accretionary complexes (Kano et al., 1998), accretionary prisms should not be ignored for the site selection of geological disposal of high-level radioactive waste. Because of many discontinuous structures such as faults and fractures formed due to the subduction of the plate in the accretionary complex, radioactive materials may migrate in the discontinuous structure together with the groundwater flow. Therefore, it is important to understand the characteristics of the mass transfer in along the discontinuous structure in the accretionary complex. In this study, we have carried out geological observation, permeability test in the laboratory, etc. using the samples containing discontinuous structures in the Neogene and Pre-Neogene accretionary complex (Takeuchi et al. 2018).

The study areas are Chichibu Belt (Akiruno City, Tokyo) for the Pre-Neogene accretionary complex, and Miura Group Misaki Formation (Miura City, Kanagawa Prefecture) for the Neogene accretionary complex. In the Misaki Formation, plain-less fault (Ijiri et al., 1955) in the mudstone are widely distributed. On the other hand, argillaceous matrix rock in the mélange which characterizes the accretionary complex are widely distributed. An optical microscope, scanning electron microscope (SEM) observation, X-ray fluorescence micro-scanner (XGT) analysis, permeability test, etc. have been were carried out using those samples.

2. Neogene accretionary complex

In the Miura Group Misaki Formation exposed to the southern tip of Miura Peninsula, plain-less faults are widely distributed. It was confirmed by SEM observation and XGT observation that there has been no change in the element distribution, although the host rock was granulated due to a cataclastic fracturing in the fault zone (Takeuchi et al. 2018). The porosity of the host rock and faults has been measured using SEM images. As a result of measurement, the porosity in the fault zone is about 1.2%, and that of the host rock is about 2.7%. In addition, hydraulic conductivity of the host rock without plain-less fault and the specimen perpendicular to the plain-less fault is estimated by the permeability test. As a result, the former is about 6 E - 9 (m / s), and in the latter is about 2E - 8 (m / s). This suggests hydraulic anisotropy in the formation with plain-less fault. From the above results, it is expected that a barrier effect on the mass transfer within the area surrounded by the plain-less fault.

3. Pre-Neogene accretionary complex

As a result of observation of thin sections, scaly cleavage due to shear deformation can be observed in the mudstone. In addition, concentrations of Fe have been confirmed along the cleavage from the XGT analysis. The concentration of Fe (the count number of XGT analysis) perpendicular to the cleavage shows almost restricted to the cleavage part, and diffusion has not been observed in the adjacent area. As a result of permeability test in the laboratory, the hydraulic conductivity parallel to the cleavage is estimated

©2019. Japan Geoscience Union. All Right Reserved. 

about 4E - 8 (m / s), on the other hand, that perpendicular to the cleavage is about 2.5 E-8 (m / s). From the result above, it is assumed that faint hydraulic anisotropy exists in the mudstone matrix part. The reason for the small difference in hydraulic conductivity is thought to be connectivity of the curvature scaly cleavage or the weathering at the surface.

From the above results, it is considered that cleavage planes in the mudstone matrix can be selective migration pathways for mass transfer.

4. Summary

From this study, we have constructed a conceptual model showing the characteristics of material transfer in discontinuous structures in Neogene and Pre-Neogene accretionary complex. In the future, we have to improve the conceptual model from the mass transfer point of view properly by using deeper samples.

# Retardation of Cs and Sr leachings by geopolymer matrices with zeolte and titanate adsorbent

*Kazuma Kuroda[1], Soonthornwiphat Natatsawas[1], Chaerun Raudhatul Islam[1], Hnin Wint Wint Two[1], Kanako Toda[1], Yutaro Kobayashi[1], Tsutomu Sato[2], Tsubasa Otake[2]

1. Graduate school of Engineering, Hokkaido University, 2. Faculty of Engineering, Hokkaido University

After the accident at the Fukushima Daiichi Nuclear Power Station (FDNPS) that occurred due to the Tohoku big earthquake in 2011, contaminated water with radioactive nuclides such as cesium (Cs) and strontium (Sr) have been continuously generated due to cooling of fuel debris by water. Zeolite or titanate adsorbents have been used for removing Cs or Sr from the contaminated water. The spent adsorbents would probably be solidified for the safety storage and disposal. Glass and cement have been proposed for solidifying binder. However, they have some disadvantages such as generation of secondary radioactive waste during vitrification and large amount of waste volume limited by bigger free water volume. Recently, geopolymer is considered as new binder which has potential to solve the above disadvantages for safety disposal of the spent adsorbent. Geopolymer has the potential to decrease total volume of solidified substances comparing cement because amount of containing free water is less than that containing cement. Primary phases of geopolymer such as calcium silicate hydrate (C-S-H) or potassium alumino silicate hydrate (K-A-S-H) may have property for sorbing radioactive nuclides. Furthermore, it is possible to obtain the desirable phases by changing the type and ratio of the starting materials. So, the appropriate primary phases could be designed depending on the type of the radioactive nuclide in disposed radioactive waste. However, there are few data about leaching behavior of radioactive nuclides from geopolymer in real disposal condition. In this context, this study was conducted leaching and sorption experiments to understand the leaching behavior from geopolymer with zeolite or titanate containing Cs or Sr.

In this study, geopolymer samples from mixing of KOH, metakaoline and water glass were investigated in leaching experiments. From the leaching experiments of Cs and Sr from geopolymer with titanate, most of Sr was tightly remained after 90 days even without titanate. This means that K-A-S-H matrix formed after the mixing has high capacity for Sr storage. On the other hand, small part of Cs (around 4%) was leached out after 90 days. However, although it is well known that Cs and Sr are easily leached out from cement matrix (A. El-Kamash, et al., 2006, and M. Takaoka, et al., 2015), K-A-S-H matrix is better in terms of Cs and Ss storage. From sorption experiments of Cs and Sr by using powder C-S-H and K-A-S-H samples as matrix components of cement and geopolymer, it is cleared that K-A-S-H has higher sorption capacity than that of C-S-H. From desorption experiment of Cs and Sr using deionized water from the C-S-H and K-A-S-H, it is cleared that almost of Cs was desorbed from C-S-H even for one day, while 90% of Cs was remained in K-A-S-H under the same condition. Consequently, K-A-S-H matrix in geopolymer has higher retention capacity than that of C-S-H matrix in cement. We conducted safety assessment for geopolymer and cement waste form in pit type disposal system using leaching ratio obtained in this study. From results of the assessment, K-geopolymer would be applicable for safety encapsulation and disposal of Cs and Sr as waste form.

## [H-CG31] Nuclear Energy and Geoscience

convener:Eiji Sasao(Tono Geoscience Center, Japan Atomic Energy Agency), Ryuta Hataya(Central Research Institute of Electric Power Industry), Shinji Takeuchi(Department of Earth and Environmental Sciences, College of Humanities & Sciences, Nihon University), Chairperson:Shinji Takeuchi

Handling of geological hazard assessments represent a major environmental concern in the modern society due to constructing nuclear facilities and their radioactive wastes, and also related to the management of contaminated biosphere after nuclear disasters of Fukushima-Daiichi Nuclear Power Plant. The session rational is to provide a forum to deal with various aspects of scientific and engineering aspects of nuclear power. The session in this year focuses on radioactive waste disposal and covers not only scientific aspect such as characterization of geological environment but also engineering aspects such as microbe-nuclide, mineral-water, and cement-water interactions. In addition to this, themes on seismic hazards at nuclear facilities, environmental behavior of radionuclides emitted from disabled nuclear plants, and volume reduction and reuse of cesium contaminated soils are welcomed. Through these presentations, we aim to promote intercultural communication and collaboration between science, engineering and social science.

Discussion

# Focus points of post-closure monitoring in geological disposal

*Hiroaki Murakami[1], Yusuke Watanabe[1], Kenji Fukuda[1], Teruki Iwatsuki[1]

1. Japan Atomic Energy Agency

To understand geological-environment stability at the deep underground, it is important to understand the hydrochemical disturbance process and its recovery process due to construction, operation and closure of the underground facility. Monitoring after closure of underground facility is effective method to understand the EdZ recovery process, however few studies have been reported on post-closure monitoring. We considered about focus points of post-closure monitoring by using hydrochemical data of groundwater in/around Mizunami Underground Research Laboratory.

As the groundwater level declined due to the construction and operation of the Mizunami URL, mixing of deep high-salinity groundwater and shallow low-salinity groundwater occurred in the monitoring section of conglomerate layer. In this section, groundwater flow will change again as water pressure recovers after closure of the Mizunami URL. Therefore, we should extract hydrogeologically important sections such as the conglomerate layer and select it as the observation section of post-closure monitoring.

An understanding of long-term environmental dynamics of radiocesium, which is released by the TEPCO’s Fukushima Dai-ichi Nuclear Power Plant accident, is a key issue for predicting the future radiocesium distribution and forest products radioactivity in a forested environment, especially $^{137}Cs$ with half-life of 30 years. We compiled the five-years monitoring results of radiocesium input-output budgets in broad-leaved deciduous forests and Japanese cedar evergreen forests of the Abukuma Mountains, Fukushima, Japan. The input-output rates were a few percent of the radiocesium inventory of the monitoring site. In addition, both rates have been decreasing with time. Belowground radiocesium occupied 90% of the total inventory in the Japanese cedar forest on October 2015. The belowground radiocesium was distributed mainly in the topsoil of 0-6 cm depth, approximately 70-80% of the underground inventory on August 2016. These results indicate that the distribution of radiocesium in the forest is similar to the distribution of tree rootlet responsible for absorption of inorganic elements, nutrients, and water. This means long residence time of radiocesium in rooting zone. In the condition of the limited amount of radiocesium input-output rates in the forest, estimation of the migration flux of radiocesium from forest floor to the forest products are considered to be most important issues in the present.

# Problems of geological disposal based on the contaminated water issues at Fukushima Daiichi NPS

*Naoaki Shibasaki[1]

1. Fukushima University

The contaminated water issues at the Fukushima Daiichi Nuclear Power Station (NPS) have not been solved yet even after 8 years since the severe nuclear accident. Many countermeasures against the issues have been implemented, however, the groundwater bypass and frozen soil wall are not effective as expected. This is due to lack of investigations and understanding on the complex geology and hydrogeology at the site. Based on the experience, the author examined the Nationwide Map of Scientific Features for Geological Disposal published in July 2017 by the Ministry of Economy, Trade and Industry, Japan. The map does not show detailed information on groundwater and hydrogeology. The author presents crucial points for geological disposal from the viewpoints of hydrogeology and groundwater flow system.

# Problems of the "Nationwide Map of Scientific Features for Geological Disposal" in Saitama prefecture and storage method of High-level Radioactive Waste (HLW)

*Kazuaki SEKINE[1], Kazuyuki SUENAGA[2], Tadao KOBAYASHI

1. Saitama Prefectural Chichibu High School, 2. SUENAGA Environmental Geology

The "Nationwide Map of Scientific Features for Geological Disposal" was announced by the Agency for Natural Resources and Energy in 2017. Candidate sites for suitable places and inappropriate places for geological disposal are shown by each color. In Saitama prefecture, the linear yellow part extending from the northwest end to the southeast direction is the most prominent unsuitable place. Other areas are mostly suitable.

In the northern part of Saitama Prefecture, there is the Kanto Plain Northwest Rim Fault Zone. The main one is the fault zone represented by the Fukaya fault and the fault zone represented by the Ayasegawa fault. This fault zone is evaluated as follows. The dip is southwest inclination of 50 ˚to 70 ˚(depth less than 500 m) , the width is about 20 to 25 km, the average slip speed is 20 to 40cm / 1,000 years, The latest activity period is after 6,200 years ago, before about 2,500 years ago. When this fault caused an earthquake, the predicted seismic intensity is the maximum magnitude 8.0 (The Headquarters for Earthquake Research Promotion Committee,2005).

The length of the Fukaya fault system is about 80 km (Sugiyama, 2000). According to the criteria of the "Nationwide Map of Scientific Features for Geological Disposal", since the inappropriate place related to the active fault is one hundredth of the length of the fault, the width of the inappropriate area of the Fukaya fault system is about 800 m. Since there is a possibility that the dip of the fault plane is 50 ˚, considering the horizontal spread, there is no sufficient basis for the width of the inappropriate area.

The depth of the epicenter of the earthquake caused by the Fukaya fault and the Ayasegawa fault is estimated to be 17 to 19 km and the magnitude of the earthquake is to be the maximum magnitude of 8.0. The area with seismic intensity of 7 is distributed in Honjo City, Yoshimi Town, etc. Also the intensity 6 is expected to be distributed in wide area in the prefecture. These areas are much wider than the areas that are regarded as inappropriate in the "Nationwide Map of Scientific Features for Geological Disposal". Since the depth of the epicenter is expected to be 17 to 19 km, there is a high possibility that a wide area suffers a strong shake.

Since the geological disposal site could be kept for more than tens of thousands of years, there is a possibility that a new active fault will destroy the site. As a result, the radioactive material leaks out and it is possible that it can be carried to the ground by groundwater. It is pointed out that groundwater flow is the most important requirement for geological disposal of radioactive waste (IAEA, 1977) , but the matter of groundwater flow is not reflected in the " Nationwide Map of Scientific Features for Geological Disposal ". Since the behavior of groundwater is not well understood in deep underground, classification of suitable sites by the "Nationwide Map of Scientific Features for Geological Disposal" requires detailed study of groundwater.

As the "Nationwide Map of Scientific Features for Geological Disposal" has many problems, construction

©2019. Japan Geoscience Union. All Right Reserved. 

of the geological disposal site is not carried out until sufficient safety and understanding of the people are obtained, and it is appropriate to temporarily keep the radioactive waste on the ground etc. (Science Council of Japan, 2012). It seems necessary to seriously consider options other than geological disposal.

1. Japan Atomic Energy Agency, 2. Graduate School of Frontier Sciences, The University of Tokyo

One of the primary issues of the geological disposal technology is to advance the techniques associated with investigation/assessment for long-term uplift and erosion in terrestrial-marine transitional zone in Japan. To examine this issue, it is essential to understand the distribution of seafloor landforms indicating uplift and erosion in the continental shelf, which widely emerged during glacial periods. This study introduces a method for better identification of submerged terraces, some of which are expected to be an indicator of regional tectonics, based on analysis of depth-area distribution of seafloor using digital elevation models constructed from digital bathymetric charts of Japan Hydrographic Association (M7000 series). Case studies of 18 sea areas in Japan show the analysis of depth-area distribution of seafloor works effectively to identify submerged terraces in the continental shelfs dominated by slopes less than 1 degree.
Acknowledgments: This study was carried out under a contract with METI (Ministry of Economy, Trade and Industry) as part of its R&D supporting program for developing geological disposal technology.

Yasue et al. (2014) focused on detached meander cores to estimate an erosional rate in alluvial region with few terraces. However, two subjects, 1) chronology of emergence age, 2) applicability of this method to other region, should be improved. To examine above, this research was conducted along the Totsugawa River in the Kii Peninsula, central Japan. This research contributes to evaluate uplift and erosion during Late Quaternary for site selection and safety assessment of a geological disposal of high-level radioactive waste.

Four sediment cores were collected from three sites of detached meander cores, located at 100 to 120 m above from the river surface, where was suitable for optically stimulated luminescence dating using feldspar (pIRIR) and identification of fluvial channel sediments by main stream. Field survey and sample collection for pIRIR and terrestrial cosmogenic nuclide (TCN) dating, microfossil and tephra analyses were performed at outcrops of alluvial terraces at elevation of 90 to 100 m, located at the downstream of detached meander cores and 40 to 50 m above from the river surface. Moreover, sample collection for pIRIR dating and microfossil analysis was performed at outcrops of marine terraces at elevation of 40 m, located around the river mouth.

Cross-laminated sand bed with rounded gravels was recognized at only one detached meander core at ca 100 m from the river surface. This sediment was interpreted as a fluvial channel sediment by main stream because the well-sorted sand layers indicated stable bed load environments. Sand and gravel beds including weathering angular gravels were mainly composed the other drilling sites. They were interpreted as slope deposits because the matrix, mixture of silt to conglomerate, implied that were provided from small water catchments. Thick (more than 54 m) slope deposits were recognized under the detached meander core at ca 120 m from the river surface. It clearly suggests that this topographic flat surface of detached meander core was not originate by the old fluvial channel.

We would like to conduct pIRIR and TCN dating on the sand samples obtained from drilling cores and outcrops. In addition, we would like to discuss the timing of emergence from river channels by conducting volcanic ash and microfossil analysis in muddy sediments. The integration will improve the estimation of the erosional rate in inland region.

Acknowledgments: This study was carried out under a contract with the Agency of Natural Resources and Energy, part of the Ministry of Economy, Trade and Industry of Japan as part of its R&D program supporting development of technology for geological disposal of high-level radioactive waste.

# Hydrothermal experiment on quartz hydration: Toward a development of new dating method for natural phenomena

*Masakazu Niwa[1], Koji Shimada[1]

1. Japan Atomic Energy Agency

In the field of archaeology, the diffusion of water into quartz exposed to the natural environment has been proposed as a dating method (quartz hydration dating: QHD) applicable to archaeological artifacts. We examined application of QHD to geologic materials to understand natural phenomena crucial for safety assessment of geological disposal, such as uplift and erosion, faulting, and hydrothermal activity.

In this study, hydrothermal experiments were conducted to understand the degree of the diffusion of water into natural quartz included in an exposed rock body. Intact granite samples (Late Cretaceous Kojaku Granite, central Japan) were mirror polished and immersed in deionized water in an autoclave apparatus. We held the samples in the apparatus at controlled temperatures (150˚C or 250˚C) and controlled pressures (9.8 MPa or 25.5 MPa) for 100 hours. The pressurization was performed by $CO_2$ gas (pH in the water is 3.2 to 3.6), or $N_2$ gas. After the experiment, secondary ion intensity of $H^+$ from the quartz surface in the samples was measured by secondary ion mass spectrometry (SIMS). We estimated thickness of hydration layer based on depth profile of $H^+$ intensity.

According to the SIMS measurement, clear increase of $H^+$ concentration within 2 $\mu$m depth from the surface was identified in the experiment at 250˚C and 25.5 MPa. The $H^+$ concentration increased more in the case of the pressurization by $CO_2$ gas than by $N_2$ gas. Based on Ericson et al. (2004, J. Archaeol. Sci.), diffusion coefficient on water uptake of quartz was calculated from the depth profile of $H^+$ concentration by fitting with complementary error function. The calculated diffusion coefficient was consistent with values from archaeological artifacts and synthetic crystals reported by previous studies. Development of hydration layer of maximum thickness several $\mu$m in quartz is possible for a ten thousand year, according to the estimation from diffusion coefficient at ambient temperature calculated by extrapolation based on the Arrhenius equation. Thus, the QHD can be promising as a new tool to understand natural phenomena.

In contrast, no clear increase of $H^+$ concentration was identified in the experiment at 150˚C. According to the estimation from diffusion coefficient at 150˚C calculated by extrapolation based on the Arrhenius equation, this infers that the hydration layer was too thin to detect by SIMS.

This study was carried out under a contract with Ministry of Economy, Trade and Industry of Japan as part of its R&D supporting program for developing geological disposal technology.

# Diffusion Coefficient and Porosity of Granite for Evaluation of Mobility Parameter

*Kenji Fukuda[1], Hiroaki Murakami[1], Kaori Itai[2], Masayuki Ishibashi[1], Eiji Sasao[1]

1. Japan Atomic Energy Agency, 2. C・TECH corporation

Matrix diffusion is one of the important for evaluating solute transport in granite. Diffusion of ions in granite pore water was studied in order to evaluate diffusivity in rock. Effective diffusion coefficient of uranine was measured using a diffusion cell. The effective diffusion coefficient of uranine in granite without fissure and alteration was found to be in the range $10^{-15}$ to $10^{-13}$ $m^2$ $s^{-1}$. The porosities of the granite samples were determined by observation of petrographic thin sections using entity fluorescence microscope. There was a positive correlation between the porosity larger than 1% and the effective diffusion coefficient.

Keywords: granite, Effective diffusion coefficient, uranine, porosity

# Hydrogeological structure of hydraulic conductive fractures in gallery scale and their rock matrix

*Ai Hamada[1]

1. Central Research Institute of Electric Power Industry

In geological disposal of high-level nuclear waste, hydraulic conductive fractures in crystalline rock such as granite have been considered as a main pathway for radionuclides. Diffusion and absorption of radionuclide through microstructure in rock matrix can make mass transport to retard. Because the change of the characteristics of microstructure in rock matrix by structural movement and hydrothermal alteration have an effect on mass transport, it is important to understand the distribution and the structures of hydrogeological continuity of fractures as well as their characteristics of microstructure in rock matrix.
The characteristics of hydraulic conductive fractures and their microstructure in rock matrix across multiple boreholes to the west side of the gallery at 300 m depth of Mizunami Underground Laboratory are summarized as follows, hydraulic conductive fractures, which mainly show NW strike and high dip angle, have two types of characteristics: calcite-filled fractures with highly matrix chloritization and fractures with poor filling minerals which is formed along cataclastic texture. The transmissibility coefficients in both types of fractures are measured about $10^{-7}$-$10^{-5}m^2/s$. They make hydraulic conductive zone connected by low dip angle fractures, which is distributed around the Upper fracture zone in Toki Granite. On the other hand, hydraulic conductive fractures on the east side of the gallery at 300 m depth, according to the investigation of 2 boreholes about 40 m each, tend to have smaller inflow, higher alteration in rock matrix and filling minerals in fractures compared to the west side. According to the result of borehole TV observation of the borehole which has larger inflow, the direction of fractures shows NW and NE strike with high dip angle and also low dip angle fractures the same as the west side of the gallery. As a result of scanning with the X-ray CT, a higher density mineral than the surroundings is filling the fractures with partly opened part. The distribution of fracture-filling minerals can be caused a low permeability at the east side of the gallery compared to the west.
This study is commissioned by the Agency for Natural Resources and Energy in the Ministry of Economy, Trade and Industry. Core sampling were conducted as a part of a collaborative research with JAEA.

## [H-CG31] Nuclear Energy and Geoscience

convener:Eiji Sasao(Tono Geoscience Center, Japan Atomic Energy Agency), Ryuta Hataya(Central Research Institute of Electric Power Industry), Shinji Takeuchi(Department of Earth and Environmental Sciences, College of Humanities & Sciences, Nihon University)

Handling of geological hazard assessments represent a major environmental concern in the modern society due to constructing nuclear facilities and their radioactive wastes, and also related to the management of contaminated biosphere after nuclear disasters of Fukushima-Daiichi Nuclear Power Plant. The session rational is to provide a forum to deal with various aspects of scientific and engineering aspects of nuclear power. The session in this year focuses on radioactive waste disposal and covers not only scientific aspect such as characterization of geological environment but also engineering aspects such as microbe-nuclide, mineral-water, and cement-water interactions. In addition to this, themes on seismic hazards at nuclear facilities, environmental behavior of radionuclides emitted from disabled nuclear plants, and volume reduction and reuse of cesium contaminated soils are welcomed. Through these presentations, we aim to promote intercultural communication and collaboration between science, engineering and social science.

# Better identification of submerged terraces based on digital terrain analysis

*Hiura Yuki[1], Tetsuya Komatsu[1], Toshihiko Sugai[2]

1. Japan Atomic Energy Agency, 2. Graduate School of Frontier Sciences, The University of Tokyo

One of the primary issues of the geological disposal technology is to advance the techniques associated with investigation/assessment for long-term uplift and erosion in terrestrial-marine transitional zone in Japan. To examine this issue, it is essential to understand the distribution of seafloor landforms indicating uplift and erosion in the continental shelf, which widely emerged during glacial periods. This study introduces a method for better identification of submerged terraces, some of which are expected to be an indicator of regional tectonics, based on analysis of depth-area distribution of seafloor using digital elevation models constructed from digital bathymetric charts of Japan Hydrographic Association (M7000 series). Case studies of 18 sea areas in Japan show the analysis of depth-area distribution of seafloor works effectively to identify submerged terraces in the continental shelfs dominated by slopes less than 1 degree.
Acknowledgments: This study was carried out under a contract with METI (Ministry of Economy, Trade and Industry) as part of its R&D supporting program for developing geological disposal technology.

1. Japan Atomic Energy Agency, 2. Chuo Kaihatsu Corporation

Yasue et al. (2014) focused on detached meander cores to estimate an erosional rate in alluvial region with few terraces. However, two subjects, 1) chronology of emergence age, 2) applicability of this method to other region, should be improved. To examine above, this research was conducted along the Totsugawa River in the Kii Peninsula, central Japan. This research contributes to evaluate uplift and erosion during Late Quaternary for site selection and safety assessment of a geological disposal of high-level radioactive waste.

Four sediment cores were collected from three sites of detached meander cores, located at 100 to 120 m above from the river surface, where was suitable for optically stimulated luminescence dating using feldspar (pIRIR) and identification of fluvial channel sediments by main stream. Field survey and sample collection for pIRIR and terrestrial cosmogenic nuclide (TCN) dating, microfossil and tephra analyses were performed at outcrops of alluvial terraces at elevation of 90 to 100 m, located at the downstream of detached meander cores and 40 to 50 m above from the river surface. Moreover, sample collection for pIRIR dating and microfossil analysis was performed at outcrops of marine terraces at elevation of 40 m, located around the river mouth.

Cross-laminated sand bed with rounded gravels was recognized at only one detached meander core at ca 100 m from the river surface. This sediment was interpreted as a fluvial channel sediment by main stream because the well-sorted sand layers indicated stable bed load environments. Sand and gravel beds including weathering angular gravels were mainly composed the other drilling sites. They were interpreted as slope deposits because the matrix, mixture of silt to conglomerate, implied that were provided from small water catchments. Thick (more than 54 m) slope deposits were recognized under the detached meander core at ca 120 m from the river surface. It clearly suggests that this topographic flat surface of detached meander core was not originate by the old fluvial channel.

We would like to conduct pIRIR and TCN dating on the sand samples obtained from drilling cores and outcrops. In addition, we would like to discuss the timing of emergence from river channels by conducting volcanic ash and microfossil analysis in muddy sediments. The integration will improve the estimation of the erosional rate in inland region.

Acknowledgments: This study was carried out under a contract with the Agency of Natural Resources and Energy, part of the Ministry of Economy, Trade and Industry of Japan as part of its R&D program supporting development of technology for geological disposal of high-level radioactive waste.

# Hydrothermal experiment on quartz hydration: Toward a development of new dating method for natural phenomena

*Masakazu Niwa[1], Koji Shimada[1]

1. Japan Atomic Energy Agency

In the field of archaeology, the diffusion of water into quartz exposed to the natural environment has been proposed as a dating method (quartz hydration dating: QHD) applicable to archaeological artifacts. We examined application of QHD to geologic materials to understand natural phenomena crucial for safety assessment of geological disposal, such as uplift and erosion, faulting, and hydrothermal activity.

In this study, hydrothermal experiments were conducted to understand the degree of the diffusion of water into natural quartz included in an exposed rock body. Intact granite samples (Late Cretaceous Kojaku Granite, central Japan) were mirror polished and immersed in deionized water in an autoclave apparatus. We held the samples in the apparatus at controlled temperatures (150˚C or 250˚C) and controlled pressures (9.8 MPa or 25.5 MPa) for 100 hours. The pressurization was performed by $CO_2$ gas (pH in the water is 3.2 to 3.6), or $N_2$ gas. After the experiment, secondary ion intensity of $H^+$ from the quartz surface in the samples was measured by secondary ion mass spectrometry (SIMS). We estimated thickness of hydration layer based on depth profile of $H^+$ intensity.

According to the SIMS measurement, clear increase of $H^+$ concentration within 2 $\mu$m depth from the surface was identified in the experiment at 250˚C and 25.5 MPa. The $H^+$ concentration increased more in the case of the pressurization by $CO_2$ gas than by $N_2$ gas. Based on Ericson et al. (2004, J. Archaeol. Sci.), diffusion coefficient on water uptake of quartz was calculated from the depth profile of $H^+$ concentration by fitting with complementary error function. The calculated diffusion coefficient was consistent with values from archaeological artifacts and synthetic crystals reported by previous studies. Development of hydration layer of maximum thickness several $\mu$m in quartz is possible for a ten thousand year, according to the estimation from diffusion coefficient at ambient temperature calculated by extrapolation based on the Arrhenius equation. Thus, the QHD can be promising as a new tool to understand natural phenomena.

In contrast, no clear increase of $H^+$ concentration was identified in the experiment at 150˚C. According to the estimation from diffusion coefficient at 150˚C calculated by extrapolation based on the Arrhenius equation, this infers that the hydration layer was too thin to detect by SIMS.

This study was carried out under a contract with Ministry of Economy, Trade and Industry of Japan as part of its R&D supporting program for developing geological disposal technology.

# Diffusion Coefficient and Porosity of Granite for Evaluation of Mobility Parameter

*Kenji Fukuda[1], Hiroaki Murakami[1], Kaori Itai[2], Masayuki Ishibashi[1], Eiji Sasao[1]

1. Japan Atomic Energy Agency, 2. C・TECH corporation

Matrix diffusion is one of the important for evaluating solute transport in granite. Diffusion of ions in granite pore water was studied in order to evaluate diffusivity in rock. Effective diffusion coefficient of uranine was measured using a diffusion cell. The effective diffusion coefficient of uranine in granite without fissure and alteration was found to be in the range $10^{-15}$ to $10^{-13}$ $m^2$ $s^{-1}$. The porosities of the granite samples were determined by observation of petrographic thin sections using entity fluorescence microscope. There was a positive correlation between the porosity larger than 1% and the effective diffusion coefficient.

# Hydrogeological structure of hydraulic conductive fractures in gallery scale and their rock matrix

*Ai Hamada[1]

1. Central Research Institute of Electric Power Industry

In geological disposal of high-level nuclear waste, hydraulic conductive fractures in crystalline rock such as granite have been considered as a main pathway for radionuclides. Diffusion and absorption of radionuclide through microstructure in rock matrix can make mass transport to retard. Because the change of the characteristics of microstructure in rock matrix by structural movement and hydrothermal alteration have an effect on mass transport, it is important to understand the distribution and the structures of hydrogeological continuity of fractures as well as their characteristics of microstructure in rock matrix.
The characteristics of hydraulic conductive fractures and their microstructure in rock matrix across multiple boreholes to the west side of the gallery at 300 m depth of Mizunami Underground Laboratory are summarized as follows, hydraulic conductive fractures, which mainly show NW strike and high dip angle, have two types of characteristics: calcite-filled fractures with highly matrix chloritization and fractures with poor filling minerals which is formed along cataclastic texture. The transmissibility coefficients in both types of fractures are measured about $10^{-7}$-$10^{-5}m^2/s$. They make hydraulic conductive zone connected by low dip angle fractures, which is distributed around the Upper fracture zone in Toki Granite. On the other hand, hydraulic conductive fractures on the east side of the gallery at 300 m depth, according to the investigation of 2 boreholes about 40 m each, tend to have smaller inflow, higher alteration in rock matrix and filling minerals in fractures compared to the west side. According to the result of borehole TV observation of the borehole which has larger inflow, the direction of fractures shows NW and NE strike with high dip angle and also low dip angle fractures the same as the west side of the gallery. As a result of scanning with the X-ray CT, a higher density mineral than the surroundings is filling the fractures with partly opened part. The distribution of fracture-filling minerals can be caused a low permeability at the east side of the gallery compared to the west.
This study is commissioned by the Agency for Natural Resources and Energy in the Ministry of Economy, Trade and Industry. Core sampling were conducted as a part of a collaborative research with JAEA.

## [H-CG34] Education and research for rehabilitation of agriculture against harmful rumors in nuclear disaster areas

convener:Masaru Mizoguchi(Graduate school of Agricultural and Life Sciences, The University of Tokyo)

Since the eastern Japan earthquake, various universities are carrying out educational programs that take students to the field and let the students recognize the importance of picking up on-site needs from the real field. This session convener also went to Iitate Village in Fukushima Prefecture three months after the nuclear accident, and continues a unique activities in cooperation with NPO and farmers. In this session, university's teachers will report changes in student's consciousness observed through on-site education and field research, and discuss social value of university.

# Calculation of water and sediment discharge from a small forested catchment for evaluating load of the particulate radioactive cesium

*Takuhei Yamasaki[1], Shoichiro Hamamoto[1], Taku Nishimura[1]

1. University of Tokyo

Vast amount of radionuclides was released into the environments by the accident of the Fukushima Dai-ichi Nuclear Power Plant (FDNPP) on March 2011. By 2018, decontamination of deposited radionuclides in the agricultural and residential areas has completed except for a zone with high air-dose rate near the FDNPP. Forested areas, however, are not planned to decontaminate radionuclides. Hence, dynamics of radionuclides, especially radioactive cesium (RCs), in forests are major concern for not only human health (external exposure), but also recontamination in the decontaminated areas (downstream migration).
Total RCs discharge for a year from the forested areas was generally small, less than 1% of the catchment deposition. However, once a large storm event occurs, RCs adsorbing on the fine sediments such as clay and silt particles and organic matter (called particulate RCs) was eroded and released into the river. Production and movement of particulate RCs were controlled by the soil erosion process, which has been well studied for a long time. Hence, it is expected that RCs discharge from a catchment can be estimated by evaluating the sediment runoff from the catchment. The aim of our study is to verify our hypothesis.

Method
Study site is located at the southeast part of the Iitate village, Fukushima Prefecture. Catchment area is 56 ha. Catchment geology was weathered granite, and whole catchment is covered with mixed forest. At the basin outlet, we measured water runoff and turbidity in every 10 min, and sampled channel water when water level exceeds threshold value due to rainfall events.
We used process based soil erosion model, GeoWEPP (Renschler, 2003), to evaluate sediment yield from the catchment. This model requires four types of input data, climate, topography, land use, and soil data. Climate data was based on the observed temperature and rainfall depth at the study site. The other weather data, daily solar radiation, wind velocity and dew point, was collected from the AMeDAS Iitate or Fukushima. Topography data was made with DEM provided by Geospatial Information Authority of Japan. Land use was set to “forest”, pre-set parameter set in GeoWEPP. Soil hydraulic parameter was fitted to reproduce observed daily direct runoff, since soil erosion mainly occurs during high flow periods just after the rainfall event. Soil erodibility was set as a granitic forest soil and channel calibrated by the gauged station with granitic rock in central Japan. Calibration was done using observed data in 2016, and fitted parameters were validated with 2017 data.

Results and Discussion
GeoWEPP well reproduced the daily channel discharge for most rainfall events in both calibration and validation year. At the typhoon event in 2017, however, model overestimated the observed runoff. This is partly because GeoWEPP is not a flood runoff model.
In calculation, sediment yield at the outlet occurred during middle to large storm events. However, sediment production during small events was not well reproduced, though SS load at the small rainfall event was small for annual total load. Since sediment production process may depend on the scale of the rainfall event, we should set the another soil erodibility to reproduce the sediment production for the small rainfall events.
Sediment production mainly occurred at the channel section. In hillslope section, soil loss area was

©2019. Japan Geoscience Union. All Right Reserved. 

limited near the channel section. This implies that RCs in most forested areas is immobile due to the low soil erodibility in the forested area. However, once vegetation at the forest floor and surface organic matter were removed by the inappropriate forest management, RCs mobility in the catchment would increase.

# Radiocesium Inter-Annual Variations and Spatial Dynamics in Watershed in Iitate, Fukushima, Japan

*Saito Mari[1], Kazutoshi Osawa[1], Naoto Nihei[2]

1. Utsunomiya University, 2. Tokyuo University

A large amount of radiocesium, $^{137}$Cs and $^{134}$Cs, were released and deposited on the soil surface due to the accident at Fukushima Daiichi Nuclear Power Plant, FDNPP, due to the Great East Japan Earthquake that occurred on March 11, 2011. Among them, $^{137}$Cs is easily absorbed by clay minerals and soil organic matter, and its physical half-life is 30.2 years. $^{137}$Cs are redistributed to waterways, rivers, lakes and coastal areas by rainfall-runoff process, so long-term influences on residents' lives and agricultural, forestry and fishery products in the area surrounding the accident are concerned. In order to evaluate the influence of secondary contamination of $^{137}$Cs, it is necessary to grasp the temporal and spatial dynamics in the watershed including areas with high $^{137}$Cs deposits.

In this study, fixed point observations was conducted on two rivers, Hiso river and Mano river, in Iitate village, Fukushima Prefecture from 2013 to 2018. In addition, multiple observation points were set up in watersheds, and simultaneous water sampling was done at multiple points. We measured SS concentration and $^{137}$Cs concentration from water samples, grasped the long-term change in $^{137}$Cs runoff, and identified the catchment area where $^{137}$Cs runoff was noticeable.

The $^{137}$Cs concentration of SS dropped drastically with extreme large flood due to Typhoon Etau in 2015, and the concentration remained low until 2018. The same result was obtained in 2018. In Hiso river, $^{137}$Cs concentration of SS in 2018 increased slightly compared to 2017. This is thought to be the effect of the decontamination work in the Nagadoro district.

As a result of simultaneous multipoint observation, spatial distribution of $^{137}$Cs concentration in the watershed was changing as merging the branch streams into the main stream. In addition, it was revealed that sediment with high $^{137}$Cs concentration flowed in from Nagadoro district where decontamination works was incomplete.

# Efforts in university to keep consciousness of disaster caused by The Great East Japan Earthquake for resurrection of agriculture at Iitate village

*Junko NISHIWAKI[1], Masaru Mizoguchi[2]

1. College of Agriculture, Ibaraki University, 2. Graduate School of Agricultural and Life Sciences, The University of Tokyo

After the Great East Japan Earthquake, the revival of agriculture, the various countermeasures have been conducted for resurrection of agriculture and rural community at the disaster area. On the other hand, the consciousness of the damage caused by the disaster is decreasing, and a lot of people tended not to consider disaster area and the life in such area. The recovery on the mental side of people who live in disaster area is important to the revival from the disaster in addition to recovery of the hardware such as the infrastructure. For that reason, the actual information should be sharing between inside and outside the disaster area, and it is necessary to push forward mutual understanding to get rid of the feeling of being estranged that the inhabitants of the disaster area feel. In addition, to prevent weathering of the consciousness is important for without forgetting disaster prevention awareness to a possible disaster in future.
Authors have held some field trips and rice planting and harvesting events in Iitate village, Fukushima to be able to grasp the situation of the earthquake disaster and really feel efforts of the reconstruction of the area for the people who attended the events by a meeting and cooperation of local farmers and the authorized NPO corporation Resurrection of Fukushima. As university staffs, we are inviting the student participants in the field trips and events to have a young generation know the tragic situation after the disaster and strength of inhabitants overcoming the damage. We want students to think about what could we do and what should we do for recovering this situation as an own problem. We also assign a report problem to think what agricultural science can do for solving the problems in Fukushima for students, after our classes about the actions of the experts in the disaster area from the field of agriculture.
The events in Iitate village had planned since 2013 with farmers in Iitate to listen the real story from those farmers. In our classes, we introduce the soil physical and agricultural engineering way to remove radioactive materials and efforts by other specialized fields. Various useful opinions for resurrection of Iitate agriculture are suggested by students. In this presentation, we introduce the contents of field trips and events, class lecture and some feelings and opinions from students.

# Effects of remaining radiocesium in bunds and slopes of paddy fields on ambient dose and downstream environment.

*Yoshida Shuichiro[1], Kazuhiro Nishida[1], Taku Fukui[1]

1. The University of Tokyo

After the devastating contamination by radionuclides in Iltate Village, removal of the contaminated surface soil from the farmlands was performed over the village. However, the paddy bunds, banks or slopes of the irrigation/drainage canals have not been subject to the removal of contaminated surface soil because of the cost to recover them. This study aimed to show the quantitative influence of these 'semi-contaminated ground' as the source of gamma beam and the contamination of downstream water.

First, we analyzed the dose rates regularly monitored by Iitate village every two weeks since 2011 at 18 points within the village, where the decontamination works were conducted during the period. From the temporal change of the dose rate, the decrease in dose rate due to the decontamination work was evaluated at each point. The spherical views around the monitoring points of dose rate was captured by a 360-degree camera (Ricoh Theta), to evaluate the ratio of solid angle for the contaminated and decontaminated surface. The woods, paddy bunds, banks or slopes were regarded as the contaminated surface, while the buildings, farmlands or paved roads were classified to the decontaminated surface.

The percentage of the dose rate reduction by the decontamination works ranged between 31% and 83% depending on the land use around the points. The dose rate reduction is negatively correlated to the ratio of the solid angle of the contaminated surfaces from the monitoring points. Thus, the bunds, banks, or slopes, where the decontamination have not covered, are functioning as the ambient source of gamma beam to the monitoring points.

Second, we measured radiocesium effluence from the slopes of a drainage canal beside paddy fields in Iitate Village. The four of five slopes were covered with weeds which have been regularly cut; the other is bushed and has trees. The contaminated surface soil of the all slopes was not removed. The total radiocesium inventory estimated by scintillation survey meter ranged between 350 and 400 $kBqm^{-2}$. The radiocesium was mainly distributed within upper 5cm of the mineral soil layer. Metal gutters were installed at the bottom of the slopes, from which the water flowing over the slopes was collected and led to the storing tanks. The water in the tank was collected to the other tanks and taken to the laboratory on 10 Aug. 2018 and 26 Oct 2018. The water samples containing contaminated sediments were filtrated by glass filters with 440 $\mu$m opening followed by membrane filter with 0.45 $\mu$m opening. The dissolved form of radiocesium in the filtrates were removed by the special cartridge. After drying and weighing, the radiocesium on the filters and cartridges were measured by Ge semi-conductor detector run by RI Research and Education Center in the Graduate School of Agricultural and Life Sciences, The University of Tokyo.

The radiocesium effluence rate from the slopes under 550 mm of total rainfall during the measured period ranged from 0.13 to 1.50 $Bqm^{-2}$. The effluence rate of suspended particles ranged as little as 0.08 $gm^{-2}$. Corresponding to this result, the ratio of particulate form of radiocesium tended to be less although the water flow over the slopes probably occurred under the intense rainfalls. Although the measured radiocesium effluence rate was too little to affect the radiocesium concentration in the downstream river

©2019. Japan Geoscience Union. All Right Reserved. 

water, it should be noted that we should monitor the radiocesium effluence from bared or collapsing slopes which can be the potential source of radiocesium to the downstream area.

# Calculation of water and sediment discharge from a small forested catchment for evaluating load of the particulate radioactive cesium

*Takuhei Yamasaki[1], Shoichiro Hamamoto[1], Taku Nishimura[1]

1. University of Tokyo

Vast amount of radionuclides was released into the environments by the accident of the Fukushima Dai-ichi Nuclear Power Plant (FDNPP) on March 2011. By 2018, decontamination of deposited radionuclides in the agricultural and residential areas has completed except for a zone with high air-dose rate near the FDNPP. Forested areas, however, are not planned to decontaminate radionuclides. Hence, dynamics of radionuclides, especially radioactive cesium (RCs), in forests are major concern for not only human health (external exposure), but also recontamination in the decontaminated areas (downstream migration).
Total RCs discharge for a year from the forested areas was generally small, less than 1% of the catchment deposition. However, once a large storm event occurs, RCs adsorbing on the fine sediments such as clay and silt particles and organic matter (called particulate RCs) was eroded and released into the river. Production and movement of particulate RCs were controlled by the soil erosion process, which has been well studied for a long time. Hence, it is expected that RCs discharge from a catchment can be estimated by evaluating the sediment runoff from the catchment. The aim of our study is to verify our hypothesis.

Method
Study site is located at the southeast part of the Iitate village, Fukushima Prefecture. Catchment area is 56 ha. Catchment geology was weathered granite, and whole catchment is covered with mixed forest. At the basin outlet, we measured water runoff and turbidity in every 10 min, and sampled channel water when water level exceeds threshold value due to rainfall events.
We used process based soil erosion model, GeoWEPP (Renschler, 2003), to evaluate sediment yield from the catchment. This model requires four types of input data, climate, topography, land use, and soil data. Climate data was based on the observed temperature and rainfall depth at the study site. The other weather data, daily solar radiation, wind velocity and dew point, was collected from the AMeDAS Iitate or Fukushima. Topography data was made with DEM provided by Geospatial Information Authority of Japan. Land use was set to “forest”, pre-set parameter set in GeoWEPP. Soil hydraulic parameter was fitted to reproduce observed daily direct runoff, since soil erosion mainly occurs during high flow periods just after the rainfall event. Soil erodibility was set as a granitic forest soil and channel calibrated by the gauged station with granitic rock in central Japan. Calibration was done using observed data in 2016, and fitted parameters were validated with 2017 data.

Results and Discussion
GeoWEPP well reproduced the daily channel discharge for most rainfall events in both calibration and validation year. At the typhoon event in 2017, however, model overestimated the observed runoff. This is partly because GeoWEPP is not a flood runoff model.
In calculation, sediment yield at the outlet occurred during middle to large storm events. However, sediment production during small events was not well reproduced, though SS load at the small rainfall event was small for annual total load. Since sediment production process may depend on the scale of the rainfall event, we should set the another soil erodibility to reproduce the sediment production for the small rainfall events.
Sediment production mainly occurred at the channel section. In hillslope section, soil loss area was

©2019. Japan Geoscience Union. All Right Reserved. 

limited near the channel section. This implies that RCs in most forested areas is immobile due to the low soil erodibility in the forested area. However, once vegetation at the forest floor and surface organic matter were removed by the inappropriate forest management, RCs mobility in the catchment would increase.

# Radiocesium Inter-Annual Variations and Spatial Dynamics in Watershed in Iitate, Fukushima, Japan

*Saito Mari[1], Kazutoshi Osawa[1], Naoto Nihei[2]

1. Utsunomiya University, 2. Tokyuo University

A large amount of radiocesium, $^{137}$Cs and $^{134}$Cs, were released and deposited on the soil surface due to the accident at Fukushima Daiichi Nuclear Power Plant, FDNPP, due to the Great East Japan Earthquake that occurred on March 11, 2011. Among them, $^{137}$Cs is easily absorbed by clay minerals and soil organic matter, and its physical half-life is 30.2 years. $^{137}$Cs are redistributed to waterways, rivers, lakes and coastal areas by rainfall-runoff process, so long-term influences on residents' lives and agricultural, forestry and fishery products in the area surrounding the accident are concerned. In order to evaluate the influence of secondary contamination of $^{137}$Cs, it is necessary to grasp the temporal and spatial dynamics in the watershed including areas with high $^{137}$Cs deposits.

In this study, fixed point observations was conducted on two rivers, Hiso river and Mano river, in Iitate village, Fukushima Prefecture from 2013 to 2018. In addition, multiple observation points were set up in watersheds, and simultaneous water sampling was done at multiple points. We measured SS concentration and $^{137}$Cs concentration from water samples, grasped the long-term change in $^{137}$Cs runoff, and identified the catchment area where $^{137}$Cs runoff was noticeable.

The $^{137}$Cs concentration of SS dropped drastically with extreme large flood due to Typhoon Etau in 2015, and the concentration remained low until 2018. The same result was obtained in 2018. In Hiso river, $^{137}$Cs concentration of SS in 2018 increased slightly compared to 2017. This is thought to be the effect of the decontamination work in the Nagadoro district.

As a result of simultaneous multipoint observation, spatial distribution of $^{137}$Cs concentration in the watershed was changing as merging the branch streams into the main stream. In addition, it was revealed that sediment with high $^{137}$Cs concentration flowed in from Nagadoro district where decontamination works was incomplete.

# Efforts in university to keep consciousness of disaster caused by The Great East Japan Earthquake for resurrection of agriculture at Iitate village

*Junko NISHIWAKI[1], Masaru Mizoguchi[2]

1. College of Agriculture, Ibaraki University, 2. Graduate School of Agricultural and Life Sciences, The University of Tokyo

After the Great East Japan Earthquake, the revival of agriculture, the various countermeasures have been conducted for resurrection of agriculture and rural community at the disaster area. On the other hand, the consciousness of the damage caused by the disaster is decreasing, and a lot of people tended not to consider disaster area and the life in such area. The recovery on the mental side of people who live in disaster area is important to the revival from the disaster in addition to recovery of the hardware such as the infrastructure. For that reason, the actual information should be sharing between inside and outside the disaster area, and it is necessary to push forward mutual understanding to get rid of the feeling of being estranged that the inhabitants of the disaster area feel. In addition, to prevent weathering of the consciousness is important for without forgetting disaster prevention awareness to a possible disaster in future.
Authors have held some field trips and rice planting and harvesting events in Iitate village, Fukushima to be able to grasp the situation of the earthquake disaster and really feel efforts of the reconstruction of the area for the people who attended the events by a meeting and cooperation of local farmers and the authorized NPO corporation Resurrection of Fukushima. As university staffs, we are inviting the student participants in the field trips and events to have a young generation know the tragic situation after the disaster and strength of inhabitants overcoming the damage. We want students to think about what could we do and what should we do for recovering this situation as an own problem. We also assign a report problem to think what agricultural science can do for solving the problems in Fukushima for students, after our classes about the actions of the experts in the disaster area from the field of agriculture.
The events in Iitate village had planned since 2013 with farmers in Iitate to listen the real story from those farmers. In our classes, we introduce the soil physical and agricultural engineering way to remove radioactive materials and efforts by other specialized fields. Various useful opinions for resurrection of Iitate agriculture are suggested by students. In this presentation, we introduce the contents of field trips and events, class lecture and some feelings and opinions from students.

# Effects of remaining radiocesium in bunds and slopes of paddy fields on ambient dose and downstream environment.

*Yoshida Shuichiro[1], Kazuhiro Nishida[1], Taku Fukui[1]

1. The University of Tokyo

After the devastating contamination by radionuclides in Iltate Village, removal of the contaminated surface soil from the farmlands was performed over the village. However, the paddy bunds, banks or slopes of the irrigation/drainage canals have not been subject to the removal of contaminated surface soil because of the cost to recover them. This study aimed to show the quantitative influence of these 'semi-contaminated ground' as the source of gamma beam and the contamination of downstream water.

First, we analyzed the dose rates regularly monitored by Iitate village every two weeks since 2011 at 18 points within the village, where the decontamination works were conducted during the period. From the temporal change of the dose rate, the decrease in dose rate due to the decontamination work was evaluated at each point. The spherical views around the monitoring points of dose rate was captured by a 360-degree camera (Ricoh Theta), to evaluate the ratio of solid angle for the contaminated and decontaminated surface. The woods, paddy bunds, banks or slopes were regarded as the contaminated surface, while the buildings, farmlands or paved roads were classified to the decontaminated surface.

The percentage of the dose rate reduction by the decontamination works ranged between 31% and 83% depending on the land use around the points. The dose rate reduction is negatively correlated to the ratio of the solid angle of the contaminated surfaces from the monitoring points. Thus, the bunds, banks, or slopes, where the decontamination have not covered, are functioning as the ambient source of gamma beam to the monitoring points.

Second, we measured radiocesium effluence from the slopes of a drainage canal beside paddy fields in Iitate Village. The four of five slopes were covered with weeds which have been regularly cut; the other is bushed and has trees. The contaminated surface soil of the all slopes was not removed. The total radiocesium inventory estimated by scintillation survey meter ranged between 350 and 400 $kBqm^{-2}$. The radiocesium was mainly distributed within upper 5cm of the mineral soil layer. Metal gutters were installed at the bottom of the slopes, from which the water flowing over the slopes was collected and led to the storing tanks. The water in the tank was collected to the other tanks and taken to the laboratory on 10 Aug. 2018 and 26 Oct 2018. The water samples containing contaminated sediments were filtrated by glass filters with 440 $\mu$m opening followed by membrane filter with 0.45 $\mu$m opening. The dissolved form of radiocesium in the filtrates were removed by the special cartridge. After drying and weighing, the radiocesium on the filters and cartridges were measured by Ge semi-conductor detector run by RI Research and Education Center in the Graduate School of Agricultural and Life Sciences, The University of Tokyo.

The radiocesium effluence rate from the slopes under 550 mm of total rainfall during the measured period ranged from 0.13 to 1.50 $Bqm^{-2}$. The effluence rate of suspended particles ranged as little as 0.08 $gm^{-2}$. Corresponding to this result, the ratio of particulate form of radiocesium tended to be less although the water flow over the slopes probably occurred under the intense rainfalls. Although the measured radiocesium effluence rate was too little to affect the radiocesium concentration in the downstream river

©2019. Japan Geoscience Union. All Right Reserved. 

water, it should be noted that we should monitor the radiocesium effluence from bared or collapsing slopes which can be the potential source of radiocesium to the downstream area.

Discussion

# Education and research for rehabilitation of agriculture against harmful rumors in nuclear disaster areas

*Masaru Mizoguchi[1]

1. Graduate school of Agricultural and Life Sciences, The University of Tokyo

Since the eastern Japan earthquake of 2011, various universities are carrying out educational programs that take students to the field and let the students recognize the importance of picking up on-site needs from the real field. This session convener also went to Iitate Village in Fukushima Prefecture three months after the nuclear accident, developed a unique agricultural land decontamination method in cooperation with NPO corporations and farmers, and has been experimentally cultivating crops. Also, since 2012, we have held students' field tours and have witnessed changes in student's awareness before and after the local visit. Through these experiences, we have come to the idea that it is necessary to nurture young people who will challenge the creation of a new Japanese type agriculture in Fukushima. "Educational research program for revitalizing agriculture and elimination of bad rumor in Iitate village" is being carried out at the Ministry of Education, Culture, Sports, Science and Technology's "Fukushima Innovation Coast Concept Promotion Project. In this session, members of the Japanese Society of Soil Physics will report changes in student’s consciousness observed through on-site education and field research, and discuss social value of university.

# Towards the reborn of Iitate village 'Agriculture'

Makoto Sugisoka[2], *Masaru Mizoguchi[1]

1. Graduate school of Agricultural and Life Sciences, The University of Tokyo, 2. Division of Reconstruction Measures, Iitate Village

In Iitate Village where all villagers were evacuated due to the accident of TEPCO Fukushima Daiichi Nuclear Power Plant, evacuation order were canceled in March 2017 except for some areas. Because of lack of living environment and anxiety about radioactivity in the environment, the number of people who actually settle in Iitate village is less than 10%. However, the Iitate Village Office has proposed four agricultural plans (For protecting agricultural lands, For fun-to -live, For livelihood, For challenging new agriculture) according to the wishes of farmers, and is striving for the revival of "agriculture". In this presentation, I will introduce such efforts.

# Difference among crop species by radiocesium absorption from different soil fractions

*Nihei Naoto[1], Yoshimi Ohmae[1], Makoto Furukawa[1], Syuichiro Yoshida[1]

1. The University of Tokyo, Graduate School of Agricultural and Life Sciences

Radioactive cesium (137 Cs) contaminated widely due to Fukushima Daiichi Nuclear Power Plant accident. The presence form of 137 Cs in soil can be divided into a fraction (adsorbed to ion exchange state or organic matter, defined as f 1 fraction) which crops are considered to be easy to absorb and utilize, and the another fraction (strong acid extraction and total decomposition component by hydrofluoric acid, defined as f2 fraction) which crops are considered to be difficult to absorb and utilize.

If we know how much 137 Cs will be absorbed from which soil fraction, we can grasp the Cs absorption characteristics of a crop. However, there has been no research report on a method showing 137 Cs absorption from each soil fraction. In this study, to grasp the soil fraction absorbing 137 Cs of the crop, the transfer factor (defined as TFf 1 and TFf 2) from each soil fraction were investigated by using the naturally occurring stable isotope cesium (133 Cs) . In addition, absorption ratios (defined as $\lambda$ 1 and $\lambda$ 2) in crops derived from each soil fraction were calculated.

Soybean, buckwheat and rice were cultivated for 30 days in a pot, and the 133 Cs and 137 Cs concentrations in the aerial part were measured. Contaminated soil (137 Cs approx 22 kBq / kg, 133 Cs approx. 3.4 mg / kg) obtained by topsoil stripping due to decontamination in Fukushima prefecture was used for soil. The soil after cultivation was successively extracted (ammonium acetate extraction, hydrogen peroxide decomposition, nitric acid decomposition, total decomposition by hydrofluoric acid), and the concentrations of 133 Cs and 137 Cs contained in each fraction were measured. In order to simplify the calculation, the soil fraction was set to two fractions of f1 (ammonium acetate extraction, hydrogen peroxide decomposition) and f2 (nitric acid decomposition, total decomposition by hydrofluoric acid). Measurement of 133 Cs was measured by ICP mass spectrometer (Perkin Elmer, Nex ION 350 S), measurement of 137 Cs by NaI scintillation counter (Perkin Elmer, Wizard). Judgment of each soil fraction absorbed by crops was calculated by 133 Cf 1 ×TFf 1 + 133 Cf 2 ×TFf 2 = 133 Ccrops, 137 Cf 1 ×TFf 1 + 137 Cf 2 ×TF f 2 = 137 Ccrops.

Cf1 or Cf2 is the Cs concentration of the soil in f1 or f2 fraction, TFf1 or TFf2 is Cs transfer factor from f1 fraction or f2 fractionation soil to crop, and Ccrop shows Cs concentration of crop.

TFf 1 and TFf 2 were different depending on the crop, soybean had higher absorption from f 2 fraction than buckwheat. Absorption from f1 fraction in 137 Cs of crops was 66% for soybean, 89% for buckwheat, 76% for rice, confirming the difference between crops. Furthermore, the effect of suppressing Cs absorption by potassium fertilization was shown to be different for each crop. By devising and defining these indices, it was possible to grasp the absorption capacity of crops.

# Wild vegetables and mushrooms retrieving agriculter in Iitate Village, Fukushima Prefecture

*Kosuke Noborio[1], Yudai Fukuyama[2], Satoko Fujita[1], Hiroaki Sugino[2], Masaru Mizoguchi[2]

1. Meiji University, 2. the Univewrsity of Tokyo

Wild vegetables and mushroom at mountaineous slopes could be key agricultural products in Iitate Village in the future. Radiocesium fallout from the Fukushima Daiichi Nuclear Powerplant contaminated surface soils in its vicinities. Removal of contaminated surface soils was recently completed in agricultural fields, but not in forest areas where wild vegetables and mushrooms were grown. Pine mushroom is one of the precious wild mushrooms in Japan because it has not been successfully grown under controlled environments. We thought pine mushroom could be a key agricultural product for retrieving agriculture in Iitate Villege. Soil and air temperatures in a litter layer were measured to know environmental condidition of growing pine mushroom. We report the preliminary results of the environmental conditions.

# Effect of Study Tour toward Participants' Attachment on the Study Site - Case Study of University Student Tour to Iitate Village, Fukushiima Prefecture -

*Natsumi Ebitani[1], Masaru Mizoguchi[1], Hiroaki Sugino[1]

1. Graduate school of Agricultural and Life Sciences, The University of Tokyo

Reconstruction in the affected areas of the Great East Japan Earthquake is progressing, but now there have been many people who feel less interested in understanding of the current situation and remained damage. In order to advance the further development after the basic reconstruction with lessons learned from the disaster, it is necessary to communicate the charm of the area to people outside of the affected area and make opportunities for rural exchange. Therefore, the authors are considering regularly holding study tours to the affected area. This presentation introduces a one-night two-day study tour as a case study for Iitate Village in Fukushima Prefecture held three times from October to November 2018. Before and after the tour, we conducted a questionnaire survey on a total of 44 participants (university students) who are mainly majoring in agriculture, and analyzed the obtained data by co-occurrence network analysis and factor analysis. In the end, this study discusses the effect of the tour on students' attachment to the tour site, and examined how future study tours should be.

## [S-SS12] Crustal Structure

convener:Kazuo Nakahigashi(Tokyo University of Marine Science and Technology)

The aim of this session is to cover seismological and geophysical studies on the Earth's crust. Contribution on seismological and geophysical structure of the crust, processes that develop in the crust which include earthquakes, volcanoes and geological descriptions of the crust are welcomed. We also welcome theoretical and methodological studies that will serve as basics in such explorations.

# Regional difference in long period surface wave phase velocity by an explosive phenomenon generated in North Korea on September 3, 2017

*Koji Yamada[1]

1. Hanshin Consultants co., ltd.

An explosive phenomenon to assume the Democratic People's Republic of Korea cause at past 12:30 of September 3, 2017 was observed in each place. The position of the seismic center is considered to be 41.3 degrees N, 129.1 degrees E, 0 kilometers in depth by Japan Meteorological Agency and almost assumes surface of the earth neighborhood cause. Because it is an explosive phenomenon generated in an earth surface, Rayleigh wave is observed other than P wave, and can considered the observed wave mortion to be an observation record of huge size surface wave exploration.

The observed Rayleigh wave shows strong dispersibility at around 0.03-0.1Hz. After performing MASW (Multichannel Analysis of Surface Wave) for the Kinki districts where P-wave velocity structure is estimated using data of the large blast observation, the provided phase velocity almost matching with the one dimension S-wave velocity structure that I set in reference to Hirose& Ito (2006). Yamada(2018) thought that the observed phase velocity dependend on velocity structure to the Moho.

Because after doing MASW at a suitable angle based on the direction from the seismic center about each domestic area, a local difference was seen in provided phase velocity, I report it.

Acknownledgement:

In this study, I used the observation record of broadband Seismograph network (F-net), high sensitivity seismograph network (Hi-net) by NIED, each national university, and Japan Meteorological Agency.

# Phase velocity estimation based on spatial gradient of surface wave arrival time of teleseismic earthquakes observed by S-net

*Akira Ishigami[1], Ryota Takagi[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science

Seismice velocity structure is fundamental information to understand environmental cause of earthquakes and slip behavior on the plate interface. In addition, recent developments of dense seismic network enable us to catch seismic waveforms as seismic wavefield. In the present study, we use S-net data to estimate phase velocity map by calculating spatial gradient of surface wave arrival time of teleseismic earthquakes.

We used long-period accelerometer records of teleseismic earthquakes. We analyzed a teleseismic earthquake occurred in Alaska Bay on January 23, 2018 (depth: 25km, Mw 7.9). We used vertical records to estimate Rayleigh wave phase velocity after converting observed records from XYZ to UNE components. To estimate phase velocity map, we followed Lin et al. (2009). We first applied frequency-time analysis (FTAN) to waveform data of each station to get phase velocity dispersion curve. We then picked surface wave arrival times at certain period and spatially interpolated to get arrival time map. Finally, we obtained phase velocity map by calculating spatial gradient of the arrival time map. We estimated phase velocity maps at 20-50 s by intervals of 5 s.

When we estimate the phase velocity curve, there is the $2\pi$ phase ambiguity. Although a reference phase velocity curve allows us to estimate the number of cycles, the discrepancy from the real phase velocity curve and the initial phase effect causes misestimation of the cycle number. Thus, we solved this problem by iteratively update the reference dispersion curve. First, we used PREM 1D model to estimate dispersion curve at each station. In the next step, we used average of the estimated dispersion curves as the reference model. We repeated the procedure until we can obtain a consistent cycle number within the all S-net stations.

The phase velocity is estimated within 3.6-3.9 km and consistent with general phase velocity of Rayleigh wave. We found high velocity anomaly which may be attributed to the subducting slab at the period of 45 s. We also found high velocity anomaly off Miyagi and Fukushima.

To confirm the spatial pattern of the phase velocity, we need to analyze other teleseismic events. We can also estimate azimuthal anisotropy of phase velocity by using several earthquakes of which surface waves propagate in different direction. In addition, we need to examine the method of spatial interpolation for robust estimation of phase velocity map.

# Crustal seismic velocity structure in the Japanese Islands from receiver function analysis using similar earthquakes

*Toshihiro Igarashi[1]

1. Earthquake Research Institute, University of Tokyo

The stress and strain changes due to the recurrence process on the inter-plate great earthquakes of the subducting plate should have a significant effect on shallow inland seismicity and velocity structure in the overriding plate. In this study, we applied receiver function analysis using similar earthquakes, which repeatedly occurred at almost the same location, to investigate the spatiotemporal change of the crustal seismic velocity structure beneath the Japanese Islands. Similar earthquakes used as data were extracted from the seismograms of medium-sized earthquakes, which observed in the seismic network of Japan and occurred in the epicentral distances between 30 degrees and 90 degrees in the periods from September 1989 to February 2016. We estimated temporal changes of crustal seismic velocity structure by receiver function analysis from the selection of pairs of similar earthquakes occurred before and after the 2011 Tohoku-Oki earthquake (M9.0). In this analysis, we assumed that the depths of the Moho discontinuity, which estimated using all available data for the above period, do not change within the analysis period. As a result, we detected areas of decreased crustal velocity to the west of the source region of the Tohoku-Oki earthquake. We suggest that the stress change by a great inter-plate earthquake affected the velocity reduction or velocity polarization. On the other hand, the crustal velocity increased to the north of the source region. This change may be caused by the effect of the postseismic deformation after the 2003 Tokachi-Oki earthquake (M8.0). However, it is difficult to specify the accurate timing of the change because of long-term data stack. The impact of the great earthquakes has been widespread for a long time. The further studies of the seismic velocity structure in arbitrary period will clarify the cause of changes.

# Estimation of the Crustal Structure beneath the Broadband Seismic Network in the Eskisehir Region, Turkey, by Using Receiver Function Method

*Pinar Duran[1], Asim Oguz Ozel[1], Hiroaki Yamanaka[2]

1. ISTANBUL UNIVERSITY-CERRAHPASA, 2. TOKYO INSTITUTE OF TECHNOLOGY

Receiver function imaging is an important tool for the investigation of the crust and upper mantle structure. The P to S conversion (Ps) from the Moho is typically one of the most prominent phase on the P-wave receiver funtions. The time delay between the Ps converted phase and direct P wave is sensitive to the depth of the velocity discontinuities, and the average S wave velocity above it. Estimates of the depth and thickness of the Moho and $V_P$ /$V_S$ ratio of the crust are important goals of many receiver funtion investigations. In the frame of the Turkey-Japan joint project, we attempt to determine S-wave velocity structure of the crust beneath Eskisehir Region, described by various tectonic settings. The teleseismic events are recorded by broadband three-component seismic stations of ANA-NET Seismic Network, which is operated by the Eskisehir Anadolu University since 2010. The seismograms from these events, whose epicenters lay at distances greater than 30$^o$, were deconvolved in the time domain to remove the unwanted noise and then stacked to obtain better receiver functions. This information will be used to establish a linear relationship between thickness and $V_P$ /$V_S$ ratio, each of which is stacked for a given station to identify a best-fit estimate for depth to the Moho and Vp/Vs ratio. To determine their accuracy, these results will be compared with other geophysical studies performed in the region, 1-D crustal models will be presented at the conference. This study is supported by the Joint Research Project under the Bilateral Program of the Japan Society for the Promotion of Science (JSPS) and The Scientific and Technological Research Council of Turkey (TUBITAK) under Grant TUBITAK 116Y524.

# Three-dimensional S-wave attenuation structure in and around Hokkaido, Japan

*Ryoichi Nakamura[1], Takahiro Shiina[1]

1. Earthquake Research Institute, The University of Tokyo

## 1. Introduction

At Hokkaido, Japan, the collision between the Kuril and the NE Japan arcs occur (e.g., Kimura, 1994, JGR), and thus complicated crustal structure would be developed. According to Kita et al. (2012), the arc-crust is subducted by the collision and reaches deep up to near the upper part of the mantle. Additionally, the 2018 Eastern Iburi Earthquake (M6.7, depth 37 km) and its aftershocks occurred at considerably deep as a crustal earthquake. This activity at the deep crust is thought to link to the complicated geologic structure in Hokkaido.

Several detailed tomographic studies of seismic velocity and Qp structures have been done in this region (e.g., Kita et al., 2014, JGR; Shiina et al., 2018, JGR). These studies showed low Qp, low Vp, low Vs, and high Vp/Vs at a depth of 10 km in the west side of the Hidaka mountain range and that these anomalous structures distribute to the depth of 50 km which comparable to the upper surface of the subducting Pacific plate. On the other hand, the Qs structure in this area has not been well investigated. Therefore, in this study, we estimate the detailed Qs structure of Hokkaido by using the 3D spectrum inversion method.

## 2. Method and Data

In this study, we adopt the 3D spectral inversion method (Nakamura and Uetake, 2002) to strong motion records observed around the Hokkaido. In the method, we estimate source spectrums, site factors, and Qs value of each block. The study area is 138 ˚- 148 ˚E and 39 ˚- 46 ˚N, and is discretized by blocks of which size is 0.1 ˚in latitude and longitude and 10 km in depth direction.

The strong motion records are collected from on the K-net and the KiK-net stations deployed near the surface. Periods collecting the records are to Nov. 2019 from operation beginnings of each station. The magnitude of earthquakes is 4.0 - 7.5. We limit stations by epicentral distances: < 100 km and < 500 km for earthquakes occurred at depths of 0-30 km and 30-200 km, respectively. Moreover, we exclude strong motion records with 100 Gal or stronger to reduce influences of ground nonlinearity effects as possible. Fourier spectrum amplitudes are computed from the strong motion records of NS component at 1-10 Hz with every 1 Hz.

## 3. Results

We show the estimated Qs structure in and around the Hokkaido obtained at 10 Hz in Figure 1. In this study, we examine the CKB resolution test and, in Figure 1, we display only the results where the assumed structures are well recovered in the resolution test. The obtained Qs structure reveal the high-attenuation (low-Qs) zones beneath the volcanoes at depths of 30-40 km and the Pacific slab with low-attenuation (high-Qs), as well as tomographic images in Tohoku district (e.g., Nakamura and Uetake, 2004; Liu et al., 2014).

©2019. Japan Geoscience Union. All Right Reserved. 

At the west side of the Hidaka mountain range, the remarkable high-attenuation zone is estimated at depths of 0-20 km and there seem to continuously distribute by about 40 km. This high-attenuation anomaly is consistent with that estimated in Qp (Kita et al., 2014). Additionally, the belt-like distribution of low-attenuation area along the Hidaka mountain range can be revealed in this study. These structures would represent heterogeneity resulted from the collision between Kuril and NE Japan arcs.
Around the source area of the 2018 Hokkaido Eastern Iburi Earthquake, high S-wave attenuation is imaged. The high-attenuation zone is extended from near the Hidaka mountain range (the result at 30-40 km in Figure 1) and the contrast of between high- and low-attenuation property clearly identified along the north-south direction. This is comparable to distributions of aftershocks of the Eastern Iburi earthquake. Therefore, we consider that the heterogeneous structures which are developed in the collision zone would closely link to the occurrence of the Eastern Iburi earthquake and its aftershocks.

# Reexamination for the subsurface structure beneath the southern part of the Hidaka Collision Zone, Hokkaido, Japan by using a numerical test of wave propagation

*Masahiro Shimazaki[1], Noriko Tsumura[2]

1. Graduate School of Science and Engineering, Chiba University, 2. Graduate School of Science, Chiba University

Hidaka Collision Zone (HCZ) is located in the central and southern part of Hokkaido where the Kuril forearc dragged by oblique subduction of the Pacific plate collided with the northeastern Japan arc. The Kuril arc’ s middle crust and its shallower part have been thrusted up along the Hidaka Main Thrust (HMT) and are exposed to the surface. Various seismic reflection surveys have been conducted for the purpose of investigating the subsurface structure of this region.
At the southernmost part of the HCZ, researchers of Hokkaido university, university of Tokyo and Chiba university conducted three seismic reflection surveys whose lines were settled across the HCZ in 1994, 1996, and 1997, respectively. From obtained time section, Tsumura et al. (1999) showed that the lower crust of the Kuril arc is divided into a northeast-dipping ascending layer and a southwest-dipping descending layer at a depth of 23km and interpreted it as delamination structure. Seismic profiles which were obtained by integrating three survey lines [Ito et al.,2000] and by applying new analysis technique of CRS / MDRS method [Ito et al.,2013] also supported the delamination structure.
Meanwhile, Kita et al. (2012) estimated the three-dimensional P wave velocity structure in the same region by travel time tomography. They suggested that a shallower part than 23km indicates the similar structure to that of Ito et al. (2000), but at deeper than 23 km, crustal material of the northeastern Japan arc reaches the plate boundary of the Pacific plate.
If delamination has occurred beneath the HCZ, it is expected that the length of southwest-dipping descending layer corresponds to the one of ascending layer having northeast inclination. Although two parallel reflectors can be recognized at the depth from 23 km to 38 km, deeper extension more than 38km cannot be found in the depth cross section of Ito et al. (2013). Then, in this study, we conducted a numerical test to know what kind of reflected waves can be observed when shots are performed with the same specification of actual surveys using analysis software Madagascar.
For the numerical test, we prepared two kind of subsurface structure models: One is a “Delami” model in which delamination occurs and lower part of the lower crust are descending into the depths deeper than 38km; and the other one is a “Non-Delami” model based on the interpretation of Kita et al. (2012). Both of the models consist of upper crust, lower crust, mantle and oceanic plate, and the average density of each material was set as density. Velocity of each layer was given referring to the result of Kita et al. (2012).
For the “Delami” model, only the reflected waves from the tip of wedge like structure of the subducting layer reached within the survey lines, whereas reflected waves from the deeper part reached the southwestern outside of the survey line. For the “Non-Delami” model, no reflected waves were seen around the arrival times which correspond to those of reflected waves from the depths at 23 km to 38 km.

# High resolution seismic surveys in the Kuril trench off Hokkaido

*Yasuyuki Nakamura[1], Shuichi Kodaira[1], Mikiya Yamashita[1], Seiichi Miura[1], Gou Fujie[1]

1. Japan Agency for Marine Earth Science and Technology

In the Kuril trench subduction zone, several large earthquakes (e.g., Tokachi-oki earthquakes) have occurred, which caused the earthquake and tsunami hazards in the Hokkaido and Tohoku region. Because the earthquake and tsunami risk was evaluated to be high in this region, more investigation and studies are required to contribute to the mitigation of those risks. In 2016 and 2018, we conducted high resolution seismic surveys in the Kuril trench from Erimo Seamount to off Kushiro by R/V *Yokosuka*. Approximately 35 km long 24 seismic profiles with ~ 6 km line separation were acquired using a 1.2 km long streamer cable and 380 inch$^3$ cluster guns. Obtained profiles demonstrate the detailed geological structure in the trench axis region. Subducting Pacific plate is deformed by the bend-related normal faults. The throw of the faults is up to ~ 300 –400 ms TWT. The thickness of the incoming sediments is > 500 ms maximum in the survey area and becomes thinner near the seamounts. Thick trench-fill sediment is deposited in the trench axis west of the Kushiro canyon, and the thickness is up to ~ 800 ms. Some profiles show weak landward dipping reflections within the hanging wall sediments. Possible slope failure is suggested in the lowermost landward slope near the Erimo Seamount.

# Subsurface Structure at the North of the Yokosuka Fault by Seismic Reflection Survey

*Shinobu Ito[1]

1. Geological Survey of Japan, AIST

The rupture of the Mikawa Earthquake on January 13, 1945 is considered to be on the Fukozu and the Yokosuka Faults. The Fukozu Fault is located relatively south and reverse L-shaped. On the other hand, the Yokosuka Fault is located relatively north and L-shaped. Ando (1974) mentioned that the NS strike section of the Yokosuka Fault in the fault zone was caused by a secondary deformation. Sugito and Okada (2004) investigated surface displacement in detail along the fault zone. They concluded that the NS strike section of the Yokosuka fault is the upper extension of the earthquake source fault although they referred to the possibility of the secondary deformation. Sugito and Okada (2004) referred that the surface earthquake fault of the Mikawa Earthquake is inconsistent with the source model of the earthquake estimated by Kikuchi et. al. (2003) from seismograms. In this way, the NS strike section of the Yokosuka Fault is not understood clearly. We carried out the P-wave seismic reflection survey at Shikoya-cho, Nishio, Aichi; at the north end of the Yokosuka Fault, in order to investigate lower extension of the Yokosuka Fault.

Not only the survey at the north of the Yokosuka Fault (GS-NSO2) but also the other survey at the south east extension of the Takahama Fault (GS-NSO1) were carried out from September 27 to October 2 in 2018. The length of the survey line GS-NSO2 is 1810m. We used one EnviroVibe manufactured by IVI. Sweep frequency is 10 to 120Hz, and sweep duration is 16S. Standard shot interval is 5m, and exceptionally 2.5m. Total shot points are 421, and we shot 3 to 5 times for each point. We used 3 string geophones of OMNI-2400 ($f_0$=15Hz) by Geospace. We used offline seismic recorder GSX system also by Geospace. Receiver interval is 5m, and total receiver points are 342. We made seismic profile by CMP stack.

We cannot see any obvious faults or signs related to the faults in the profile. Trenching survey indicate that the Mikawa Earthquake was preceded by one earthquake 2000 years ago. Total displacement of the Mikawa Earthquake and the preceding event is not more than 2m. It is impossible to detect the displacement in case of 2m displacement. However, it is possible in case that the displacement increase with depth. At least, we cannot detect the cumulative displacement in the survey.

Keywords: Yokosuka Fault, fault, seismic reflection survey

# Crust and Uppermost mantle P-wave velocity structure of the Ordos block and its neighbors based on travel time tomography

*Yaning Liu[1], Jianping Wu[1], Shuxian Bao[1], Xiaohong Meng[2]

1. Institute of Geophysics, China Earthquake Administration, 2. China University of Geosciences (Beijing)

The Ordos block is located on the west side of the North China Carton, adjacent to the northeastern part of the Tibetan Plateau, with the Yinshan organic belt to the north and the South China block to the south. And the tectonic evolution of Ordos block is controlled by the North China basin extension caused with subduction of the Pacific plate and the extrusion and sheared from the northeastern margin of the Tibet Plateau follow the collision of the Indian-Eurasian plate.

The study area spans from 32˚N to 42˚N and 108˚E to 114˚E , which includes the Ordos block and its adjacent structures . The seismic data we used for inversion were recorded by 1244 stations including: 198 permanent stations and 1043 temporary stations (ChinArray II and III), from November 2013 to August 2017. The study uses local-seismic for inversion. After manual labeled the seismic phase, we select events with more than ten phase records of individual seismic events. The epicentral distance is less than 200km. Finally, we obtained about 22,500 phase records of 1882 local seismic events.

Our preliminary research results are consistent with previous studies and surface structures of a wide range of velocity distributions. However, in the middle-upper crust under the Liupan Mountain, the low-speed anomaly extending downward is shown, which may be caused by the horizontal extrusion caused by the eastward asthenosphere flow driven by the continuous compression of the northeastern margin of the Qinghai-Tibet Plateau during the Cenozoic. While, in the middle crust of the Ordos Basin, there are weak high-speed anomalies that divide the low-speed disturbances in the basin into three parts, showing the fluctuation of the crystalline basement of the basin. In the Taihang Mountains in the west of the study area, low-velocity anomalies extending to the upper layer of the mantle are shown. We initially believe that this anomaly is related to the volcanic thermal motion that once existed on the area.

# Seismic imaging of the 2016 Kumamoto earthquake area using P and PmP data

*Dapeng Zhao[1], Haibo Wang[2], Zhouchuan Huang[2], Mingjie Xu[2], Liangshu Wang[2]

1. Department of Geophysics, Tohoku University, 2. School of Earth Sciences and Engineering, Nanjing University

We determined a high-resolution model of 3-D P-wave velocity (Vp) tomography of the crust in the source zone of the 2016 Kumamoto earthquake (M 7.3) in Kyushu, SW Japan using a large number of arrival times of first P-waves and reflected P-waves from the Moho discontinuity (PmP). The PmP data are collected from original seismograms of the Kumamoto aftershocks and other local crustal events in Kyushu. Detailed resolution tests show that the addition of the PmP data can significantly improve the resolution of the crustal tomography, especially that of the lower crust. Our results show that significant low-velocity (low-Vp) anomalies exist in the entire crust beneath the active volcanoes, which may reflect the pathway of arc magma. The 2016 Kumamoto earthquake occurred at the edge of a small low-Vp zone in the upper crust. A significant low-Vp anomaly is revealed in the lower crust beneath the source zone, which may reflect the arc magma and fluids ascending from the mantle wedge. These results suggest that the rupture nucleation of the 2016 Kumamoto earthquake was affected by fluids and arc magma.

# Estimation of 3D velocity structure in Kyushu region by the seismic tomography

*Toya Mitsuhiro[1], Koji Yamada[1]

1. Hanshin Consultants Co., Ltd.

## 1. Introduction

A high-resolution crustal structure in the volcanic zone is basic information for prediction of volcanic activity in the future. Therefore, in this study, we carry out preliminary research in Kyushu region aiming at the estimation of three-dimensional (3D) velocity structure in the volcanic zone by the 3D seismic tomography. In this region, it is suitable for this study because a large number of earthquake records of the main shock and aftershocks of the Kumamoto earthquake that occurred in April 2016 can be used and there are many volcanoes such as Mt. Aso and Mt. Unzen. Thus, we perform the 3D seismic tomography in Kyushu region for the estimation of 3D velocity structure, and consider problems on application to the volcanic zone.

## 2. Data and Method

We used arrival time data downloaded from the website of National Research Institute for Earth Science and Disaster Resilience (NIED). We selected 59011 earthquakes observed at 141 stations from April 2016 to March 2017. The selected area is 129.3˚E ~ 132.1˚E, 30.9˚N~ 34.0˚N, 0 ~ 50 km in depth. And, for P-wave arrivals, we added 804 earthquakes observed at 4 V-net stations at Mt. Aso and travel time data obtained by explosion seismic observations in the Hinagu fault area, Kyushu (The Research Group for the 2003 Hinagu Fault Seismic Expedition, 2008) and Eastern Kyushu (RESEARCH GROUP FOR EXPLOSION SEISMOLOGY, 1999). In total, our selection result in 871,690 P-wave arrivals and 840,633 S-wave arrivals.

We estimate 3D seismic velocity structure using the Fast Marching Tomography (FMTOMO) method of Rawlinson et al. (2006). This program uses the fast marching method via finite difference solution of the eikonal equation (Sethian, 1996) for calculation of synthetic travel times. The model area is 129.2˚E ~ 132.2˚E, 30.8˚N~ 34.1˚N, -4 ~ 52 km in depth. The horizontal grid spacing is 0.1˚(about 10 km) and the vertical is 4 km (the number of grids is 34×31×15 for three coordinate axis). An initial velocity structure model is JMA2001 (Ueno et al. 2002) and we set six iterations of the tomographic inversion scheme. Then, we examined the resolution of the tomographic inversion using a checkerboard resolution test (CRT). The size of checker is 2×2×2 in grid number, and the velocity perturbation for the initial velocity structure model is ±0.1 km/s. As a result of the CRT, we confirmed that checkerboard pattern is well resolved up to about 20 km deep in the Kumamoto area.

## 3. Results

Figure 1 shows plan views of the P-wave velocity and the S-wave velocity structures obtained here at 4 km depth. The pattern of velocity variation is similar to each other and pronounced low velocity area exists in the southern Kumamoto. At 0 ~ 1 km depth, low velocity area exists in the Kumamoto Plain. However, in this study, pronounced velocity variation is not seen beneath Mt. Aso and other volcanic zones. So, for improving the resolution, we are going to add earthquakes in the area with less them and stations (K-net, V-net and so on).

# Estimation of the structure of the Philippine Sea slab under south Kyushu using receiver function analysis

*Masaki Uchida[1], Takahiro Ohkura[1], Takuo Shibutani[1], Yuki Abe[2], Shintaro Komatsu[1], Ken'ichi Yamazaki[1], Yusuke Yamashita[1], Shin Yoshikawa[1], Masato Iguchi[1], Takeshi Tameguri[1], Tadaomi Sonoda[1]

1. Kyoto Univ., 2. Hot Springs Research Institute

In the subduction zone, it is considered that magmatism is caused by fluid transported to the upper mantle from the subducting slab [Tatsumi, 1986, GRL]. In order to clarify the relation between the magmatism and the subsurface structure of Sakurajima and Kirishima volocanoes, we investigate seismic velocity discontinuities beneath these regions by receiver function analyses of the teleseismic waveform.

A Receiver function (RF) is calculated by deconvolving the vertical component of a waveform of a teleseismic P-wave from its horizontal component, and phases converted at seismic velocity discontinuities in its coda can be detected with RFs [Langston, 1979, JGR]. In order to estimate the geometry of steeply dipping discontinuities, such as the upper boundary of the subducting Philippine Sea plate, with RFs, refraction of the seismic rays at the dipping discontinuities should be taken into account. For this purpose, we apply the method for stacking RFs using the multi-stage fast marching method developed by Abe et al. [2011, GJI].

Abe et al. [2013, JGR] revealed the regional variation of S wave velocity discontinuity across the Philippine Sea plate, which is divided by the Kyushu - Palau Ridge, from RF analyses of the waveform data obtained at the permanent stations. In this research, we use waveform data obtained at dense observation networks along Miyazaki-Akune and Miyazaki-Sakurajima lines from teleseismic earthquakes with magnitude greater than 5.5 occurred from November 2009 to March 2017. We use 3-D seismic velocity model [Matsubara et al. 2007, Tectonophysics] for stacking RFS, although Abe et al. [2013] used one dimensional IASP91 model.

Beneath the south Kyushu where the Western Philippine Basin formed at about 50 Ma subducts [Hilde and Lee, 1984, Tectonophysics], it is suggested that the fluid dehydrated from the Philippine Sea slab is transported to the back-arc and may cause arc volcanism activity by Abe et al. [2013]. In addition, low velocity zone of mantle wedge is detected, and this zone is considered to correspond to a serpentinized mantle by a fluid derived from oceanic crust [Bostock et al. 2002, Nature], based on the S wave velocity of serpentinite estimated by Hacker et al. [2003, JGR] and Christensen [2004, Int Geol Rev].

We obtain more precise receiver function images using dense network data and discuss the seisimic structure of Sakurajima and Kirishima volcanoes.

# Imaging subduction structure beneath the eastern part of Kii Peninsula, SW Japan, using an earthquake reflection method

*Eiji Kurashimo[1], Takashi Iidaka[1], Noriko Tsumura[2], Takaya Iwasaki[1]

1. Earthquake Research Institute, the University of Tokyo, 2. Chiba University

The Nankai trough region, where the Philippine Sea Plate (PHS) subducts beneath SW Japan arc, is a well-known seismogenic zone of interplate earthquakes. The most recent great earthquakes occurred in 1944 (Tonankai Earthquake, M=7.9) and 1946 (Nankai Earthquake, M=8.0). In recent years, various slip motions with a different time scale have been recognized at or near the updip and downdip limits of seismogenic zone [e.g., Obara, 2002; Ito and Obara, 2006]. Revealing structural factors that control the fault slip behavior is important to understand the earthquake rupture dynamics. Seismic reflection characteristics and seismic velocity variations can provide important information on the heterogeneous structure around plate interface. Recent seismic experiments reveal the relation between the crustal structure and the fault slip behavior. However, little is known about the deeper part of the plate boundary, especially the down-dip side of the seismogenic zone. In 2015, seismic array observation was conducted to obtain the subduction structure beneath the eastern part of the Kii Peninsula [Kurashimo et al., 2016]. Ninety 3-component portable seismographs were installed on a 90-km-long line nearly parallel to the direction of the subduction of the PHS. Waveforms were continuously recorded during a six-month period. During the seismic array observation, Japan Meteorological Agency determined 45 events within 10 km of our survey line. Prominent late arrivals, probably reflected waves from the deeper part of the crust can be recognized on the record sections. Earthquake data is useful to obtain a deep image. So, in order to clarify the spatial distribution of the reflectors, we applied the reflection method to the earthquake data. We used horizontal-component seismograms, because high amplitude S-wave reflection can be recognized on the record sections. Conventional common mid-point processing cannot be applied to earthquake data because the reflection point does not lie at the mid-point between source and receiver, so, we applied the Common Reflection Point (CRP) transformation [e.g., Quiros et al., 2016] to the earthquake data set using a tomography-derived 3D S-wave velocity model [Kurashimo et al., 2016]. Reflection points and their relevant travel-time from earthquake to receiver were calculated using a 3D finite difference travel-time algorithm [Hole and Zelt, 1995]. Before applying the CRP transformation, the waveform data were filtered by a band-pass filter (1 -8 Hz). After applying the CRP transformation and the stacking process, we applied a post-stack migration technique. The migrated shear wave reflection image shows that the northward dipping reflective zone interpreted to be the upper boundary of the PHS can be recognized at a depth range of about 25 -30 km. The top of the low-frequency earthquakes (LFEs) occurrence zone well corresponds to the high amplitude S-wave reflective zone. LFEs are also located in and around the low Vp and high Vp/Vs zone [Kurashimo et al., 2016]. These results suggest the occurrence of the LFEs may be associated with fluids.

# Tomography of Mejillones Peninsula using cross-correlation of ambient seismic noise

*Kellen Azua Quezada[1], Sergio Ruiz[1], Francisco Pasten-Araya[2,3], José Salomón[4], Pablo Salazar[2,3], Miguel Saez[1], César Pastén[4], Felipe Leyton[5], Wasja Bloch[6]

1. DGF, UChile, 2. DG, UCN, 3. CIGIDEN, 4. DIC, UChile, 5. CSN, Chile, 6. GFZ

The Mejillones Peninsula (MP) is locate in northern Chile (-23.28º, -70.5º). MP is a geomorphic atypical uplifted block of the coastal platform of 100 km length. This structure has been proposed as a segment boundary for large subduction earthquakes, as the case of Mw 8.0 Antofagasta (1995) and Mw 7.7 Tocopilla (2007) events. Additionally, the Peninsula presents a wide and deep layer of sediments that could enhance site effects. For this reason, in this work we study the shallow structure of MP basin. We deployed a dense temporary seismic network in the MP, which registered in continuous time from July 2013 to September 2015. From the continuous records, we built a local tomography using the spectral ambient seismic noise. We use vertical component of seismograms to obtain the Green function from cross-correlation between station pairs. The frequency domain method allows determine of phase velocity relating the zero-crossing of the real part of cross-correlation spectrum with the zero crossing of the zero-order Bessel function of the first order. The Rayleigh wave phase velocities are inverted by means of a non-linear iterative 2-D tomographic technique; finally we recover phase velocity maps at different frequencies. The tomographic maps present significant features that correlate with surface geology. We found in the West part of the MP lower velocities that East zone. We can associate this with fractured metamorphic rock. Higher velocities in the Eastern part of the peninsula are associated with the presence of intrusive rocks. The difference in velocity of these two anomalies is maintained at differents depth.

# Crustal thickness beneath Central Indonesia by the cross-correlation analysis of seismic ambient noise (2)

*Masyitha Retno Budiati[1], Genti Toyokuni[1], Tomomi Okada[1], Toru Matsuzawa[1]

1. Graduate School of Science, Geophysics Department, Tohoku University

Central Indonesia has complex tectonic structures where is characterized by several subduction zones at northern and eastern part and also active faults (e.g., Palu Koro, Matano and Hamilton faults). These complexities affect crustal structures around the region. In this study, we estimated spatial variation of crustal thickness and their relation with active tectonics. We used waveform data recorded at 10 BMKG broadband stations around Sulawesi Island. Firstly, the continuous data were divided into 20 minutes segments with time shift in every 5 minutes. Once the pre-processing steps for each segment were done, we calculated the CCFs between two contemporaneous segments from two stations and stacked the daily-averaged CCFs over 5 months. We further compressed the two-sided signal into one-sided signal by taking the average of positive and negative lag part of the CCFs in order to stabilize the dispersion curves of group velocities. To fit the synthetic and the observed group velocities, we adjusted the two layers crustal velocity model from CRUST 1.0 (Laske et al., 2013) corresponding to the observation group velocities. The velocity model that is faster than the observation was subtracted 5% and 10% to find the best crustal thickness with minimum RMS between observations and synthetics at period of 20s –30s. To confirm our procedure above, we currently apply the similar procedure to estimate the well-known Moho discontinuity in Tohoku region, Japan. We collected 5 months continuous waveform data from vertical components of 10 F-net stations around Tohoku region. The results showed that the slower velocity models makes the crustal thickness shallower. The estimated depth of Moho discontinuity beneath Tohoku region is about 20km –30km using subtracted velocity models. This is almost consistent with previous studies (e.g. Zhao et al., 1990). While the estimated depth of Moho discontinuity at eastern part of Central Indonesia is about 27km –35km which is related to the ocean crust, Batui and Sula thrust and at the continent of Sulawesi Island the estimated depth of Moho is about 35km –45km.

# Subsurface structure below the southernmost area of South Japanese Alps estimated by seismic interferometry imaging

*Toshiki Watanabe[1], Hasegawa Daima[1], Tanio Ito[2], Ken'ichi Kano[3], Susumu Abe[4], Akira Fujiwara[5], Yoshinori Kouchi[6]

1. Graduate School of Environmental Studies, Nagoya University, 2. Association for the Development of Earthquake Prediction, 3. Shizuoka Univertity, 4. JAPEX, Co. Ltd., 5. JOGMEC, 6. Geosys, Inc.

In the Tokai area, seismological events, such as low frequency events and slow slip events as well as large earthquakes, are occurred caused by subduction of the Philippine Sea (PHS) plate. The eastern Tokai area is a transition zone from the collision zone of Izu arc to the subduction area. To understand the subsurface structure in this area and fill the gap between the previous seismic surveys, a seismic observation using a dense seismic linear array composed of 34 receivers was conducted in 2013.
In this study, we applied seismic interferometry imaging to the seismic records of the array observation. Seismic interferometry can retrieve the reflection response between two receivers as if one receiver is a virtual shot and the other is a receiver by calculating the cross-correlation of the transmission responses recorded at the two receivers. For a single receiver, the reflection response recorded at the receiver from a source at the same location is retrieved by calculating the autocorrelation of the transmission response recorded at the receiver. In this study, we used regional deep earthquakes occurred in the Pacific Oceanic slab as the seismic sources to image the PHS plate and crustal structures. We conducted autocorrelation analysis and created reflection profiles for both P- and S-waves. We projected the cross-correlation between two adjacent stations to their mid-point to improve the spatial density of the stations. After migration using the velocity structure obtained by the tomography analysis, we obtained the P- and S-wave reflection depth profiles.
In the S-wave depth profile, the shallower area above 25 km shows reflective, while the deeper area is less reflective. The boundary becomes shallower to the north-east of the profile. By comparing this profile with the result of other seismic surveys and with pre-existing plate models, we interpreted that the strong reflectors shown at the depth about 25 km in the southwest of this profile are the plate boundary. This interpretation is consistent with the result of Hirose et al. (2008) showing that the basaltic oceanic crust of the PHS plate shows low Vs and high Vp/Vs. In the eastern half of the profile lacks reflectors that correspond to the plate boundary. This may be attributed to a weak contrast of physical properties between the felsic island arc crust proposed by Kodaira et al. (2004) and the Japanese island arc crust, or complicated geological structure due to the collision of Izu arc.

# Strong variations of near-surface seismic anisotropy of Taiwan revealed by coda interferometry

*Hsin-Yu Lee[1], Yuancheng Gung[1], Li-Wei Chen[2], Ling-Yun Chiao[3]

1. Department of Geosciences, National Taiwan University, Taiwan, 2. Department of Earth and Planetary Science, University of California at Berkeley, CA, USA, 3. Institute of Oceanography, National Taiwan University, Taiwan

We report the near-surface (<500 m) seismic structure, Vs, Vp and Vs anisotropy, of Taiwan using the empirical Green’ s function of body waves extracted by applying coda interferometry to the vertical station pairs at 56 borehole sites. We find clear characteristic cos2θ dependence of Vs in all the determinations of Vs azimuthal anisotropy. Because the borehole sites are located at very diverse geological structures of Taiwan, we are able to notice the following interesting features about the near-surface Vs anisotropy: (1) The patterns of the observed anisotropy fall into two categories, OPA (Orogeny-Parallel Anisotropy) and SAA (Stress-Aligned Anisotropy), and both types of anisotropy fit well the local geological fabrics and/or the ambient stress. (2) About half of the amplitudes of anisotropy are larger than 10 %. The site with the largest amplitude of anisotropy (34%) is located in the slate belt of the Central Ranges, while the sites with weak anisotropy (~1%) are associated with low Vs and/or small strain rate. (3) The amplitudes of OPA are generally stronger than SAA, and the types of anisotropy are closely related to the Poisson’ s ratios at the borehole sites. (4) The strong variations of the OPA amplitudes can be explained by the rock types in the well body with the metamorphic rocks carrying stronger anisotropy than the sedimentary rocks. (5) The strong near-surface anisotropy also implies that delay times contributed by the shallow crust might have been underestimated in studies of shear-wave splitting measurements using the direct arrivals of earthquakes waves.

# Investigating anomalous crustal structures along the convergent zone in eastern Taiwan with the new airborne magnetic survey and updated seismic tomographic models

*Chi-Hsuan Chen[1], Hsin-Hua Huang[2], Lun-Tao Tong[3], Wayne Lin[3], Po-Tsun Lee[1], Shou-Fang Chang[1], Jin-Fa Lee[1]

1. Cntrl. Geo. Surv., MOEA, Taiwan, 2. Inst. Earth. Sc., Acad. Sinica, Taiwan , 3. Industr. Technol. Res. Inst., Taiwan

The convergence between Eurasian plate and Philippine sea plate produces the tectonically and geodynamically complex regions of Taiwan. The orogeny has been suggested as from ancient oceanic-oceanic plate subduction transforming to the continental-oceanic plate collision as the proceeding of the accreted volcanic arcs. The major suture of the plate boundary in eastern Taiwan, the Longitudinal Valley, contributes most of the seismic activities and absorbed about half of the plate convergence. How the shortening and disappearance of the oceanic plate provoked multidisciplinary researches in discussing the kinematics and the related earthquake structures.

Local seismic tomography is a useful technique for unraveling the subsurface structures. The Taiwan seismic tomographic studies that are advanced by large projects or by integrating multiple data sets have been proposed in recent years. Furthermore, since 2012 the seismic signal digitization of the Central Weather Bureau (CWB) seismic network was upgraded from 12 to 24 bit, and the potential timing issue of telemetry delays has been eliminated with onsite GPS time system. Additionally, the new airborne magnetic survey has been carried out in eastern Taiwan by the Central Geological Survey (CGS) and the Industrial Technology Research Institute (ITRI) recently. High magnetic anomalies were detected not only in the volcanic arc but also in the eastern Central Range along the north-south trending Longitudinal Valley. These observations motivate us to revisit the subsurface structures with updated seismic tomographic models using new CWB data sets from 2012 to 2015.

The iso-velocity contours of the updated model keep similar structures with the previous model at first order but furtherly reveal more details. A continuous high-Vp and high-Vp/Vs bulge which extends to the shallow depths of the eastern Central Range has been interpreted as a high-pressure rock exhumation along the subduction of South China sea plate or an obducted Luzon forearc sliver. On the other hand, the new airborne magnetic survey reveals two individual high magnetic stripes that share the same high magnetic characteristics with the oceanic crust. However, the magnetization vectors behave oppositely in the direction at both flanks of the Longitudinal Valley. Such findings of these integrated geophysical analyses enable us to discuss the anomalous crustal structures and their tectonic implications.

[J] Poster | S (Solid Earth Sciences)：S-SS Seismology

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_20

## [S-SS12] Crustal Structure

convener:Kazuo Nakahigashi(Tokyo University of Marine Science and Technology)

The aim of this session is to cover seismological and geophysical studies on the Earth's crust. Contribution on seismological and geophysical structure of the crust, processes that develop in the crust which include earthquakes, volcanoes and geological descriptions of the crust are welcomed. We also welcome theoretical and methodological studies that will serve as basics in such explorations.

# Regional difference in long period surface wave phase velocity by an explosive phenomenon generated in North Korea on September 3, 2017

*Koji Yamada[1]

1. Hanshin Consultants co., ltd.

An explosive phenomenon to assume the Democratic People's Republic of Korea cause at past 12:30 of September 3, 2017 was observed in each place. The position of the seismic center is considered to be 41.3 degrees N, 129.1 degrees E, 0 kilometers in depth by Japan Meteorological Agency and almost assumes surface of the earth neighborhood cause. Because it is an explosive phenomenon generated in an earth surface, Rayleigh wave is observed other than P wave, and can considered the observed wave mortion to be an observation record of huge size surface wave exploration.

The observed Rayleigh wave shows strong dispersibility at around 0.03-0.1Hz. After performing MASW (Multichannel Analysis of Surface Wave) for the Kinki districts where P-wave velocity structure is estimated using data of the large blast observation, the provided phase velocity almost matching with the one dimension S-wave velocity structure that I set in reference to Hirose& Ito (2006). Yamada(2018) thought that the observed phase velocity dependend on velocity structure to the Moho.

Because after doing MASW at a suitable angle based on the direction from the seismic center about each domestic area, a local difference was seen in provided phase velocity, I report it.

Acknownledgement:

In this study, I used the observation record of broadband Seismograph network (F-net), high sensitivity seismograph network (Hi-net) by NIED, each national university, and Japan Meteorological Agency.

# Phase velocity estimation based on spatial gradient of surface wave arrival time of teleseismic earthquakes observed by S-net

*Akira Ishigami[1], Ryota Takagi[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science

Seismice velocity structure is fundamental information to understand environmental cause of earthquakes and slip behavior on the plate interface. In addition, recent developments of dense seismic network enable us to catch seismic waveforms as seismic wavefield. In the present study, we use S-net data to estimate phase velocity map by calculating spatial gradient of surface wave arrival time of teleseismic earthquakes.

We used long-period accelerometer records of teleseismic earthquakes. We analyzed a teleseismic earthquake occurred in Alaska Bay on January 23, 2018 (depth: 25km, Mw 7.9). We used vertical records to estimate Rayleigh wave phase velocity after converting observed records from XYZ to UNE components. To estimate phase velocity map, we followed Lin et al. (2009). We first applied frequency-time analysis (FTAN) to waveform data of each station to get phase velocity dispersion curve. We then picked surface wave arrival times at certain period and spatially interpolated to get arrival time map. Finally, we obtained phase velocity map by calculating spatial gradient of the arrival time map. We estimated phase velocity maps at 20-50 s by intervals of 5 s.

When we estimate the phase velocity curve, there is the $2\pi$ phase ambiguity. Although a reference phase velocity curve allows us to estimate the number of cycles, the discrepancy from the real phase velocity curve and the initial phase effect causes misestimation of the cycle number. Thus, we solved this problem by iteratively update the reference dispersion curve. First, we used PREM 1D model to estimate dispersion curve at each station. In the next step, we used average of the estimated dispersion curves as the reference model. We repeated the procedure until we can obtain a consistent cycle number within the all S-net stations.

The phase velocity is estimated within 3.6-3.9 km and consistent with general phase velocity of Rayleigh wave. We found high velocity anomaly which may be attributed to the subducting slab at the period of 45 s. We also found high velocity anomaly off Miyagi and Fukushima.

To confirm the spatial pattern of the phase velocity, we need to analyze other teleseismic events. We can also estimate azimuthal anisotropy of phase velocity by using several earthquakes of which surface waves propagate in different direction. In addition, we need to examine the method of spatial interpolation for robust estimation of phase velocity map.

# Crustal seismic velocity structure in the Japanese Islands from receiver function analysis using similar earthquakes

*Toshihiro Igarashi[1]

1. Earthquake Research Institute, University of Tokyo

The stress and strain changes due to the recurrence process on the inter-plate great earthquakes of the subducting plate should have a significant effect on shallow inland seismicity and velocity structure in the overriding plate. In this study, we applied receiver function analysis using similar earthquakes, which repeatedly occurred at almost the same location, to investigate the spatiotemporal change of the crustal seismic velocity structure beneath the Japanese Islands. Similar earthquakes used as data were extracted from the seismograms of medium-sized earthquakes, which observed in the seismic network of Japan and occurred in the epicentral distances between 30 degrees and 90 degrees in the periods from September 1989 to February 2016. We estimated temporal changes of crustal seismic velocity structure by receiver function analysis from the selection of pairs of similar earthquakes occurred before and after the 2011 Tohoku-Oki earthquake (M9.0). In this analysis, we assumed that the depths of the Moho discontinuity, which estimated using all available data for the above period, do not change within the analysis period. As a result, we detected areas of decreased crustal velocity to the west of the source region of the Tohoku-Oki earthquake. We suggest that the stress change by a great inter-plate earthquake affected the velocity reduction or velocity polarization. On the other hand, the crustal velocity increased to the north of the source region. This change may be caused by the effect of the postseismic deformation after the 2003 Tokachi-Oki earthquake (M8.0). However, it is difficult to specify the accurate timing of the change because of long-term data stack. The impact of the great earthquakes has been widespread for a long time. The further studies of the seismic velocity structure in arbitrary period will clarify the cause of changes.

# Estimation of the Crustal Structure beneath the Broadband Seismic Network in the Eskisehir Region, Turkey, by Using Receiver Function Method

*Pinar Duran[1], Asim Oguz Ozel[1], Hiroaki Yamanaka[2]

1. ISTANBUL UNIVERSITY-CERRAHPASA, 2. TOKYO INSTITUTE OF TECHNOLOGY

Receiver function imaging is an important tool for the investigation of the crust and upper mantle structure. The P to S conversion (Ps) from the Moho is typically one of the most prominent phase on the P-wave receiver funtions. The time delay between the Ps converted phase and direct P wave is sensitive to the depth of the velocity discontinuities, and the average S wave velocity above it. Estimates of the depth and thickness of the Moho and $V_P$ /$V_S$ ratio of the crust are important goals of many receiver funtion investigations. In the frame of the Turkey-Japan joint project, we attempt to determine S-wave velocity structure of the crust beneath Eskisehir Region, described by various tectonic settings. The teleseismic events are recorded by broadband three-component seismic stations of ANA-NET Seismic Network, which is operated by the Eskisehir Anadolu University since 2010. The seismograms from these events, whose epicenters lay at distances greater than 30$^o$, were deconvolved in the time domain to remove the unwanted noise and then stacked to obtain better receiver functions. This information will be used to establish a linear relationship between thickness and $V_P$ /$V_S$ ratio, each of which is stacked for a given station to identify a best-fit estimate for depth to the Moho and Vp/Vs ratio. To determine their accuracy, these results will be compared with other geophysical studies performed in the region, 1-D crustal models will be presented at the conference. This study is supported by the Joint Research Project under the Bilateral Program of the Japan Society for the Promotion of Science (JSPS) and The Scientific and Technological Research Council of Turkey (TUBITAK) under Grant TUBITAK 116Y524.

# Three-dimensional S-wave attenuation structure in and around Hokkaido, Japan

*Ryoichi Nakamura[1], Takahiro Shiina[1]

1. Earthquake Research Institute, The University of Tokyo

## 1. Introduction

At Hokkaido, Japan, the collision between the Kuril and the NE Japan arcs occur (e.g., Kimura, 1994, JGR), and thus complicated crustal structure would be developed. According to Kita et al. (2012), the arc-crust is subducted by the collision and reaches deep up to near the upper part of the mantle. Additionally, the 2018 Eastern Iburi Earthquake (M6.7, depth 37 km) and its aftershocks occurred at considerably deep as a crustal earthquake. This activity at the deep crust is thought to link to the complicated geologic structure in Hokkaido.

Several detailed tomographic studies of seismic velocity and Qp structures have been done in this region (e.g., Kita et al., 2014, JGR; Shiina et al., 2018, JGR). These studies showed low Qp, low Vp, low Vs, and high Vp/Vs at a depth of 10 km in the west side of the Hidaka mountain range and that these anomalous structures distribute to the depth of 50 km which comparable to the upper surface of the subducting Pacific plate. On the other hand, the Qs structure in this area has not been well investigated. Therefore, in this study, we estimate the detailed Qs structure of Hokkaido by using the 3D spectrum inversion method.

## 2. Method and Data

In this study, we adopt the 3D spectral inversion method (Nakamura and Uetake, 2002) to strong motion records observed around the Hokkaido. In the method, we estimate source spectrums, site factors, and Qs value of each block. The study area is 138 ˚- 148 ˚E and 39 ˚- 46 ˚N, and is discretized by blocks of which size is 0.1 ˚in latitude and longitude and 10 km in depth direction.

The strong motion records are collected from on the K-net and the KiK-net stations deployed near the surface. Periods collecting the records are to Nov. 2019 from operation beginnings of each station. The magnitude of earthquakes is 4.0 - 7.5. We limit stations by epicentral distances: < 100 km and < 500 km for earthquakes occurred at depths of 0-30 km and 30-200 km, respectively. Moreover, we exclude strong motion records with 100 Gal or stronger to reduce influences of ground nonlinearity effects as possible. Fourier spectrum amplitudes are computed from the strong motion records of NS component at 1-10 Hz with every 1 Hz.

## 3. Results

We show the estimated Qs structure in and around the Hokkaido obtained at 10 Hz in Figure 1. In this study, we examine the CKB resolution test and, in Figure 1, we display only the results where the assumed structures are well recovered in the resolution test. The obtained Qs structure reveal the high-attenuation (low-Qs) zones beneath the volcanoes at depths of 30-40 km and the Pacific slab with low-attenuation (high-Qs), as well as tomographic images in Tohoku district (e.g., Nakamura and Uetake, 2004; Liu et al., 2014).

©2019. Japan Geoscience Union. All Right Reserved. 

At the west side of the Hidaka mountain range, the remarkable high-attenuation zone is estimated at depths of 0-20 km and there seem to continuously distribute by about 40 km. This high-attenuation anomaly is consistent with that estimated in Qp (Kita et al., 2014). Additionally, the belt-like distribution of low-attenuation area along the Hidaka mountain range can be revealed in this study. These structures would represent heterogeneity resulted from the collision between Kuril and NE Japan arcs.
Around the source area of the 2018 Hokkaido Eastern Iburi Earthquake, high S-wave attenuation is imaged. The high-attenuation zone is extended from near the Hidaka mountain range (the result at 30-40 km in Figure 1) and the contrast of between high- and low-attenuation property clearly identified along the north-south direction. This is comparable to distributions of aftershocks of the Eastern Iburi earthquake. Therefore, we consider that the heterogeneous structures which are developed in the collision zone would closely link to the occurrence of the Eastern Iburi earthquake and its aftershocks.

# Reexamination for the subsurface structure beneath the southern part of the Hidaka Collision Zone, Hokkaido, Japan by using a numerical test of wave propagation

*Masahiro Shimazaki[1], Noriko Tsumura[2]

1. Graduate School of Science and Engineering, Chiba University, 2. Graduate School of Science, Chiba University

Hidaka Collision Zone (HCZ) is located in the central and southern part of Hokkaido where the Kuril forearc dragged by oblique subduction of the Pacific plate collided with the northeastern Japan arc. The Kuril arc’ s middle crust and its shallower part have been thrusted up along the Hidaka Main Thrust (HMT) and are exposed to the surface. Various seismic reflection surveys have been conducted for the purpose of investigating the subsurface structure of this region.
At the southernmost part of the HCZ, researchers of Hokkaido university, university of Tokyo and Chiba university conducted three seismic reflection surveys whose lines were settled across the HCZ in 1994, 1996, and 1997, respectively. From obtained time section, Tsumura et al. (1999) showed that the lower crust of the Kuril arc is divided into a northeast-dipping ascending layer and a southwest-dipping descending layer at a depth of 23km and interpreted it as delamination structure. Seismic profiles which were obtained by integrating three survey lines [Ito et al.,2000] and by applying new analysis technique of CRS / MDRS method [Ito et al.,2013] also supported the delamination structure.
Meanwhile, Kita et al. (2012) estimated the three-dimensional P wave velocity structure in the same region by travel time tomography. They suggested that a shallower part than 23km indicates the similar structure to that of Ito et al. (2000), but at deeper than 23 km, crustal material of the northeastern Japan arc reaches the plate boundary of the Pacific plate.
If delamination has occurred beneath the HCZ, it is expected that the length of southwest-dipping descending layer corresponds to the one of ascending layer having northeast inclination. Although two parallel reflectors can be recognized at the depth from 23 km to 38 km, deeper extension more than 38km cannot be found in the depth cross section of Ito et al. (2013). Then, in this study, we conducted a numerical test to know what kind of reflected waves can be observed when shots are performed with the same specification of actual surveys using analysis software Madagascar.
For the numerical test, we prepared two kind of subsurface structure models: One is a “Delami” model in which delamination occurs and lower part of the lower crust are descending into the depths deeper than 38km; and the other one is a “Non-Delami” model based on the interpretation of Kita et al. (2012). Both of the models consist of upper crust, lower crust, mantle and oceanic plate, and the average density of each material was set as density. Velocity of each layer was given referring to the result of Kita et al. (2012).
For the “Delami” model, only the reflected waves from the tip of wedge like structure of the subducting layer reached within the survey lines, whereas reflected waves from the deeper part reached the southwestern outside of the survey line. For the “Non-Delami” model, no reflected waves were seen around the arrival times which correspond to those of reflected waves from the depths at 23 km to 38 km.

# High resolution seismic surveys in the Kuril trench off Hokkaido

*Yasuyuki Nakamura[1], Shuichi Kodaira[1], Mikiya Yamashita[1], Seiichi Miura[1], Gou Fujie[1]

1. Japan Agency for Marine Earth Science and Technology

In the Kuril trench subduction zone, several large earthquakes (e.g., Tokachi-oki earthquakes) have occurred, which caused the earthquake and tsunami hazards in the Hokkaido and Tohoku region. Because the earthquake and tsunami risk was evaluated to be high in this region, more investigation and studies are required to contribute to the mitigation of those risks. In 2016 and 2018, we conducted high resolution seismic surveys in the Kuril trench from Erimo Seamount to off Kushiro by R/V *Yokosuka*. Approximately 35 km long 24 seismic profiles with ~ 6 km line separation were acquired using a 1.2 km long streamer cable and 380 inch$^3$ cluster guns. Obtained profiles demonstrate the detailed geological structure in the trench axis region. Subducting Pacific plate is deformed by the bend-related normal faults. The throw of the faults is up to ~ 300 –400 ms TWT. The thickness of the incoming sediments is > 500 ms maximum in the survey area and becomes thinner near the seamounts. Thick trench-fill sediment is deposited in the trench axis west of the Kushiro canyon, and the thickness is up to ~ 800 ms. Some profiles show weak landward dipping reflections within the hanging wall sediments. Possible slope failure is suggested in the lowermost landward slope near the Erimo Seamount.

# Subsurface Structure at the North of the Yokosuka Fault by Seismic Reflection Survey

*Shinobu Ito[1]

1. Geological Survey of Japan, AIST

The rupture of the Mikawa Earthquake on January 13, 1945 is considered to be on the Fukozu and the Yokosuka Faults. The Fukozu Fault is located relatively south and reverse L-shaped. On the other hand, the Yokosuka Fault is located relatively north and L-shaped. Ando (1974) mentioned that the NS strike section of the Yokosuka Fault in the fault zone was caused by a secondary deformation. Sugito and Okada (2004) investigated surface displacement in detail along the fault zone. They concluded that the NS strike section of the Yokosuka fault is the upper extension of the earthquake source fault although they referred to the possibility of the secondary deformation. Sugito and Okada (2004) referred that the surface earthquake fault of the Mikawa Earthquake is inconsistent with the source model of the earthquake estimated by Kikuchi et. al. (2003) from seismograms. In this way, the NS strike section of the Yokosuka Fault is not understood clearly. We carried out the P-wave seismic reflection survey at Shikoya-cho, Nishio, Aichi; at the north end of the Yokosuka Fault, in order to investigate lower extension of the Yokosuka Fault.

Not only the survey at the north of the Yokosuka Fault (GS-NSO2) but also the other survey at the south east extension of the Takahama Fault (GS-NSO1) were carried out from September 27 to October 2 in 2018. The length of the survey line GS-NSO2 is 1810m. We used one EnviroVibe manufactured by IVI. Sweep frequency is 10 to 120Hz, and sweep duration is 16S. Standard shot interval is 5m, and exceptionally 2.5m. Total shot points are 421, and we shot 3 to 5 times for each point. We used 3 string geophones of OMNI-2400 ($f_0$=15Hz) by Geospace. We used offline seismic recorder GSX system also by Geospace. Receiver interval is 5m, and total receiver points are 342. We made seismic profile by CMP stack.

We cannot see any obvious faults or signs related to the faults in the profile. Trenching survey indicate that the Mikawa Earthquake was preceded by one earthquake 2000 years ago. Total displacement of the Mikawa Earthquake and the preceding event is not more than 2m. It is impossible to detect the displacement in case of 2m displacement. However, it is possible in case that the displacement increase with depth. At least, we cannot detect the cumulative displacement in the survey.

Keywords: Yokosuka Fault, fault, seismic reflection survey

# Crust and Uppermost mantle P-wave velocity structure of the Ordos block and its neighbors based on travel time tomography

*Yaning Liu[1], Jianping Wu[1], Shuxian Bao[1], Xiaohong Meng[2]

1. Institute of Geophysics, China Earthquake Administration, 2. China University of Geosciences (Beijing)

The Ordos block is located on the west side of the North China Carton, adjacent to the northeastern part of the Tibetan Plateau, with the Yinshan organic belt to the north and the South China block to the south. And the tectonic evolution of Ordos block is controlled by the North China basin extension caused with subduction of the Pacific plate and the extrusion and sheared from the northeastern margin of the Tibet Plateau follow the collision of the Indian-Eurasian plate.

The study area spans from 32˚N to 42˚N and 108˚E to 114˚E , which includes the Ordos block and its adjacent structures . The seismic data we used for inversion were recorded by 1244 stations including: 198 permanent stations and 1043 temporary stations (ChinArray II and III), from November 2013 to August 2017. The study uses local-seismic for inversion. After manual labeled the seismic phase, we select events with more than ten phase records of individual seismic events. The epicentral distance is less than 200km. Finally, we obtained about 22,500 phase records of 1882 local seismic events.

Our preliminary research results are consistent with previous studies and surface structures of a wide range of velocity distributions. However, in the middle-upper crust under the Liupan Mountain, the low-speed anomaly extending downward is shown, which may be caused by the horizontal extrusion caused by the eastward asthenosphere flow driven by the continuous compression of the northeastern margin of the Qinghai-Tibet Plateau during the Cenozoic. While, in the middle crust of the Ordos Basin, there are weak high-speed anomalies that divide the low-speed disturbances in the basin into three parts, showing the fluctuation of the crystalline basement of the basin. In the Taihang Mountains in the west of the study area, low-velocity anomalies extending to the upper layer of the mantle are shown. We initially believe that this anomaly is related to the volcanic thermal motion that once existed on the area.

# Seismic imaging of the 2016 Kumamoto earthquake area using P and PmP data

*Dapeng Zhao[1], Haibo Wang[2], Zhouchuan Huang[2], Mingjie Xu[2], Liangshu Wang[2]

1. Department of Geophysics, Tohoku University, 2. School of Earth Sciences and Engineering, Nanjing University

We determined a high-resolution model of 3-D P-wave velocity (Vp) tomography of the crust in the source zone of the 2016 Kumamoto earthquake (M 7.3) in Kyushu, SW Japan using a large number of arrival times of first P-waves and reflected P-waves from the Moho discontinuity (PmP). The PmP data are collected from original seismograms of the Kumamoto aftershocks and other local crustal events in Kyushu. Detailed resolution tests show that the addition of the PmP data can significantly improve the resolution of the crustal tomography, especially that of the lower crust. Our results show that significant low-velocity (low-Vp) anomalies exist in the entire crust beneath the active volcanoes, which may reflect the pathway of arc magma. The 2016 Kumamoto earthquake occurred at the edge of a small low-Vp zone in the upper crust. A significant low-Vp anomaly is revealed in the lower crust beneath the source zone, which may reflect the arc magma and fluids ascending from the mantle wedge. These results suggest that the rupture nucleation of the 2016 Kumamoto earthquake was affected by fluids and arc magma.

# Estimation of 3D velocity structure in Kyushu region by the seismic tomography

*Toya Mitsuhiro[1], Koji Yamada[1]

1. Hanshin Consultants Co., Ltd.

## 1. Introduction

A high-resolution crustal structure in the volcanic zone is basic information for prediction of volcanic activity in the future. Therefore, in this study, we carry out preliminary research in Kyushu region aiming at the estimation of three-dimensional (3D) velocity structure in the volcanic zone by the 3D seismic tomography. In this region, it is suitable for this study because a large number of earthquake records of the main shock and aftershocks of the Kumamoto earthquake that occurred in April 2016 can be used and there are many volcanoes such as Mt. Aso and Mt. Unzen. Thus, we perform the 3D seismic tomography in Kyushu region for the estimation of 3D velocity structure, and consider problems on application to the volcanic zone.

## 2. Data and Method

We used arrival time data downloaded from the website of National Research Institute for Earth Science and Disaster Resilience (NIED). We selected 59011 earthquakes observed at 141 stations from April 2016 to March 2017. The selected area is 129.3˚E ~ 132.1˚E, 30.9˚N~ 34.0˚N, 0 ~ 50 km in depth. And, for P-wave arrivals, we added 804 earthquakes observed at 4 V-net stations at Mt. Aso and travel time data obtained by explosion seismic observations in the Hinagu fault area, Kyushu (The Research Group for the 2003 Hinagu Fault Seismic Expedition, 2008) and Eastern Kyushu (RESEARCH GROUP FOR EXPLOSION SEISMOLOGY, 1999). In total, our selection result in 871,690 P-wave arrivals and 840,633 S-wave arrivals.

We estimate 3D seismic velocity structure using the Fast Marching Tomography (FMTOMO) method of Rawlinson et al. (2006). This program uses the fast marching method via finite difference solution of the eikonal equation (Sethian, 1996) for calculation of synthetic travel times. The model area is 129.2˚E ~ 132.2˚E, 30.8˚N~ 34.1˚N, -4 ~ 52 km in depth. The horizontal grid spacing is 0.1˚(about 10 km) and the vertical is 4 km (the number of grids is 34×31×15 for three coordinate axis). An initial velocity structure model is JMA2001 (Ueno et al. 2002) and we set six iterations of the tomographic inversion scheme. Then, we examined the resolution of the tomographic inversion using a checkerboard resolution test (CRT). The size of checker is 2×2×2 in grid number, and the velocity perturbation for the initial velocity structure model is ±0.1 km/s. As a result of the CRT, we confirmed that checkerboard pattern is well resolved up to about 20 km deep in the Kumamoto area.

## 3. Results

Figure 1 shows plan views of the P-wave velocity and the S-wave velocity structures obtained here at 4 km depth. The pattern of velocity variation is similar to each other and pronounced low velocity area exists in the southern Kumamoto. At 0 ~ 1 km depth, low velocity area exists in the Kumamoto Plain. However, in this study, pronounced velocity variation is not seen beneath Mt. Aso and other volcanic zones. So, for improving the resolution, we are going to add earthquakes in the area with less them and stations (K-net, V-net and so on).

# Estimation of the structure of the Philippine Sea slab under south Kyushu using receiver function analysis

*Masaki Uchida[1], Takahiro Ohkura[1], Takuo Shibutani[1], Yuki Abe[2], Shintaro Komatsu[1], Ken'ichi Yamazaki[1], Yusuke Yamashita[1], Shin Yoshikawa[1], Masato Iguchi[1], Takeshi Tameguri[1], Tadaomi Sonoda[1]

1. Kyoto Univ., 2. Hot Springs Research Institute

In the subduction zone, it is considered that magmatism is caused by fluid transported to the upper mantle from the subducting slab [Tatsumi, 1986, GRL]. In order to clarify the relation between the magmatism and the subsurface structure of Sakurajima and Kirishima volocanoes, we investigate seismic velocity discontinuities beneath these regions by receiver function analyses of the teleseismic waveform.

A Receiver function (RF) is calculated by deconvolving the vertical component of a waveform of a teleseismic P-wave from its horizontal component, and phases converted at seismic velocity discontinuities in its coda can be detected with RFs [Langston, 1979, JGR]. In order to estimate the geometry of steeply dipping discontinuities, such as the upper boundary of the subducting Philippine Sea plate, with RFs, refraction of the seismic rays at the dipping discontinuities should be taken into account. For this purpose, we apply the method for stacking RFs using the multi-stage fast marching method developed by Abe et al. [2011, GJI].

Abe et al. [2013, JGR] revealed the regional variation of S wave velocity discontinuity across the Philippine Sea plate, which is divided by the Kyushu - Palau Ridge, from RF analyses of the waveform data obtained at the permanent stations. In this research, we use waveform data obtained at dense observation networks along Miyazaki-Akune and Miyazaki-Sakurajima lines from teleseismic earthquakes with magnitude greater than 5.5 occurred from November 2009 to March 2017. We use 3-D seismic velocity model [Matsubara et al. 2007, Tectonophysics] for stacking RFS, although Abe et al. [2013] used one dimensional IASP91 model.

Beneath the south Kyushu where the Western Philippine Basin formed at about 50 Ma subducts [Hilde and Lee, 1984, Tectonophysics], it is suggested that the fluid dehydrated from the Philippine Sea slab is transported to the back-arc and may cause arc volcanism activity by Abe et al. [2013]. In addition, low velocity zone of mantle wedge is detected, and this zone is considered to correspond to a serpentinized mantle by a fluid derived from oceanic crust [Bostock et al. 2002, Nature], based on the S wave velocity of serpentinite estimated by Hacker et al. [2003, JGR] and Christensen [2004, Int Geol Rev].

We obtain more precise receiver function images using dense network data and discuss the seisimic structure of Sakurajima and Kirishima volcanoes.

# Imaging subduction structure beneath the eastern part of Kii Peninsula, SW Japan, using an earthquake reflection method

*Eiji Kurashimo[1], Takashi Iidaka[1], Noriko Tsumura[2], Takaya Iwasaki[1]

1. Earthquake Research Institute, the University of Tokyo, 2. Chiba University

The Nankai trough region, where the Philippine Sea Plate (PHS) subducts beneath SW Japan arc, is a well-known seismogenic zone of interplate earthquakes. The most recent great earthquakes occurred in 1944 (Tonankai Earthquake, M=7.9) and 1946 (Nankai Earthquake, M=8.0). In recent years, various slip motions with a different time scale have been recognized at or near the updip and downdip limits of seismogenic zone [e.g., Obara, 2002; Ito and Obara, 2006]. Revealing structural factors that control the fault slip behavior is important to understand the earthquake rupture dynamics. Seismic reflection characteristics and seismic velocity variations can provide important information on the heterogeneous structure around plate interface. Recent seismic experiments reveal the relation between the crustal structure and the fault slip behavior. However, little is known about the deeper part of the plate boundary, especially the down-dip side of the seismogenic zone. In 2015, seismic array observation was conducted to obtain the subduction structure beneath the eastern part of the Kii Peninsula [Kurashimo et al., 2016]. Ninety 3-component portable seismographs were installed on a 90-km-long line nearly parallel to the direction of the subduction of the PHS. Waveforms were continuously recorded during a six-month period. During the seismic array observation, Japan Meteorological Agency determined 45 events within 10 km of our survey line. Prominent late arrivals, probably reflected waves from the deeper part of the crust can be recognized on the record sections. Earthquake data is useful to obtain a deep image. So, in order to clarify the spatial distribution of the reflectors, we applied the reflection method to the earthquake data. We used horizontal-component seismograms, because high amplitude S-wave reflection can be recognized on the record sections. Conventional common mid-point processing cannot be applied to earthquake data because the reflection point does not lie at the mid-point between source and receiver, so, we applied the Common Reflection Point (CRP) transformation [e.g., Quiros et al., 2016] to the earthquake data set using a tomography-derived 3D S-wave velocity model [Kurashimo et al., 2016]. Reflection points and their relevant travel-time from earthquake to receiver were calculated using a 3D finite difference travel-time algorithm [Hole and Zelt, 1995]. Before applying the CRP transformation, the waveform data were filtered by a band-pass filter (1 -8 Hz). After applying the CRP transformation and the stacking process, we applied a post-stack migration technique. The migrated shear wave reflection image shows that the northward dipping reflective zone interpreted to be the upper boundary of the PHS can be recognized at a depth range of about 25 -30 km. The top of the low-frequency earthquakes (LFEs) occurrence zone well corresponds to the high amplitude S-wave reflective zone. LFEs are also located in and around the low Vp and high Vp/Vs zone [Kurashimo et al., 2016]. These results suggest the occurrence of the LFEs may be associated with fluids.

# Tomography of Mejillones Peninsula using cross-correlation of ambient seismic noise

*Kellen Azua Quezada[1], Sergio Ruiz[1], Francisco Pasten-Araya[2,3], José Salomón[4], Pablo Salazar[2,3], Miguel Saez[1], César Pastén[4], Felipe Leyton[5], Wasja Bloch[6]

1. DGF, UChile, 2. DG, UCN, 3. CIGIDEN, 4. DIC, UChile, 5. CSN, Chile, 6. GFZ

The Mejillones Peninsula (MP) is locate in northern Chile (-23.28º, -70.5º). MP is a geomorphic atypical uplifted block of the coastal platform of 100 km length. This structure has been proposed as a segment boundary for large subduction earthquakes, as the case of Mw 8.0 Antofagasta (1995) and Mw 7.7 Tocopilla (2007) events. Additionally, the Peninsula presents a wide and deep layer of sediments that could enhance site effects. For this reason, in this work we study the shallow structure of MP basin. We deployed a dense temporary seismic network in the MP, which registered in continuous time from July 2013 to September 2015. From the continuous records, we built a local tomography using the spectral ambient seismic noise. We use vertical component of seismograms to obtain the Green function from cross-correlation between station pairs. The frequency domain method allows determine of phase velocity relating the zero-crossing of the real part of cross-correlation spectrum with the zero crossing of the zero-order Bessel function of the first order. The Rayleigh wave phase velocities are inverted by means of a non-linear iterative 2-D tomographic technique; finally we recover phase velocity maps at different frequencies. The tomographic maps present significant features that correlate with surface geology. We found in the West part of the MP lower velocities that East zone. We can associate this with fractured metamorphic rock. Higher velocities in the Eastern part of the peninsula are associated with the presence of intrusive rocks. The difference in velocity of these two anomalies is maintained at differents depth.

# Crustal thickness beneath Central Indonesia by the cross-correlation analysis of seismic ambient noise (2)

*Masyitha Retno Budiati[1], Genti Toyokuni[1], Tomomi Okada[1], Toru Matsuzawa[1]

1. Graduate School of Science, Geophysics Department, Tohoku University

Central Indonesia has complex tectonic structures where is characterized by several subduction zones at northern and eastern part and also active faults (e.g., Palu Koro, Matano and Hamilton faults). These complexities affect crustal structures around the region. In this study, we estimated spatial variation of crustal thickness and their relation with active tectonics. We used waveform data recorded at 10 BMKG broadband stations around Sulawesi Island. Firstly, the continuous data were divided into 20 minutes segments with time shift in every 5 minutes. Once the pre-processing steps for each segment were done, we calculated the CCFs between two contemporaneous segments from two stations and stacked the daily-averaged CCFs over 5 months. We further compressed the two-sided signal into one-sided signal by taking the average of positive and negative lag part of the CCFs in order to stabilize the dispersion curves of group velocities. To fit the synthetic and the observed group velocities, we adjusted the two layers crustal velocity model from CRUST 1.0 (Laske et al., 2013) corresponding to the observation group velocities. The velocity model that is faster than the observation was subtracted 5% and 10% to find the best crustal thickness with minimum RMS between observations and synthetics at period of 20s –30s. To confirm our procedure above, we currently apply the similar procedure to estimate the well-known Moho discontinuity in Tohoku region, Japan. We collected 5 months continuous waveform data from vertical components of 10 F-net stations around Tohoku region. The results showed that the slower velocity models makes the crustal thickness shallower. The estimated depth of Moho discontinuity beneath Tohoku region is about 20km –30km using subtracted velocity models. This is almost consistent with previous studies (e.g. Zhao et al., 1990). While the estimated depth of Moho discontinuity at eastern part of Central Indonesia is about 27km –35km which is related to the ocean crust, Batui and Sula thrust and at the continent of Sulawesi Island the estimated depth of Moho is about 35km –45km.

# Subsurface structure below the southernmost area of South Japanese Alps estimated by seismic interferometry imaging

*Toshiki Watanabe[1], Hasegawa Daima[1], Tanio Ito[2], Ken'ichi Kano[3], Susumu Abe[4], Akira Fujiwara[5], Yoshinori Kouchi[6]

1. Graduate School of Environmental Studies, Nagoya University, 2. Association for the Development of Earthquake Prediction, 3. Shizuoka Univertity, 4. JAPEX, Co. Ltd., 5. JOGMEC, 6. Geosys, Inc.

In the Tokai area, seismological events, such as low frequency events and slow slip events as well as large earthquakes, are occurred caused by subduction of the Philippine Sea (PHS) plate. The eastern Tokai area is a transition zone from the collision zone of Izu arc to the subduction area. To understand the subsurface structure in this area and fill the gap between the previous seismic surveys, a seismic observation using a dense seismic linear array composed of 34 receivers was conducted in 2013.
In this study, we applied seismic interferometry imaging to the seismic records of the array observation. Seismic interferometry can retrieve the reflection response between two receivers as if one receiver is a virtual shot and the other is a receiver by calculating the cross-correlation of the transmission responses recorded at the two receivers. For a single receiver, the reflection response recorded at the receiver from a source at the same location is retrieved by calculating the autocorrelation of the transmission response recorded at the receiver. In this study, we used regional deep earthquakes occurred in the Pacific Oceanic slab as the seismic sources to image the PHS plate and crustal structures. We conducted autocorrelation analysis and created reflection profiles for both P- and S-waves. We projected the cross-correlation between two adjacent stations to their mid-point to improve the spatial density of the stations. After migration using the velocity structure obtained by the tomography analysis, we obtained the P- and S-wave reflection depth profiles.
In the S-wave depth profile, the shallower area above 25 km shows reflective, while the deeper area is less reflective. The boundary becomes shallower to the north-east of the profile. By comparing this profile with the result of other seismic surveys and with pre-existing plate models, we interpreted that the strong reflectors shown at the depth about 25 km in the southwest of this profile are the plate boundary. This interpretation is consistent with the result of Hirose et al. (2008) showing that the basaltic oceanic crust of the PHS plate shows low Vs and high Vp/Vs. In the eastern half of the profile lacks reflectors that correspond to the plate boundary. This may be attributed to a weak contrast of physical properties between the felsic island arc crust proposed by Kodaira et al. (2004) and the Japanese island arc crust, or complicated geological structure due to the collision of Izu arc.

# Strong variations of near-surface seismic anisotropy of Taiwan revealed by coda interferometry

*Hsin-Yu Lee[1], Yuancheng Gung[1], Li-Wei Chen[2], Ling-Yun Chiao[3]

1. Department of Geosciences, National Taiwan University, Taiwan, 2. Department of Earth and Planetary Science, University of California at Berkeley, CA, USA, 3. Institute of Oceanography, National Taiwan University, Taiwan

We report the near-surface (<500 m) seismic structure, Vs, Vp and Vs anisotropy, of Taiwan using the empirical Green’ s function of body waves extracted by applying coda interferometry to the vertical station pairs at 56 borehole sites. We find clear characteristic cos2θ dependence of Vs in all the determinations of Vs azimuthal anisotropy. Because the borehole sites are located at very diverse geological structures of Taiwan, we are able to notice the following interesting features about the near-surface Vs anisotropy: (1) The patterns of the observed anisotropy fall into two categories, OPA (Orogeny-Parallel Anisotropy) and SAA (Stress-Aligned Anisotropy), and both types of anisotropy fit well the local geological fabrics and/or the ambient stress. (2) About half of the amplitudes of anisotropy are larger than 10 %. The site with the largest amplitude of anisotropy (34%) is located in the slate belt of the Central Ranges, while the sites with weak anisotropy (~1%) are associated with low Vs and/or small strain rate. (3) The amplitudes of OPA are generally stronger than SAA, and the types of anisotropy are closely related to the Poisson’ s ratios at the borehole sites. (4) The strong variations of the OPA amplitudes can be explained by the rock types in the well body with the metamorphic rocks carrying stronger anisotropy than the sedimentary rocks. (5) The strong near-surface anisotropy also implies that delay times contributed by the shallow crust might have been underestimated in studies of shear-wave splitting measurements using the direct arrivals of earthquakes waves.

# Investigating anomalous crustal structures along the convergent zone in eastern Taiwan with the new airborne magnetic survey and updated seismic tomographic models

*Chi-Hsuan Chen[1], Hsin-Hua Huang[2], Lun-Tao Tong[3], Wayne Lin[3], Po-Tsun Lee[1], Shou-Fang Chang[1], Jin-Fa Lee[1]

1. Cntrl. Geo. Surv., MOEA, Taiwan, 2. Inst. Earth. Sc., Acad. Sinica, Taiwan , 3. Industr. Technol. Res. Inst., Taiwan

The convergence between Eurasian plate and Philippine sea plate produces the tectonically and geodynamically complex regions of Taiwan. The orogeny has been suggested as from ancient oceanic-oceanic plate subduction transforming to the continental-oceanic plate collision as the proceeding of the accreted volcanic arcs. The major suture of the plate boundary in eastern Taiwan, the Longitudinal Valley, contributes most of the seismic activities and absorbed about half of the plate convergence. How the shortening and disappearance of the oceanic plate provoked multidisciplinary researches in discussing the kinematics and the related earthquake structures.

Local seismic tomography is a useful technique for unraveling the subsurface structures. The Taiwan seismic tomographic studies that are advanced by large projects or by integrating multiple data sets have been proposed in recent years. Furthermore, since 2012 the seismic signal digitization of the Central Weather Bureau (CWB) seismic network was upgraded from 12 to 24 bit, and the potential timing issue of telemetry delays has been eliminated with onsite GPS time system. Additionally, the new airborne magnetic survey has been carried out in eastern Taiwan by the Central Geological Survey (CGS) and the Industrial Technology Research Institute (ITRI) recently. High magnetic anomalies were detected not only in the volcanic arc but also in the eastern Central Range along the north-south trending Longitudinal Valley. These observations motivate us to revisit the subsurface structures with updated seismic tomographic models using new CWB data sets from 2012 to 2015.

The iso-velocity contours of the updated model keep similar structures with the previous model at first order but furtherly reveal more details. A continuous high-Vp and high-Vp/Vs bulge which extends to the shallow depths of the eastern Central Range has been interpreted as a high-pressure rock exhumation along the subduction of South China sea plate or an obducted Luzon forearc sliver. On the other hand, the new airborne magnetic survey reveals two individual high magnetic stripes that share the same high magnetic characteristics with the oceanic crust. However, the magnetization vectors behave oppositely in the direction at both flanks of the Longitudinal Valley. Such findings of these integrated geophysical analyses enable us to discuss the anomalous crustal structures and their tectonic implications.

[J] Oral | S (Solid Earth Sciences)：S-SS Seismology

Thu. May 30, 2019 1:45 PM - 3:15 PM JST | Thu. May 30, 2019 4:45 AM - 6:15 AM UTC | A05 TOKYO BAY MAKUHARI HALL

## [S-SS12] Crustal Structure

convener:Kazuo Nakahigashi(Tokyo University of Marine Science and Technology), Chairperson:Yoshio Murai(Hokkaido University), Genti Toyokuni(東北大学)

The aim of this session is to cover seismological and geophysical studies on the Earth's crust. Contribution on seismological and geophysical structure of the crust, processes that develop in the crust which include earthquakes, volcanoes and geological descriptions of the crust are welcomed. We also welcome theoretical and methodological studies that will serve as basics in such explorations.

### [SSS12-01] Shrinking and draining continental lower crust: its binary effects of stress and fluid on crustal activities

# Shrinking and draining continental lower crust: its binary effects of stress and fluid on crustal activities

*Takehito Koyama[1]

1. Institute of Industrial Science, the University of Tokyo

Basically, the continental crust itself is presumed to be static passive polycrystalline rocks with its ductility in the aseismic deep. However, this ductility seems difficult to explain crustal activities still debated: not only the long-standing stability (the resistivity to the isostatic decay) but also the short-term activities, e.g., inland horizontal compressive state (Zoback, et al. (1989)), intracrustal seismicity (Calais, et al. (2016)), and rare lower crustal earthquakes (Simpson (1999)).

Then, can we rethink the crust, especially its controversial lower? Actually, I presented a possibility of the shrinking and draining of the continental crust through “phase separation or phase demixing” at JpGU in 2012. Thus, I will propose a new lower crust causing the deformation, qualitatively but comprehensively discussing the activities.

As basic components of the lower crust, I consider $SiO_2$ and $H_2O$ (with other elements and volatiles). Their melt mixtures cause phase separation under lower crustal temperatures and pressures (Kawamoto (2006), Hack, et al. (2007)). Furthermore, melt $SiO_2$ forms 3-dimensional macromolecular network (Stebbins (2016)). Thus, I regard this process as the volume shrinking of this elastic $SiO_2$ network separating from an aqueous fluid (Tanaka (2012), Koyama, et al. (2009), Koyama and Tanaka (2018); also the shrinking $SiO_2$ in Tognonvi, et al. (2011)): This network macroscopically behaves as a phase-separating glass (before crystallization) or an elastically hard self-squeezing wet sponge.

Then, the new lower crust, constructed by the shrinking $SiO_2$ network draining the $H_2O$ fluid, combines and interacts with the usual upper crust (Figure): The elastic shrinking laterally compress the upper crust from below, bringing the long-term stability and intermittent drained-fluid injections triggering the intra-upper-crustal earthquakes. Importantly, this lower crust, aiming at shrinking, must follow some degree of external compression: the aseismicity or the apparent ductility. However, when the elastic $SiO_2$ network suffers a large local differential stresses under the stress/fluid interlayer interactions, the brittleness should arise as lower crustal seismicity.

Therefore, assuming the lower crust to be not monistic solid but dualistic solid/fluid coexisting during their phase separation, we can qualitatively explain the crustal movements using the actively shrinkable/drainable lower crust mechanically/materially interacting with the upper crust.

# Seismic velocity structure in southern Hokkaido deduced from ocean-bottom seismographic and land observations

*Yoshio Murai[1], Kei Katsumata[1], Tetsuo Takanami[2], Tomoki Watanabe[3], Tadashi Yamashina[4], Ikuo Cho[5], Masayuki Tanaka[6], Ryosuke Azuma[7]

1. Institute of Seismology and Volcanology, Faculty of Science, Hokkaido University, 2. Department of Terrestrial Magnetism, Carnegie Institution of Washington, 3. Marine Works Japan LTD, 4. Kochi University, 5. National Institute of Advanced Industrial Science and Technology, 6. Meteorological Research Institute, 7. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

The Kuril arc collides with the northeast Japan arc in the southern part of Hokkaido, Japan. Such a collision results in building the Hidaka Mountains and is related to the seismic activity and large earthquake occurrence such as the Urakawa-Oki earthquake (Ms 6.8) on March 21, 1982. It is important to image the three-dimensional crustal structure in order to clarify the collision tectonics and understand the patterns of earthquake occurrence and the mechanism of large earthquake occurrence. A group of seismologists from eleven universities operated a dense temporary network of land stations from 1999 to 2001 in and around the Hidaka Collision Zone [Katsumata *et al.* (2002, Bull. Earthq. Res. Inst., **77**)]. In addition, we conducted ocean-bottom seismographic observations in 1999 and 2000 in the south off Hokkaido region. Murai *et al.* (2003, GRL **30**) estimated P-wave velocity (Vp) structure by the 3-D tomographic inversion [Zhao *et al.* (1992, JGR **97**)] of seismic travel time data obtained from networks of ocean-bottom seismographs (OBSs) and land stations in 1999. However, their spatial resolution was poor for the deep crustal structure and they could not obtain S-wave velocity (Vs) structure because of limitation of the number of data. Murai *et al.* (2016, JpGU) estimated structure of both Vp and Vs by the tomographic inversion of travel time data from OBSs and land stations in 1999 and 2000. We found a problem in the reduction of the travel time residuals due to errors of station corrections in their analysis. Here we estimate Vp and Vs structure again after correcting their errors.

The results from the tomographic analysis are as follows.

1. A high-velocity body seems to be obducted toward the crest of the Hidaka Mountains from east beneath the land area, which is interpreted as the obducted lower crust of the Kuril arc. The high-velocity region extends to the east of the Hidaka Mountains at depths of 15-35 km. A low-velocity region is located to the west of the Hidaka Mountains so as to contact with the high-velocity region at the Hidaka main thrust. It is interpreted as the northeast Japan arc. These results are consistent with those obtained by previous tomographic studies.

2. We found a distinct low velocity region dipping southwestward from beneath the Hidaka Mountains to the source area of the 1982 Urakawa-oki earthquake at depths of 35-45 km which was imaged only by the tomographic analysis using the data from OBSs. It is interpreted as the lower part of the delaminated Kuril arc lower crust, which has an area of about 50 km wide by 50 km long.

3. The colliding low-velocity crustal material disappears in the southeast of Cape Erimo. Moreover many microearthquakes occurred in the low-velocity region whereas the seismic activity was low outside it. These results suggest the effect of arc-arc collision is reduced abruptly in the offshore area as the southeastward extension of the Hidaka Mountains.

©2019. Japan Geoscience Union. All Right Reserved. 

4. The hypocenter of the 1970 Hidaka earthquake (M 6.7) is located at the boundary between the high and low velocity regions. The fault plane of the 1982 Urakawa-oki earthquake is located at the western boundary of the high Vp anomaly faster than 8.0 km/s. Thus these M7 class inland earthquakes occurred at material boundaries, which is consistent with Kita *et al.* (2012, JGR **117**).

5. The overriding plate above the seismogenic asperity of the 2003 Tokachi-oki earthquake (M 8.0) is characterized by high Vp/Vs on the northeast side of Cape Erimo. This result is consistent with Machida *et al.* (2009, Tectonophysics **465**).

Acknowledgments
We thank the crew of the R/V Kofu Maru of the former Hakodate Marine Observatory for their cooperation during deployment of OBSs. We thank D. Zhao for permitting us to use his computer program for 3-D tomographic inversion.

# Structural Complexity Associated with Arc-Arc Collision in Hokkaido Island, Japan - Review on Controlled-Source Seismic Researches in Western and Central Hokkaido -

*Takaya Iwasaki[1], Noriko Tsumura[2], Tanio Ito[3], Kazunori Arita[4], Hiroshi Sato[1]

1. Eathquake Research Institute, the University of Tokyo, 2. Graduate School of Science, Chiba University, 3. Association for the Development of Earthquake Prediction, 4. Hokkaido Research Center of Geology

Hokkaido Island has a complicated crustal structure reflecting subduction, accretion and collision processes from Late Jurassic to the present (e.g. Niida and Kito, 1986; Kimura, 1986; Ueda 2016). Central Hokkaido is composed of almost N-S trending geological units of the Sorachi-Yezo Belt (SYB), Hidaka Belt (HB) and Tokoro Belt (TB) from west to east. This region has been highly deformed under the dextral oblique collision between the Eurasia and North America (Okhotsk) Plates and the following westward movement of the Kuril Arc due to the oblique subduction of the Pacific Plate. The latter event has formed the Hidaka Collision Zone (HCZ) with the uplift of the Hidaka metamorphic rocks along the Hidaka Main Thrust (HMT) and the development of the west-verging fold-and-thrust belt with thick sedimentary package on the SYB.

In this paper, we review the previous controlled-source seismic studies in western and central Hokkaido, focusing the structural complexity formed by the arc-arc collision. The first seismic refraction study was undertaken in western Hokkaido in 1968-1969 (Okada et al., 1973). The crust obtained is 20-30 km thick, consisting of 5.9 and 6.6 km/s layers overlying the uppermost mantle of 7.5 km/s. Seismic refraction studies in 1984 and 1992 revealed the complicated structure in central Hokkaido (Iwasaki et al., 1998). The result from the 1984 profile along the Pacific coast is characterized by a rather thick (> 7 km) sedimentary package with a velocity of 2.5-5.5 km/s in SYB. The 1992 refraction/wide-angle reflection profile, which was extended from the western SYB to the eastern TB with SW-NE direction, also show a thick (~8 km) sedimentary package with a velocity of 2.6-5.8 km/s in the southwestern part of SYB, The upper crustal velocity show significant increase from 5.6 km in HB to 5.7-6.15 km in TB.

In 1990’s, several seismic reflection and refraction/wide-angle refraction experiments were undertaken in the southern HCZ (Arita et al., 1998; Tsumura et al., 1999; Ito et al., 2000) and the northern HCZ (Iwasaki et al., 2004, 2016). In the southern HCZ, the crustal delamination by the collision was clearly imaged from the reflection data by applying an advanced method of CRS/MDRS stacking (Tsumura et al., 2014). Namely, the upper 22-23 km crust in the Kuril Arc side is obducted along the HMT, while the lower part of the crust is descending almost to reach the Pacific plate. In the northern part of the HCZ, the detailed structure was obtained along the 227-km profile with E-W direction. In the fold-and-thrust belt of SYB, there exists a very thick (> 10-12 km) sediments including two or three velocity reversals. East of this package, several west-verging events are recognized down to a depth of 7-8 km, probably corresponding to the faults and structural boundaries formed by the collision process. The HMT was well imaged both by seismic reflection processing and refraction/wide-angle reflection analysis, along which the crystalline basement is almost outcropped. Beneath these complicated structures, we succeeded in imaging the NE Japan Arc crust which descends eastward to a depth of about 40 km under the hinterland side.

In the northern HCZ, the clear crustal delamination is not seen. The obduction of the upper Kuril crust starts at a deeper crustal level of at least 27-30 km and more easterly (~20 km) of the HMT as compared

©2019. Japan Geoscience Union. All Right Reserved. 

with the case in the southern HCZ. If the metamorphic rocks outcropped east of the HMT are the same crustal materials at depths shallower than 23 km as in the case of the southern HCZ, the deeper crustal portion originally situated at 23-27~30 km depth must exist in the western side of the present HMT. The very strong and deep reflectors found west of the HMT might result from the mixture of upper crustal (low velocity) materials of the NE Japan Arc and middle/lower crustal (high velocity) materials of the Kuril Arc.

# Seismic imaging of the eastern Japan forearc region using S-net data

*Genti Toyokuni[1], Dapeng Zhao[1], Naoki Uchida[1], Takashi NAKAYAMA[1]

1. RCPEVE, Tohoku Univ.

The great 2011 Tohoku-oki earthquake (Mw 9.0) occurred off the Pacific coast of Northeast Japan, where the Pacific plate is subducting beneath the Okhotsk plate. The S-net (the Seafloor observation network for earthquakes and tsunamis along the Japan Trench), initiated in 2016, is a large-scale, permanent, ocean-floor seismograph network with cabled 150 stations, which covers a wide oceanic region off Northeast Japan (Kanazawa, 2013). In this study, we aim to reveal the 3-D seismic velocity structure beneath the forearc region covered by the S-net.

We carefully picked 3754 first P-wave arrival times of 63 local earthquakes (M3.5–6.2) in the Tohoku forearc region from the continuous S-net records. Then, the newly picked data are integrated with the existing arrival-time data (Zhao et al., 2012) of 360 teleseismic and 1,180 local earthquakes recorded at 3,205 Hi-net stations on the Japanese land areas. These combined data are inverted to obtain a new 3-D P-wave velocity (Vp) model beneath the entire Northeast Japan arc by using the seismic tomography method of Zhao et al. (2012).

In this work we focus on the obtained 3-D images at depths < 40 km below the region covered by the S-net. The major results are summarized as follows.
(1) Prominent low-Vp anomalies are revealed in the off-Iwate and off-Fukushima areas. These features are consistent with those revealed by previous works (e.g., Zhao et al., 2011; Huang & Zhao, 2013; Liu and Zhao, 2018), indicating that our hand-picked arrival-time data are quite accurate and robust.
(2) A significant high-Vp anomaly is revealed along the Japan Trench especially beneath the off-Miyagi region where the 2011 Tohoku-oki earthquake (Mw 9.0) occurred, which may reflect that the sedimentary layer is very thin above the subducting Pacific plate.

# The relationship between the location of the mid crustal reflector and seismicity in Iwaki area, northeastern Japan

*Takashi Iidaka[1], Shin'ichi Sakai[1], Toshihiro Igarashi[1], Kazushige Obara[1], Aitaro Kato[1], Tetsuya Takeda[2], Shigeki Nakagawa[1]

1. Earthquake Research Institute, University of Tokyo, 2. National Research Institute for Earth Science and Disaster Resilience

The Tohoku-Oki earthquake occurred on March 11, 2011. After the 2011 Tohoku-Oki earthquake, the seismicity in Japan changed. The seismicity increased in some areas. The seismicity decreased areas also exist. It has been considered that the change of the seismicity is related to the change of the stress field caused by the large slip at the plate boundary. The Iwaki area, northeastern part of Japan, is one of the areas that the seismicity changed. The seismicity in this area increased drastically. Before the 2011 Tohoku-Oki earthquake, the seismicity was very low. But, the seismicity increased after the Tohoku-Oki earthquake. The cause of the changes of seismicity was not clear. It is very important to survey the crustal structure in order to understand the mechanism of the seismicity in this region. The characteristics of the seismicity of the area are following. The earthquakes were occurred within a triangle area. The size of the one side of the triangle was around 50 km. The crustal seismicity in the area divided into two depth range. The seismicity in the shallower area is less than 15 km. The depth range of the other group is 15–25 km.

A temporary dense seismic array (63 seismometers) has been deployed to know the seismicity and mechanism in this area. Usuda (Master thesis 2018) studied the crustal structure using this data. The crustal structure was studied with a reversed VSP (Vertical Seismic Profile) method. The clear two later phases were detected. One of the later phases was the reflected wave at the Moho boundary. The other phase was the reflected phase at the middle of crust. The location of the boundary of the middle of the crust was consistent with that of seismic activity area inside the crust. The amplitude of the reflected wave was very large. It was expected that the reflected wave was caused by the reflector with fluid.

We researched that the relationship between the seismicity in this area and location of the mid-crustal reflector. In this area, the seismicity increases from March, 11, 2011. The seismicity started at the southern part the reflector. The seismicity increased in and around reflector area from Mar., 11 to Apr. 10, 2011. At the northern part of the reflector, a relatively low-seismicity area appeared. On the Apr., 11, 2011, the Hamadori earthquake occurred in the low-seismicity area. We suppose that there is some relationship between the seismicity of the area and reflector. If the reflector is caused by the crustal fluid, the increase of the seismicity in Iwaki area might be related to the crustal fluid.
The outline of reflector obtained by Usuda (Master thesis 2018) is related to the location of the temporally seismic stations. In Iwaki region, the earthquakes are located at the north of the reflector. We want to know the true size of the reflector. We researched the waveforms of the seismic stations located in the north of the reflector area. Hi-net and F-net stations were used. The later phase with large amplitude was found at the seismic stations. We found the reflector at the north of the reflector of Usuda (2018).

# Abnormal Seismic Anisotropy beneath the Tokyo Metropolitan Area (1) Mantle of the Philippine Sea Slab

*Motoko Ishise[1], Shin'ichi Sakai[1], Aitaro Kato[1], Shin Aoi[2], Makoto MATSUBARA[2]

1. Earthquake Reseach Institute, University of Tokyo, 2. National Research Institute for EarthScience and Disaster Resillience

## 1. Introduction

The Tokyo metropolitan area is located on a unique convergence zone associated with the North American (NA) plate: beneath the metropolitan area, dual subduction system was formed by the Pacific (PAC) and Philippine Sea (PHS) plates. Furthermore, subduction of the PHS slab brings a collision zone between the NA plate and the Izu-Ogasawara islands arc, which is on the PHS slab, in the vicinity of the metropolitan area. Therefore, the metropolitan area is seismically active and has various types of earthquakes. However, the relationship between the configuration of plates (the NA, PAC, and PHS plates) and the seismicity remains unknown, although seismo-tectonics of the region has been studied from the various points of view, such as earthquake mechanism, hypocenter distribution, and seismic velocity structure. Thus, we focus on seismic anisotropy that could provide useful information on dynamics and tectonic. In this study, we investigate the three-dimensional (3D) structure of P-wave azimuthal anisotropy beneath the Tokyo metropolitan area.

## 2. Data and Method

The modeling space is the Tokyo metropolitan area (34.7 - 36.8˚N, 138.5 - 141.5˚E, 0 - 150 km). In order to determine 3D P-wave azimuthal anisotropy velocity structure, seismic anisotropy tomography method of Ishise and Oda [2008] was applied to 442960 P wave arrival time data from 1859 local earthquakes recorded at 500 seismic stations, including 296 Meso-net stations. Initial source parameters (location and origin time of earthquake) used in this analysis were determined independently by NIED. The 3D velocity structure in the modeling space is described by velocity parameters assigned to a 3D grid structure. The grid structure was composed of 0.1˚ - 0.2˚ grid spacing in the latitude and longitude directions. In the vertical direction, grid nodes were spaced at 5 - 20 km.

## 3. Results

As a result of the tomographic analysis, we found a unique anisotropy region in the lower edge of the PHS slab mantle, or rather the contact zone between the PHS and PAC slabs. The region has strong anisotropy, and the fast axes are uniformly oriented in the N-S trending direction. Generally, anisotropy in the slab can be explained by lattice preferred orientation of mantle minerals or alignments of cracks and faults. However, any mechanism cannot explain the N-S trending anisotropy in the PHS slab beneath the study area. It might suggest that the modeling under the assumption of azimuthal anisotropy would be inappropriate for the study area. Alternatively, it is possible that we have to change our basic idea of the subduction zone.

Acknowledgments: We used Hi-net seismological data. This study was supported by the Tokyo metropolitan project.

## [S-SS12] Crustal Structure

convener:Kazuo Nakahigashi(Tokyo University of Marine Science and Technology), Chairperson:Tsuruga Kayoko(Tokyo University of Marine Science and Technology), Yojiro Yamamoto(Japan Agency for Marine-Earth Science and Technology)

The aim of this session is to cover seismological and geophysical studies on the Earth's crust. Contribution on seismological and geophysical structure of the crust, processes that develop in the crust which include earthquakes, volcanoes and geological descriptions of the crust are welcomed. We also welcome theoretical and methodological studies that will serve as basics in such explorations.

An onshore-offshore seismic data set was collected across the Suruga bay in 2018 to determine the deep structure of the subducting Philippine Sea plate (PHS), whose upper surface is estimated to be a seismogenic source fault of the Fujikawa fault system. Three-component of land seismometers (GSX) were deployed with a spacing 100 –200 m from the southern range of Akaishi Mountains to Yui and western part of Izu Peninsula along the seismic lines using total 300 seismometers along the 40-km-long seismic lines. Three-component of ocean bottom seismometers (OBSs) were deployed with spacing of 1 km on the sea bottom deeper than 500 m along the 18 km-long marine part. Five shallow marine ocean bottom seismometers (OBXs) were deployed at the shallow marine western part of Suruga Bay along the 2-km-long interval. They recorded seismic shots generated from four, 200 kg dynamite shots and air gun array with a total volume of 1950 cu. inch. Total number of shots by air gun array was 1479 and shot spacing was 25 m. Data quality is good, allowing the identification of clear refraction by air gun array in the integrated shot gathers. Multi-channel seismic data were also collected towing a 600-m-long streamer cable with 96-ch hydrophones (Tsuruga et al., 2019 JpGU). The redatumed seismic data were produced using interferometric OBS imaging method (Shiraishi et al., 2016). All seismic data were processed according to a standard common-midpoint (CMP) stacking and a post stack time migration. We used refraction tomography to determine the P-wave velocity structure, that revealed down to 10 km in depth beneath the central part of the seismic line. Obtained post-migrated time section portrays the west-dipping reflectors from 3.5 sec (TWT) to 7 sec beneath the eastern part of the Suruga bay, from 5 to 11 sec beneath thesouthern range of Akaishi Mountains. The migrated time section was depth converted using the velocity structure obtained by earthquake tomography based on Hi-net data. On the depth section the depth to an estimated upper surface of PHS is 7 km beneath Yui, western coast of Suruga bay, and 15 km in beneath the central part of land seismic line in the Shizuoka side. The p-wave velocity structure deduced by refraction tomography reveal the wedge-shaped low-velocity area beneath the western part of Suruga bay. The velocity structure accords well to the subduction of PHS and distribution of hypocenters.

The onshore-offshore seismic survey was performed under the Integrated Research Project on the Fujikawa-kako fault zone funded by MEXT. This survey also supported by the research fund of ERI, Univ. Tokyo.

# Multi-channel seismic profiling in the northern part of Suruga bay using the Shiyomaru-vessel of Tokyo University of Marine Science and Technology (Preliminary report)

*Kayoko Tsuruga[1], Hiroshi Sato[2], Hisatoshi Baba[3], Yoshihiro Sekino[1], Toshifumi Hayashi[1], Hayato Kondotec[1], Chiharu Aoyama[1], Tetsutaro Aikawa[1], Tatsuya Ishiyama[2], Masanao Shinohara[2], Shinji Kawasaki[4], Yasuhisa Tanaka[4]

1. Tokyo University of Marine Science and Technology, 2. University of Tokyo, 3. Tokai University, 4. JGI, Inc.

There is few detail observations and studies about the subduction structure in Suruga trough area as a plate boundary between the Philippine sea plate and Eurasia plate. It is very important to understand the detail structure of Fujigawa fault system to prevent and reduce earthquake disaster by future Tokai earthquake. We have been trying to clarify a shallow structure in this important area by means of both seismic reflection and refraction surveys since 2016 and 2017 (Tsuruga *et al.*, 2016, 2017, 2018). In this report, we show the preliminary results of the seismic reflection and refraction surveys in Suruga Bay, Central Japan, conducted by Shiyomaru-vessel of Tokyo University of Marine Science and Technology (TUMSAT) cooperated with University of Tokyo and Tokai University.

We conducted the 2-D seismic reflection and refraction survey with air-guns and streamer cable system in Suruga Bay, from Oct. 1 to 9, 2018, along three surrey lines (*i.e.*, H30-L00/R00, H30-L01 and H30-L02 lines) which were located in the northern part of Suruga bay with the length of 19.5 km, 20.0 km and 16.1 km, respectively. We used two Bolt air-gun source systems of ‘Tri-Gun’ 1500LL (350 cu.in x 3) and 1500LL (300cu.in x 3) with a total air volume of 1,950 cu.in for H30-L00/R00 and H30-L02 survey lines with a shot interval of 50 m while we used Tri-Gun 1500LL (350cu.in x 3 ) with a volume of 1050cu.in with a shot interval of 25 m along H30-L01 line. Total shot number was 2717. Hydrophone receivers array consisted of Hydroscience digital streamer cable including 96 channel sensors with an interval of 6.25 m inside a cable of 600 m long, and a small tailbouy. TUMSAT research vessel ‘Shinyomaru’ has the following principle specifications: length, beam, and gross tonnage are 65 m, 12.5m, and 986 tons, respectively. Details of the refraction survey across a land area and oceanic area will be shown by Sato *et al*. and Baba *et al*. (in this meeting, 2019).

Preliminary results show some important features as follows: Reflection section of H30-L00 indicates a continuous west-tilting reflection phase which may be located around an upper boundary of the sedimentary layers over the subducting oceanic plate toward west. These reflection phases might be continued to the those along H29-L02 located in the northern area and H30-L02 and H28-L03 located in the southern area. We have not found the dominant characteristics of subduction boundary in these observations. Along H30-L01 we might find an interesting feature as a boundary between Honshu block and Izu peninsula. The details of our result will be shown in the presentation.

This study was supported by fond from the Ministry of Education, Culture, Sports, Science and Technology. We appreciate the big cooperation by Shizuoka prefecture Federation of Fisheries Cooperative Associations and many Fishery Cooperatives around Suruga Bay to understand our study. We thank Tokai University for helping us in an ocean by a vessel ‘Hokuto’. Finally, we greatly thank Shinyomaru's crews and many staffs of our university for their encouragement and helps.

# Crustal structure refraction survey using Airgun-OBS in the northern part of Suruga Bay -Fujikawa fault zone- (Preliminary Report)

*Hisatoshi Baba[1], Kayoko Tsuruga[2], Hiroshi Sato[3], Tatsuya Ishiyama[3], Masanao Shinohara[3], Takahito Nishimiya[4], Shintaro Abe[5]

1. Department of Marine and Earth Science, Tokai University, 2. Tokyo University of Marine Science and Technology, 3. Earthquake Research Institute, University of Tokyo, 4. Meteorological Research Institute, Japan Meteorological Agency, 5. Association for the Development of Earthquake Prediction

As part of the exploration of the crustal structure of the Ministry of Education, Culture, Sports, Science and Technology "Priority investigation observation in the Fujikawa fault zone" (Sato et al., 2019 (the present Society); Tsuruga et al., 2019 (the present Society)), in Suruga Bay Reflection and refraction seismic survey by the Tokyo University of Marine Science and Technology, practice ship "Shinyo Maru (986 tons)" was carried out at a survey line of about 19 km (H30 - L00 main line) traversing north to east and west. In this our presentation, we present a preliminary report on the outline of Airgun-OBS structure exploration (refraction seismic survey) and the results obtained.

The H30 - L00 main line starts at the water depth of 485 m in Shizuoka, Shimizu, Okitsu City coastal area, the deepest part is 1320 m in the vicinity of the central part of Suruga Trough and the eastern end is over 500 m in the coastal area of Numazu, Heda City. It is a survey line of trough topography sandwiched by slopes. Since the distance between east and west distances in the northern part of Suruga Bay is short and the coastal area is also a fishing ground, the length of the survey line is limited to about 19 km.

For the refraction seismic survey in the main line, two sets of Tri-Gun by Bolt Co., Ltd. (total capacity 1950 $in^3$) were towed, and at about 50 m intervals (since the shooting points were adjusted so as to be interposed between practically approximately blast occurred at intervals of 25 m), 18 sets OBS were deployed at about 980 m intervals. Typhoon 24 passed around Suruga Bay on the day of the exploration, so six of the 18 OBSs caused abnormal floating and so on, and they stranded to the coast (Nakao et al., 2019 (the present Society)), so data could not be obtained near the Suruga trough central axis. However, good records were obtained with 12 OBS.

Analysis is ongoing. Looking at the state of each Record Section obtained, the first arrival data can be clearly confirmed throughout the survey line, but a complex structure is presumed because it is also a line surrounding the plate boundary. The earliest layer of apparent velocity is about 6.8 km / sec, and the velocity structure model is estimated to be roughly 5-layer structure. The sedimentary layer of the first, the second and the third layer (acoustic basement layer) are inclined to the west side towards the Suruga Bay central axis, and the reflection cross section (Tsuruga et al., 2019 (the present Society)) and Match. Detailed structure model results will be reported in this presentation.

We have greatly cooperated and inconvenienced the Yui Port Fishery Cooperative Association, Shimizu Fisher Cooperative Cooperative Association and Toda Fisher Cooperative Cooperative Association for the establishment of OBS.

# 3D seismic attenuation profiling for imaging an active fault in Uchiura wan

*Tetsuro Tsuru[1], Shio Shimizu[1], Mayu Ogawa[1], Jin-Oh Park[2], Seishiro Furuyama[1], Kosaku Arai[3], Takahiko Inoue[3], Chen Guo[2]

1. Tokyo University of Marine Science and Technology, 2. Atmosphere and Ocean Research Institute, The University of Tokyo, 3. National Institute of Advanced Industrial Science and Technology

We tested seismic attenuation profiling (SAP) to image active faults on a mini-3D seismic reflection dataset observed at Uchiura wan in 2018. Seismic reflection surveys are often conducted to investigate not only geological structures but also development of faults in sedimentary basins, because the past activities of faults are recorded as offsets of geological formations at their locations. However, it is sometimes difficult to specify the existence of faults within highly faulted/fractured areas because seismic reflections are inherently invisible there. SAP has been, therefore, applied to image faults as well as fractures and investigate their activities in poorly reflective areas: the igneous oceanic crust and volcanic areas.

SAP is a method to map seismic attenuation property using seismic reflection data. The authors use the spectral ratio method to estimate Q from seismic reflection data in frequency domain, because the method can be robustly applied in poorly reflective area. Reversely, Q-estimation methods in time domain are not stable in such areas because no reliable amplitude information is available there. However, SAP using the spectral ratio method has not been applied to image faults and fractures developed in sedimentary units (e.g. Tsuru et al, 2017; 2018), because the accuracy in Q-estimation decreases due to spectrum distortions. The spectrum distortions are mostly caused by interruption between primary reflections and interbed multiples within the sedimentary layers. Shimizu (2019) investigated the influences of several Q-estimation methods to interbed multiples by numerical experiments and then improved some processing parameters in the estimation of Q in the frequency domain. As a result, the authors successfully imaged a trend of an active fault on SAP time-slices (Q-slices) from a mini-3D seismic reflection dataset.

A high-resolution mini-3D seismic survey was conducted at Uciura wan in Suruga Bay on August 7$^{th}$ in 2018, by chartering R/V Daini Ikoi Maru of Oki Seatec Co., Ltd. During the survey, twenty of seismic lines were collected with sampling rate of 1 ms. An underwater speaker was adopted as an energy source in consideration of mitigating impact on marine ecosystem. Shot records were collected every 10 s (equivalent to about 10 m with the vessel speed of 2 knots) with a streamer cable of 16 channels. The source and the streamer cable were towed at 0.5 and about 1 m depths, respectively.

As a result of seismic data processing, including band-pass filter, NMO corrections and stacking with one velocity of 1500 m/s, a 3D seismic cube was created. The seismic cube was used for input data of SAP analysis. The data processing was conducted by MATLAB. On the other hand, as a result of the SAP analysis, a 3D cube of average Q was created. An active fault, which cuts seafloor, was clearly demonstrated over several seismic reflection profiles. However, its trend was not clear on seismic time-slices. Reversely, the trend of active fault was clearly figured out on several Q-slices as high attenuation anomalies. In this paper, we would like to show the results of SAP analysis from the mini 3D seismic reflection data observed in Uchiura wan.

# Gravity survey at the extension of the Takahama fault and the Yokosuka fault in Nishio City, Aichi Prefecture

*Tokunosuke Tatsuzawa[1,2], Tatsuya Sumita[2], Shinobu Ito[2], Tomoya Abe[2]

1. Department of Earth Sciences, Resources and Environmental Engineering, Creative Science and Engineering, Faculty of Science and Engineering, Waseda University, 2. National Institute of Advanced Industrial Science and Technology

We conducted a gravity survey in Nishio city, Aichi Prefecture to clarify the subsurface structure related to the Takahama fault and the Yokosuka fault (Fig.1). Seismic reflection survey was held in that area in September 2018 (Ito, 2019) and the velocity structure was also obtained by refraction analysis. Then, we consider that we can clarify more detailed subsurface structure by conducting gravity survey on the seismic survey lines and their extensions (Line1 and Line2) and also by comparing gravity survey results with the seismic survey results. We also conducted gravity survey along the Yahagi Furukawa river (Line 3) that is supposed to cross the northern extension of the Yokosuka fault in the active fault map “Gamagori” (Okada et al., 2004) issued by Geospatial Information Authority of Japan and that is also crossing the concealed fault inferred by Sugito and Okada(2004).
In this survey, a total of 150 points of relative gravity was measured by the Lacoste D-type gravimeter (D68) and the Lacoste G-type gravimeter (G304). Measurement distance intervals were about 50m or 100m on Line1 and Line 2, about 30m or 50m on Line 3. The location coordinates of each gravity measurement point were mainly measured by GNSS(network type RTK-VRS), while some points were also measured by Total Station. Gravity anomaly was calculated by the standard procedure SPECG1988 (GSJ Gravity Survey Group, 1989). We performed terrain correction with 50m mesh DEM (Murata et al., 1996) for the Bouguer anomaly calculation. The contribution of terrain on gravity anomaly is small because the surveyed area is nearly flat. In fact, the maximum difference between simple Bouguer anomaly and the Bouguer anomaly calculated with 50m mesh DEM is 0.074mGal, and the pattern of the anomaly profile does not differ greatly between them.
As a result of gravity survey, the pattern of the Bouguer anomaly profile on Line1 and Line 2 is well related to the contour line of 3000m/s in P wave velocity section by the refraction analysis. On Line3, the Bouguer anomaly shows significant change around the point where the presence of the concealed fault of the Yokosuka fault was estimated (Sugito and Okada, 2004; Imaizumi et al., 2018). In addition, the Bouguer anomaly shows complex change on the eastern part of Line 2, where the P wave velocity is also lower than surrounding area by the result of the refraction analysis. In the coming months, we are going to make the density structure model by using the reflection boundary of the seismic profile and the gravity anomaly to reveal the details.

# Subduction geometry and seismicity around northern Ryukyu subduction zone

*Yojiro Yamamoto[1], Tsutomu Takahashi[1], Yasushi Ishihara[1], Koichiro Obana[1], Seiichi Miura[1], Shuichi Kodaira[1], Yoshiyuki Kaneda[2]

1. Japan Agency for Marine-Earth Science and Technology (JAMSTEC), 2. Kagawa University

At the Ryukyu subduction zone, located forearc region of Japan’ s Southwest Islands, the Philippine Sea plate is subducting beneath the Eurasian plate toward northwest direction. Due to the subduction, not only active seismicity but also short-term slow slip event (SSE) (Nishimura, 2014) and low frequency tremor (LFT) activity (Yamashita et al., 2015) were observed in the forearc region of Ryukyu arc. However, the subduction geometry is still unclear since seismic and geodetic stations are limited to the sparsely distributed islands. To know the seismicity, lithospheric structures and subduction geometry, Japan Agency for Marine-Earth Science and Technology (JAMSTEC) launched a series of seismic observations and active-source seismic surveys at the Ryukyu arc from 2013, as a part of research project funded by Ministry of Education, Culture, Sports, Science and Technology, Japan. In FY2016, we have conducted a passive source observation in the northern Ryukyu forearc region. We have deployed 47 seismic stations including 43 ocean bottom seismographs (OBS) and 4 onshore stations at Tanegashima (two stations), Nakano-shima, and Akuseki-jima. The observation period of OBS is about 4 months, from September to December 2016.

In this study, we conduct double-difference seismic tomography (Zhang and Thurber, 2006) to obtain both precious hypocenter location and structural information around plate boundary. We combine 1,303 events detect from our observation data with 454 events from Japan Meteorological Agency (JMA) with our data set. To improve the spatial resolution and ray coverage, we also used the arrival time data at 33 permanent stations from JMA seismic catalogue and dataset of a part of previous OBS observation in Hyuga-nada (Yamamoto et al., 2013; 161 events and 27 OBSs). After the tomographic inversion, we estimate the focal mechanisms by using P-wave first arrival polarity data. Then, we establish the subduction geometry model with reference to the velocity model, distribution of low-angle thrust type earthquakes, previous geometry model based on active source surveys (Nishizawa et al., 2009, 2017; Nakanishi et al., 2018).

Estimated subduction geometry indicates that there is no obvious roughness in this study area. Interplate earthquake, defined as earthquakes within 5 km from plate boundary of this study, is active at depth between 15 and 30 km especially in the southern part. The down-dip limit of interplate earthquakes is corresponding to the high Vp/Vs just above the plate boundary, suggesting that the existence of serpentinized mantle wedge. In addition, LFT, SSE, and interplate earthquake seem to be separately occurred along the plate boundary. Intraslab earthquake is also active. Some of them occurred in the seaward of trench axis. The separation between intraslab earthquakes and plate boundary is larger (25 ~ 30 km) in northern part than that in southern part (15 ~ 20 km). This regionality might be relate to the subduction of Amami Plateau.

## [S-IT25] Planetary cores: Structure, formation, and evolution

convener:Hidenori Terasaki(Graduate School of Science, Osaka University), Eiji Ohtani(Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University), William F McDonough(University of Maryland College Park), George Helffrich(Earth-Life Science Institute, Tokyo Institute of Technology), Chairperson:George Helffrich(ELSI, Tokyo Institute of Technology), Hidenori Terasaki

There are fundamental links between the formation and evolution of planets and their satellites to that of their cores. Defining the physical and chemical properties of the cores of these terrestrial bodies are fundamental for understanding their internal structures and thermal profile. Recent advances in experimental and theoretical studies provide new insights and applications to the Earth's cores and other terrestrial bodies. Near-future exploration missions will obtain data on the internal structure of terrestrial planets (e.g., Mars and Mercury) and planet-satellite systems. We anticipate presentations on recent advances on the physical and chemical properties of cores and discussions regarding the latest views of their formation and evolution. We welcome contributions from mineral/rock physics, geophysics, geochemistry, geodynamics, and planetary science.

# High-pressure Equation of State of Schreibersite $Fe_{2.15}Ni_{0.85}P$: Implications for the Martian Core

*Xuejing He[1], Jiazeng Guo[2], Xiang Wu[3], Shengxuan Huang[1], Fei Qin[1], Xiangping Gu[4], Shan Qin[1]

1. Peking Univ., 2. Nanyang Normal Univ., 3. China Univ. of Geosciences, 4. Central South Univ.

Phosphorus is thought to be an important light element existing in planetary cores. The phosphorus abundance is evaluated to be ~0.20 wt% in the Earth's core, and ~0.32 wt% in the Martian core. To fully understand its existence in planetary cores, structural and physical properties of iron-nickel phosphides should be investigated under high pressure and high temperature. $(Fe,Ni)_3P$-schreibersite is observed as a common accessory in the veinlet of iron and stony-iron meteorites, so that it is of significance to discuss and constrain the properties of planetary cores. The equation of state of a natural single-crystal schreibersite, $Fe_{2.15}Ni_{0.85}P$, has been studied up to ~50 GPa at room temperature in a diamond anvil cell using *in situ* synchrotron-radiation X-ray diffraction. The sample kept its tetragonal structure ($I\bar{4}$) up to the highest pressure with no observation of phase transition. Experimental results have shown that the magnetic collapse of $Fe_{2.15}Ni_{0.85}P$ is weakened because of the substitution of nickel, leading to an isotropic axial compressibility. The pressure-volume data were fitted by the third-order Birch-Murnaghan equation of state, yielding $K_0$ = 184(4) GPa, $K_0'$ = 4.1(2), $V_0$ = 365.9(1) $Å^3$. The density of $Fe_{2.15}Ni_{0.85}P$, along with several iron sulfides and iron phosphides has been calculated under relative pressure-temperature conditions of the Martian core. The comparison with that of $\gamma$-Fe and a density model of the Martian core evidences that nickel and phosphorus dopant would result in density reduction of iron sulfides, suggesting that $(Fe,Ni)_3(S,P)$ might be a possible compound existing in the Martian core.

# Bottom-up solidification versus top-down solidification of the liquid core of the relatively small planetary bodies

*Satoru Urakawa[1], Hidenori Terasaki[2]

1. Department of Earth Sciences, Okayama University, 2. Department of Earth and Space Science, Osaka University

Some planetary bodies, such as Mercury and Ganymede, have their own magnetic fields and other bodies, such as the Moon and Mars, once had a magnetic field. These magnetic fields of the relatively small bodies are thought to be originated from core dynamo driven by compositional convection. Compositional convection is related to the density fluctuation due to partial crystallization of liquid core. The phenomenon that iron solidified at the upper part of the core settles is called ‘Fe snowing’ and it is considered as the main cause of compositional convection in the core of the small planetary bodies. However, crystallization of iron occurs from the top of the core in some cases and from the bottom of the core in another case, due to the complexity of melting relationships of iron-light element system under pressure. Whether the top-down freezing occurs or the bottom-up freezing occurs depends on the adiabat in the liquid core and the melting slope of the constituent substance of the core. We have investigated the adiabatic temperature gradient of the Fe-S liquid core based on the thermal expansivity which is determined by X-ray absorption density measurements at high pressures. Then, we divided the pressure-composition space for the Fe-FeS system into the bottom-up solidification field and the top-down solidification field at the pressures up to 10 GPa. These would contribute to understand the generation of magnetic field in the relatively small bodies.

Department of Earth and Space Science, Graduate School of Science, Osaka University, 4. Graduate School of Material Science, University of Hyogo, 5. RIKEN, 6. JASRI

Martian cores have been thought to include a certain amount of sulfur as a light element. Sohl and Spohn (1997) proposed seismic wave velocity and density profiles of the interior of Mars based on equations of state of core matrials although seismic wave velocities of core materials are needed for presice estimation. However, there have been only a limited number of works for $V_P$ of Fe alloys with sulfur. In the Fe-FeS system, $V_P$ of FeS and $FeS_2$ have been studied (e.g. Badro et al. 2007) but these compounds are not appropriate for the core materials of Mars because $Fe_3S$ is a stable phase above 20 GPa corresponding to Martian core conditions (Fei et al., 1997, 2000) up to at least 200 GPa (Kamada et al., 2010, 2012). Therefore, $Fe_3S$ is a subsolidus phase together with $\varepsilon$ -Fe in the Fe-$Fe_3S$ system at Martian core conditions and it is essential to study $V_P$ of $Fe_3S$ to understand seismic properties of the Martian core. We have measured sound $V_P$ of $Fe_3S$ under high temperature and pressure at BL35XU of SPring-8.
In this study, a synthesized $Fe_3S$ was used as a starting material. A symmetric diamond anvil cell was used to generate high pressures. IXS(Inelastic X-ray Scattering) and XRD experiments were performed at the beamline 35XU of SPring-8, Japan (Baron et al., 2000). $V_P$ of $Fe_3S$ were measured up to 100 GPa and 2000 K. We will discuss temperature effect on the $V_P$ of $Fe_3S$ and the Birch's law and seismic wave velocity profile of the Martian core.

# The sound velocity of liquid Fe-Ni-S-Si alloys under Mercury’s core condition

*Iori Yamada[1], Hidenori Terasaki[1], Asaka Kamiya[1], Ryo Tsuruoka[1], Yuji Higo[2], Akihiko Machida[3]

1. Graduate School of Science, Osaka University, 2. Japan Synchrotron Radiation Research Institute, 3. National Institute for Quantum and Radiological Science and Technology

Mercury has a large liquid core and it mainly consists of Fe-Ni and possibly contains some light elements. The X-ray spectroscopy measurements by the MESSENGER spacecraft indicates that surface on Mercury contains 1-4wt% S (Nittler et al. 2011). When silicate containing 1-4 wt%S coexists with liquid metal, S and Si tend to dissolve into liquid metal based on partitioning of S and Si between metal and silicate melts. This suggests that both S and Si are likely to be included in the outer core of Mercury (Chabot et al. 2014). Thus, elastic properties of liquid Fe-Ni-S-Si at BL04B1 and BL22XU beamlines, SPring-8 Facility. High pressure was generated using 1500ton Kawai-type or 180 ton cubic multianvi press. The sound velocity was measured using the pulse-echo overlap method. We used two kinds of compositions (Fe-11wt%Ni-6wt%S-4wt%Si and Fe-11wt%Ni-3wt%S-8wt%Si) for Fe-Ni-S-Si sample. The P-wave velocity ($V_P$) was measured up to 16 GPa and 2000 K and it increases with pressure. Temperature dependence on the $V_P$ of liquid Fe-Ni (Kuwabara et al. 2016), the $V_P$ of liquid Fe-Ni decreases approximately 1.6 % by addition of 6 wt%S and 4 wt%Si and increases approximately 3.1 % by addition of 3wt%S and 8wt%Si. This suggests that the effect of S reduces the $V_P$ effectively also in the Fe-Ni-S-Si system.

# In situ observation of Rayleigh–Taylor instability growth of liquid Fe-Si using laser shock

*Hidenori Terasaki[1], Tatsuhiro Sakaiya[1], Keisuke Shigemori[2], Hiroki Kato[2], Yoichiro Hironaka[2], Tadashi Kondo[1]

1. Graduate School of Science, Osaka University, 2. Institute of Laser Engineering, Osaka University

Rayleigh–Taylor instability occurs at the interface between two fluids with different densities when a heavy fluid overlies a light one in a gravitational field. The RT instability is considered as one of the important core formation mechanism beneath the magma ocean. This mechanism has been discussed from simulations (e.g., Honda et al. 1993, Ricard et al. 2009) and analog experiment (e.g., Olson and Weeraratne, 2008). However, experimental approach using liquid Fe-alloys for this mechanism has never been performed under high pressure. In this study, we applied the laser-shock technique to observe *in situ* the Rayleigh–Taylor instability of liquid Fe-Si alloy under high pressure. The growth of the Rayleigh–Taylor instability was successfully observed using *in situ* x-ray radiography under shock compression. The growth rate of the Rayleigh–Taylor instability was estimated to 0.3 $ns^{-1}$. The present results provide useful information to constrain the time scale of the Earth’ s and planetary core formation.

Discussion

# *P-V-T* equation-of-state of liquid Fe from *ab-initio* simulations to the TPa regime

*Gerd Steinle-Neumann[1], Fabian Wagle[1]

1. Bayerisches Geoinstitut, University of Bayreuth, Germany

The pressure-volume-temperature (*P-V-T*) equation-of-state (EoS) of liquid iron provides important information (reference adiabat, density $\rho$, and higher order thermodynamic parameters) in the modelling of the internal structure of planetary bodies with Fe-based cores. Relevant P-conditions range from a few GPa (Moon, Mercury) through the Mbar range (Earth) to several TPa (super-Earth exoplanets). Experimental data on $\rho$ in the liquid stability field are scarce and a thermodynamic assessment of $\rho$ depends on matching Gibbs energy along the melting line which remains controversial to this day. The alternative determination of a *P-V-T* EoS based on ab-initio simulations, on the other hand, suffer from the fact that $\rho$ at ambient P is predicted too large by as much as 20% in the simulations [e.g., 1]. Here, we have fitted *P-V-T* triplets from *ab-initio* molecular dynamics simulations with an EoS formulation that is thermodynamically self-consistent [2] and combined it with a correction formalism that accounts for the known $\rho$-mismatch at ambient *P* [3]. As the correction is additive to the Helmholtz potential and shows the correct limiting behavior at high and low $\rho$, the thermodynamic self-consistency of the results is not affected. Using this combination, the EoS we have developed reproduces $\rho$ from shock-wave experiments as well as previous models, but shows a significantly improved agreement at ambient *P*, the critical point and the sole low $\rho$ measurement at 4.3 GPa [4] (T11 in Figure). We explore the performance of our thermodynamic potential and various previously published models [1,5,6] for liquid iron over a wide range of conditions: (i) at ambient pressure as a function of temperature, (ii) along the melting curve of Fe to 40 GPa, relevant for the cores of smaller terrestrial bodies in our solar system (Figure), (iii) along isentropes in the Earth's outer core and (iv) for the core of super-Earth Kepler-36b. The correction term significantly improves the agreement of computed properties with experiments and other thermodynamic models that are based on an assessment of the phase diagram at ambient and moderate pressure, showing how *ab-initio* molecular dynamics simulations can be used at par with other thermodynamic techniques. For the Earth's core, densities from the various models are similar, but higher-order derivatives (acoustic velocities and Grüneisen parameter) show significant differences. Evaluated along a core-temperature profile in Kepler-36b, differences in density from various models are negligible, for core mass they do not exceed 2%, showing robust extrapolation of all equation of state models.

# *Ab initio* study of Iron-Nickel alloys in Super-Earths cores

*Francois Soubiran[1], Razvan Caracas[1]

1. Ecole normale superieure de Lyon, Laboratoire de Géologie de Lyon, Université Lyon 1, CNRS UMR 5276, Lyon, France

Iron-nickel alloys are considered the main components of Earth and Super-Earth cores, which make them crucial systems in order to comprehend the properties of these planets. While the relative nickel content is anticipated to be around 10% in the Earth, this value could differ slightly in other planets because of different host star metallicity and formation history. It is thus important to understand the properties of iron-nickel systems with various compositions in the multi-megabar regime.

While pure iron is anticipated to have hexagonal close packing at high pressure, nickel is expected to have face-centered cubic packing. This means there is a structural change as the composition is modified, which can also mean a limited stability of the solid solutions of iron-nickel.

We will discuss the properties of iron-nickel alloys in the megabar regime as predicted by *ab initio* simulations. We will examine the relative stability of different iron-nickel solid solution compositions and the interplay of the spin states. After characterizing the properties of these alloys at pressure-temperature conditions relevant for Super-Earth, we will discuss possible consequences their cores.

# Impurity effect on the iron’s transport properties at Earth’s core conditions: A key constraint for the evolution of the Earth’s core

*Youjun Zhang[1], Mingqiang Hou[2], Nilesh Salke[2], Jung-Fu Lin[3]

1. Sichuan University, 2. HPSTAR, 3. University of Texas at Austin

The Earth’s core is mainly composed of Fe-Ni alloyed with some light elements, such as Si, S, O and C [1]. The transport properties of Fe alloys at Earth’s core conditions constrain the heat flow from the core into mantle, which governs the geodynamo, dynamics and thermal evolution of Earth’s core [2,3]. While, this property is still not well understood and remains controversial in previous work due to the experimental challenging at very high pressure and temperature [4,5]. Here, we directly measure the electrical resistivity of hcp-Fe-Ni and hcp-Fe-Si alloys at the relevant conditions of Earth’s core using double-side laser-heated Diamond Anvil Cells. Our results show a quasi-linear relation between temperature and resistivity in hcp-Fe-Ni and hcp-Fe-Si at the core pressures. Compared with hcp-Fe [6], the impurities like Ni and Si can elevate iron’s resistivity but they show different magnitude. Thermal conductivity of an Fe-Ni-Si alloy as a candidate core composition was modelled via the Wiedemann-Franz law based on our measured resistivity. Our results show that the core’s thermal conductivity could be strongly reduced by impurities, supporting a Mesoproterozoic inner core age and a self-consistent convection-driven geodynamo.

# Melting in the Fe-FeO system to 214 GPa

*Kenta Oka[1], Yuto Kidokoro, Kei Hirose[1], Yoichi Nakajima[2], Guillaume Morard[3], Guillaume Fiquet[3], Nicolas Coudurier[3]

1. Department of Earth and Planetary Science, The University of Tokyo, 2. Priority Organization for Innobation and Excellence, 3. Sorbonne Université

Oxygen is one of the likely candidates as the light elements in the Earth’ s core. If oxygen is the primary one, the oxygen content in the outer core should be less than that of the eutectic liquid composition in the Fe-FeO system, which is required to explain the dense solid inner core compared to the liquid outer core. The eutectic liquid composition in the Fe-FeO system has been estimated under high pressures, on the basis of thermodynamic calculations and high-pressure experiments. However, large inconsistency is found among these previous studies, especially below 100 GPa.
In this study, we have conducted high-temperature and high-pressure experiments up to 214 GPa and 3650 K. Liquidus phase relations were determined from textural and chemical characterizations of recovered samples using FIB/FE-EDS/FE-EPMA. Liquid-liquid immiscibility reported below 21 GPa in previous multi-anvil studies (Tsuno et al., 2007) was not observed above 42 GPa in the present DAC experiments. Our results demonstrate that the eutectic liquid composition in the Fe-FeO binary system changed largely from Fe+1.3wt.%O at 15 GPa (Tsuno et al., 2007) to >8 wt.% O at 42 GPa. It then further increased gradually to ~13 wt.% O with increasing pressure to 214 GPa.
These results are in reasonably good agreement with the previous DAC experiments by Seagle et al. (2008) based on XRD measurements and the earlier thermodynamic model by Komabayashi (2014) that considered non-ideal mixing between liquid Fe and FeO. Our data also showed contamination by variable amounts of carbon in liquid, which may explain the difference from the results by Morard et al. (2017) below 80 GPa. The large change in the liquidus phase relations in the Fe-FeO system observed between 15 and 42 GPa is likely related to the disappearance of liquid-liquid immiscibility.
The outer core may include 5.5 wt.% O if oxygen is a sole light element (Badro et al., 2014). When extrapolating our data to 330 GPa, the eutectic liquid in the Fe-FeO binary system includes about 15 wt.% O, which is much higher than the 5.5 wt.% O and therefore allows the outer core liquid containing oxygen as one of important light elements to crystallize solid Fe at the ICB. These results support the presence of oxygen in the core.

# B2 phase in the inner core: constraints from high pressure experiments

*Eiji Ohtani[1], Daijo Ikuta[1], Seiji Kamada[2], Tatsuya Sakamaki[1], Naohisa Hirao[3]

1. Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University, 2. Frontier Institute for Interdisciplinary Research, Tohoku University, 3. SRring-8, Japan Synchrotron Research Institute

The Earth inner core is considered to be composed of hcp-iron alloy with small amounts of light elements, and intensive efforts have been made to clarify the physical properties of hcp-iron. On the other hand, there are many seismological observations on existence of heterogeneities, layering, and anisotropy in the inner core, which cannot be accounted for only by hcp-iron.

It has been suggested that B2 or bcc phase can exit in the inner core mainly by theoretical calculations (e.g., Belonoshko et al., 2003). Therefore, it has been a debated matter on the existence of a stable B2 structure of iron alloys in the inner core. There is experimental reports suggesting existence of B2 phase in Fe-Si alloy (Fischer et al., 2013). Coexistence of hcp+B2 is observed by Fishcer et al. (2013) in the Fe-Si system with silicon greater than 6 wt. %.

Nickel is an important metallic component in meteorites, and it can modify the phase relations of iron alloy systems significantly. In order to clarify the stability of B2 phase in the inner core, we studied the phase relations of the Fe-Ni-Si system at high pressure and temperature relevant in the core. The in-situ X-ray observations of the Fe-Ni-Si alloys at high pressure and temperature were conducted at BL10XU of SPring-8 by using the double sided laser heating diamond anvil cell. We observed a wide stability field of coexistence of B2 phase and hcp at high pressure and temperature above 100 GPa and 2500 K in the composition of Fe7wt%Ni5wt%Si alloy.

The nickel and silicon contents in the inner core were estimated to be 0~8 wt% and 3-6 wt% respectively in order to account for the PREM inner core based on the equation of state of hcpFe-Ni-Si alloy (Asanuma et al., 2013) and the sound velocity of hcpFe-Si alloy (Sakairi et al., 2018). Combined with the phase relations together with the sound velocity measurements, we can suggest that the inner core is mainly composed of hcp-iron with a small amount of B2 phase. Coexistence of B2 phase with hcp-Fe alloy in the inner core can explain the heterogeneity and fine structure of the inner core reported in seismology.

# Stratification of the Earth's core by $SiO_2$ crystallisation

*George Helffrich[1], Satoshi Kaneshima[2], Kei Hirose[1,3]

1. Earth-Life Science Institute, Tokyo Institute of Technology, 2. Earth and Planetary Sciences, Kyushu University, 3. Earth and Planetary Sciences Department, University of Tokyo

Based on various studies reporting seismic wavespeed deviations from PREM in the outermost outer core, the core appears to be stratified. Compositional layering, where liquids of different densities overlie one another is one stratification possibility. This mechanism, however, inhibits vertical flows in the liquid near the surface of the core implied by models of secular variation of the Earth's magnetic field. To avoid this limitation, we propose a mechanism by which the layering arises in an analogous way to atmospheric cloud formation. If liquid metal containing dissolved Si+O reaches a saturation level in the outermost outer core, $SiO_2$ will crystallize and rise to the core-mantle boundary (CMB), causing density changes in the liquid by release of latent heat and changing composition. We present an physical model for this process and show that it explains the observed outer core wavespeed variations better than previous parameterizations. For a CMB temperature of 3800 K and a core light element content of 5 wt% Si+O, $SiO_2$ begins crystallizing 260 km below the CMB through an interval about 160 km thick, yet core liquid can flow freely through the crystallization interval, facilitating magnetic field changes on decadal to century time scales.

# Relation between sound velocity and density for liquid iron alloys under Earth's core pressures by laser-shock compression

*Tatsuhiro Sakaiya[1], Tadashi Kondo[1], Hidenori Terasaki[1], Keisuke Shigemori[2], Yoichiro Hironaka[2]

1. Graduate School of Science, Osaka University, 2. Institute of Laser Engineering, Osaka University

Sound velocity at Earth's core conditions are one of the most important physical properties in Earth science because it can be directly compared with the seismological Earth model (PREM: Preliminary Reference Earth Model) [1]. The composition of solid inner core is estimated from the comparison of the model [1] and the extrapolation of sound velocities as a function of density of iron and iron alloys obtained by the static compression experiment [2, 3]. Birch's law, a linear sound velocity–density relation [4], is used to extrapolate sound velocities to densities in the core condition. On the other hand, the composition of liquid outer core is estimated from the partitioning and solubility data in the inner core boundary condition for the composition of solid core. There has been some works for the sound velocity of iron and iron alloys on the Earth's core condition by dynamic techniques using explosive [5], gas gun [5-11], and laser [12-14]. In this study, we measure the sound velocity and density of liquid iron alloys by shock-compression method using high-power laser.
We conducted shock-compression experiments using a High Intensity Plasma Experimental Research (HIPER) system at the GEKKO-XII laser irradiation facility [15] at the Institute of Laser Engineering, Osaka University. The samples were Fe-Ni alloys, pure nickel, Fe-Si alloys, pure silicon, and pyrrhotite. The sound velocities and densities of shock-compressed iron alloys using the high-power laser were measured by x-ray radiography [12-14] at pressures up to 1000 GPa.
Part of this work was performed under the joint research project of the Institute of Laser Engineering, Osaka University and supported by JSPS KAKENHI Grant Number JP16K05541.

# Geochemical estimates of Earth's core heat content at the end of accretion

*Vincent Clesi[1], Renaud Deguen[1]

1. Laboratoire de Geologie de Lyon - Terre, Planètes, Environnement, Université Claude Bernard Lyon 1, CNRS, ENS-Lyon, 69622 Villeurbanne, France.

The composition of Earth's mantle, when compared to experimentally determined partitioning coefficients, can be used to constrain the conditions of equilibration - pressure *P*, temperature *T*, and oxygen fugacity $fO_2$ - of the metal and silicates during core-mantle differentiation.
This places constraints on the thermal state of the planet during its accretion, and it is tempting to try to use these data to estimate the heat content of the core at the end of accretion.
To do so, we develop an analytical model of the thermal evolution of the metal phase during its descent through the solid mantle toward the growing core, taking into account compression heating, viscous dissipation heating, and heat exchange with the surrounding silicates. For each impact, the model takes as initial condition the pressure and temperature at the base of the magma ocean, and gives the temperature of the metal when it reaches the core. The growth of the planet results in additional pressure increase and compression heating of the core.
The thermal model is coupled to a Monte-Carlo inversion of the metal/silicates equilibration conditions ($P$, $T$, $fO_2$) in the course of accretion from the abundance of Ni, Co, V and Cr in the mantle, and provides an estimate of the core heat content at the end of accretion for each geochemically successful accretion.
The core heat content depends on the mean degree of metal-silicates equilibration, on the mode of metal/silicates separation in the mantle (diapirism, percolation, or dyking), but also very significantly on the shape of the equilibration conditions curve (equilibration *P* and *T* vs. fraction of Earth accreted).
We find that many accretion histories which are successful in reproducing the mantle composition yield a core that is colder than its current state.
Imposing that the temperature of the core at the end of accretion is higher than its current values therefore provides strong constraints on the accretion history.
In particular, we find that the core heat content depends significantly on the last stages of accretion

# The effect of temperature on density of solid metals

*Asaka Kamiya[1], Hidenori Terasaki[1], Tadashi Kondo[1]

1. Osaka University

It is reported that sound velocities of several solid metals show drastic non-linear reduction at near the melting temperature. This is called premelting effect. Nadal and Le Poac (2013) reported that the sound velocity (P-wave and S-wave velocities) of solid tin (Sn) decreased drastically just before melting ($T/T_m$ ~0.99) at ambient pressure. They suggested that this decrease is due to reduction of elastic moduli (bulk and shear moduli). To understand the premelting effect more accurately, density data of tin near the melting temperature is also required in addition to sound velocity data. However, the precise density behavior of tin around the melting temperature is still missing. In this study, we measured the density of solid metals (tin and nickel) at ambient pressure and studied the effect of temperature on the density near melting temperature. The densities of solid metals were measured from optical image of the sample in the high-temperature furnace up to 673 K for Sn and 1873 K for fcc-Ni. The densities in this study were measured with error of 0.07 % for Sn and 0.4 % for Ni. Density of Sn decreases linearly with increasing temperature up to 490 K and reduced drastically above 490 K (at $T/T_m$~0.97). This drastic decrease in density of Sn is likely to relate to the premelting effect suggested from sound velocity measurement. In contrast, density of Ni decreases almost linearly with increasing temperature up to melting point and no drastic density change was observed in solid state.

# Phase relations in the Fe-Ni-Si system at high pressures and high temperatures

*Daijo Ikuta[1], Eiji Ohtani[1], Saori Kawaguchi[2], Naohisa Hirao[2], Yasuo Ohishi[2]

1. Department of Earth Science, Tohoku University, 2. JASRI

The Earth's core has supposed to be constituted by iron-nickel alloys with some light elements. Silicon is one of the most convincing candidates among the light elements. Therefore, the study of high pressure and high temperature properties and behaviors for the Fi-Ni-Si system is important in understanding and constraining to the properties of the Earth's core. In this study, high pressure and high temperature properties for three different contents of Fe-Ni-Si alloys were investigated by using laser heated diamond anvil cells and in situ X-ray diffraction with synchrotron radiation. We determined the phase relations of $Fe_{(0.94-x)}Ni_{0.06}Si_x$ ($x$ = 0.10, 0.17, 0.26) up to 166 GPa and 2800 K, respectively. According to previous Fe-Si system studies, $Fe_{0.83}Si_{0.17}$ alloys transform from hcp to hcp+B2 and fcc+hcp+B2 phases with increasing temperature in isobaric conditions. We observed the change in temperature increase and positive slope of these boundaries due to the nickel containing effect and the difference in silicon content. We report the details of phase relations in the Fe-Ni-Si system and discuss with the differences from the Fe-Si system.

## [S-IT25] Planetary cores: Structure, formation, and evolution

convener:Hidenori Terasaki(Graduate School of Science, Osaka University), Eiji Ohtani(Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University), William F McDonough(University of Maryland College Park), George Helffrich(Earth-Life Science Institute, Tokyo Institute of Technology)

There are fundamental links between the formation and evolution of planets and their satellites to that of their cores. Defining the physical and chemical properties of the cores of these terrestrial bodies are fundamental for understanding their internal structures and thermal profile. Recent advances in experimental and theoretical studies provide new insights and applications to the Earth's cores and other terrestrial bodies. Near-future exploration missions will obtain data on the internal structure of terrestrial planets (e.g., Mars and Mercury) and planet-satellite systems. We anticipate presentations on recent advances on the physical and chemical properties of cores and discussions regarding the latest views of their formation and evolution. We welcome contributions from mineral/rock physics, geophysics, geochemistry, geodynamics, and planetary science.

# Stratification of the Earth's core by $SiO_2$ crystallisation

*George Helffrich[1], Satoshi Kaneshima[2], Kei Hirose[1,3]

1. Earth-Life Science Institute, Tokyo Institute of Technology, 2. Earth and Planetary Sciences, Kyushu University, 3. Earth and Planetary Sciences Department, University of Tokyo

Based on various studies reporting seismic wavespeed deviations from PREM in the outermost outer core, the core appears to be stratified. Compositional layering, where liquids of different densities overlie one another is one stratification possibility. This mechanism, however, inhibits vertical flows in the liquid near the surface of the core implied by models of secular variation of the Earth's magnetic field. To avoid this limitation, we propose a mechanism by which the layering arises in an analogous way to atmospheric cloud formation. If liquid metal containing dissolved Si+O reaches a saturation level in the outermost outer core, $SiO_2$ will crystallize and rise to the core-mantle boundary (CMB), causing density changes in the liquid by release of latent heat and changing composition. We present an physical model for this process and show that it explains the observed outer core wavespeed variations better than previous parameterizations. For a CMB temperature of 3800 K and a core light element content of 5 wt% Si+O, $SiO_2$ begins crystallizing 260 km below the CMB through an interval about 160 km thick, yet core liquid can flow freely through the crystallization interval, facilitating magnetic field changes on decadal to century time scales.

# Relation between sound velocity and density for liquid iron alloys under Earth's core pressures by laser-shock compression

*Tatsuhiro Sakaiya[1], Tadashi Kondo[1], Hidenori Terasaki[1], Keisuke Shigemori[2], Yoichiro Hironaka[2]

1. Graduate School of Science, Osaka University, 2. Institute of Laser Engineering, Osaka University

Sound velocity at Earth's core conditions are one of the most important physical properties in Earth science because it can be directly compared with the seismological Earth model (PREM: Preliminary Reference Earth Model) [1]. The composition of solid inner core is estimated from the comparison of the model [1] and the extrapolation of sound velocities as a function of density of iron and iron alloys obtained by the static compression experiment [2, 3]. Birch's law, a linear sound velocity–density relation [4], is used to extrapolate sound velocities to densities in the core condition. On the other hand, the composition of liquid outer core is estimated from the partitioning and solubility data in the inner core boundary condition for the composition of solid core. There has been some works for the sound velocity of iron and iron alloys on the Earth's core condition by dynamic techniques using explosive [5], gas gun [5-11], and laser [12-14]. In this study, we measure the sound velocity and density of liquid iron alloys by shock-compression method using high-power laser.
We conducted shock-compression experiments using a High Intensity Plasma Experimental Research (HIPER) system at the GEKKO-XII laser irradiation facility [15] at the Institute of Laser Engineering, Osaka University. The samples were Fe-Ni alloys, pure nickel, Fe-Si alloys, pure silicon, and pyrrhotite. The sound velocities and densities of shock-compressed iron alloys using the high-power laser were measured by x-ray radiography [12-14] at pressures up to 1000 GPa.
Part of this work was performed under the joint research project of the Institute of Laser Engineering, Osaka University and supported by JSPS KAKENHI Grant Number JP16K05541.

# Geochemical estimates of Earth's core heat content at the end of accretion

*Vincent Clesi[1], Renaud Deguen[1]

1. Laboratoire de Geologie de Lyon - Terre, Planètes, Environnement, Université Claude Bernard Lyon 1, CNRS, ENS-Lyon, 69622 Villeurbanne, France.

The composition of Earth's mantle, when compared to experimentally determined partitioning coefficients, can be used to constrain the conditions of equilibration - pressure *P*, temperature *T*, and oxygen fugacity $fO_2$ - of the metal and silicates during core-mantle differentiation.
This places constraints on the thermal state of the planet during its accretion, and it is tempting to try to use these data to estimate the heat content of the core at the end of accretion.
To do so, we develop an analytical model of the thermal evolution of the metal phase during its descent through the solid mantle toward the growing core, taking into account compression heating, viscous dissipation heating, and heat exchange with the surrounding silicates. For each impact, the model takes as initial condition the pressure and temperature at the base of the magma ocean, and gives the temperature of the metal when it reaches the core. The growth of the planet results in additional pressure increase and compression heating of the core.
The thermal model is coupled to a Monte-Carlo inversion of the metal/silicates equilibration conditions ($P$, $T$, $fO_2$) in the course of accretion from the abundance of Ni, Co, V and Cr in the mantle, and provides an estimate of the core heat content at the end of accretion for each geochemically successful accretion.
The core heat content depends on the mean degree of metal-silicates equilibration, on the mode of metal/silicates separation in the mantle (diapirism, percolation, or dyking), but also very significantly on the shape of the equilibration conditions curve (equilibration *P* and *T* vs. fraction of Earth accreted).
We find that many accretion histories which are successful in reproducing the mantle composition yield a core that is colder than its current state.
Imposing that the temperature of the core at the end of accretion is higher than its current values therefore provides strong constraints on the accretion history.
In particular, we find that the core heat content depends significantly on the last stages of accretion

## [S-GL27] Geochronology and Isotope Geology

convener:Takahiro Tagami(Graduate School of Science, Kyoto University), Yuji Sano(Division of Ocean and Earth Systems, Atmosphere and Ocean Research Institute, University of Tokyo),
Chairperson:Takahiro Tagami, Yuji Sano

Reliable reconstruction of geohistory is of primary importance to better envision the present and future of the Earth. Geochronology and isotope geology play major roles in the reconstruction. This session offers an opportunity to present the results of fundamental studies, including the developments / improvements of analytical methods and age calibration, as well as applications to the Earth and planetary materials. We particularly focus on: (1) radiometric dating, bio-stratigraphy, magneto-stratigraphy and stable isotopic time series that provide the age information, (2) radioisotopes and stable isotopes widely employed for analyzing the Earth and planetary systems and (3) hypothesis and numerical modeling that utilize / assimilate the age and isotopic data. We also welcome contributions that integrate a variety of relevant disciplines.

# Terrestrial cosmogenic nuclides as a dating tool of landforms and near-surface materials: applicability and limitations

*Yuki Matsushi[1]

1. Disaster Prevention Research Institute, Kyoto University

This study overviews methodology for application of terrestrial cosmogenic nuclides for dating of diverse types of landforms and near-surface materials. Accumulation of the nuclides in the bedrock or sediment on land surfaces enables us to determine exposure ages of the landform. This methodology targets reconstruction of environmental changes in mountainous areas due to climatic transition, timings of large landslide occurrence, and formation ages of fluvial or marine terraces. In this application, post-event erosion or sedimentation, and/or pre-event irradiation of cosmic rays enlarge uncertainty in the model ages. The nuclide concentration in an eroding bedrock or current sediment reflects residence time of the material near the land surface, which then can be converted to denudation rates of the landform. This application has revealed rates of carbonate denudation as a function of climatic conditions of the sites, soil production and catchment-wide denudation rates in silicate areas, which corresponds to topography of the terrain. For samples of deeply-buried sediments, ratio of paired nuclides in identical mineral grains indicates ages of burying of the debris. The pair of $^{10}$Be and $^{26}$Al in quartz has been used for dating sediments in caves, for a timescale of $10^6$ years. Analysis of such samples provides also a clue to reconstruct paleo denudation rates of the source areas of the debris. In this presentation, applicability and limitations of this method will be discussed with several actual data and outputs from various models of nuclide accumulation.

# Dating of marine erosional terraces using cosmogenic nuclides: A case study of the Hyuga City, Miyazaki Prefecture, southwest Japan (preliminary results)

*Shigeru Sueoka[1], Tetsuya Komatsu[1], Yuki Matsushi[2], Yusuke Yonaga[1], Naomi Sano[1], Noriaki Hirao[1], Tadamasa Ueki[1], Natsuko Fujita[1], Yoko Kokubu[1], Masakazu Niwa[1]

1. Japan Atomic Energy Agency, 2. Disaster Prevention Research Institute, Kyoto University

Uplift rate in an inland region and coastal region in the past $10^4$ to $10^5$ years can be estimated based on the elevation and emergent age of marine terraces (e.g., Ota and Omura, 1991). Marine depositional terraces in Japan have been dated by using radioactive carbon dating, tephrochronology, and recently developed optically stimulated luminescence dating (especially pIRIR dating for feldspar; e.g., Ito et al., 2015). On the other hand, it is difficult to date marine erosional terraces which lack sedimentary layers on the surfaces to apply these dating methods.

This study attempted to date marine erosional terraces by using terrestrial cosmogenic nuclide (TCN) dating methods, especially $^{10}$Be and $^{26}$Al methods. The $^{10}$Be and $^{26}$Al methods can reconstruct an exposure age and/or erosion rate of a rock based on the contents of $^{10}$Be and $^{26}$Al which are produced by irradiations of cosmic rays to oxygen and silicon in the rock (Wakasa et al., 2004; Matsushi et al., 2007). The production rates of $^{10}$Be and $^{26}$Al at the surface or at a certain depth depend on the cosmic-ray intensity (related to the latitude and altitude), density of the covering materials, and depth of the rock. The cosmic-ray intensity is computed theoretically, and the density of the covering materials can be also measured or assumed. Therefore, time-depth process of the rock, namely erosion and deposition history at the site, can be constrained by measuring the $^{10}$Be and $^{26}$Al contents.

We studied marine erosional terraces in Hyuga City, Miyazaki Prefecture, southwest Japan. Three groups of marine terraces were identified in this region, which are hereinafter named M1, M2 and L surfaces, respectively. The elevations of the surfaces are 30-50 m for M1 surface, 19-30 m for M2 surfaces, and sea-level to ~8 m for L surface. Considering the elevation, M1 and M2 surfaces can be correlated to the Sanzaibaru surface and Nyutabaru surface (Nagaoka et al., 2010), respectively, whereas L surface is thought to be the Holocene terraces. We collected rock samples for TCN dating by excavating three pits on M2 surface. The cross-sections of the pits consist of the basement rock, angular to subangular gravel layer interpreted as *in-situ* weathered basement rock, and soil from the base to the top. Rock samples were collected from the top of the gravel layer (depth: ~50 cm to 1 m) which is thought to be the surface of the former wave-cut benches. The lithology of the samples is the granite porphyry of the Osuzuyama acidic rocks formed in the middle Miocene (Nakata, 1978). The samples were processed by following the procedures of Kohl and Nishizumi (1992) and the $^{10}$Be and $^{26}$Al contents were measured using JAEA-AMS-TONO, an accelerator mass spectrometer at the Tono Geoscience Center, Japan Atomic Energy Agency (Saito-Kokubu et al., 2013).

The $^{26}$Al contents measured were rejected because these values were lower than the theoretical values. The $^{10}$Be contents yielded ~100 to 70 ka of the minimum exposure ages. More realistic erosion/deposition scenarios were adopted for better dating of the terrace surfaces, in which sedimentary layers were assumed to be deposited at a constant rate after the emergent of the surface. Consequently, M2 surface is thought to be emerged in MIS 5a although the correlated Nyutabaru surface emerged in

# Estimation of thermal history of Toki granite over 0.1Myr timescale by Multi-OSL-thermochronometry

*Manabu Ogata[1], Georgina E King[2], Frédéric Herman[2], Shigeru Sueoka[1]

1. Tono Geoscience Center, Japan Atomic Energy Agency, 2. University of Lausanne

Estimation of denudation history is important for geological disposal of high-level radioactive waste because denudation influences underground water flow and distance between the surface and underground facility. Terrestrial cosmogenic nuclide ($^{10}$Be, $^{26}$Al) dating is used to evaluate denudation rate in a few meters, whereas low-temperature thermochronology, such as fission-track and (U-Th)/He methods, is applied to estimate denudation histories for a few to several kilometers in the last $10^6$-$10^8$ years. However, the middle-term ($10^4$-$10^5$ years) denudation history over several hundred meters is more important for geological disposal because it takes tens of thousands of years to reduce the radioactivity of radioactive waste to the level of that of natural uranium ore.
Recently, multi- OSL-thermochronometry has been proposed as a tool that offers the potential for tight constraint of cooling histories in the low-temperature domain (< 75℃) over recent (0.1-0.2 Myr) timescales. This method determines the timing and rate at which electrons are trapped and thermally released in minerals, in response to in situ radiation and rock cooling. The technique of OSL thermochronometry is able to be used to unravel denudation histories.
Application of OSL thermochronometry is currently limited to regions that have experienced denudation rates higher than 3 mm/year, assuming a general geothermal gradient and surface temperature; luminescence signals saturate before the rocks are exhumed to the surface in a slowly-denuded region. Given such limitations on the cooling/denudation rate, previous researches on OSL themochronometry has focused on tectonically active mountain ranges, such as the Himalayas, the Southern Alps of New Zealand and Hida range in Japan.
We attempt to apply multi-OSL-thermochronometry to the tectonics that have experienced slowly denudation rate using long borehole. We used the borehole MIZ-1 which was drilled at Mino plateau, Gifu, Japan. The denudation rate in this area is expected to be around 0.1 mm/year or less from the denudation rate since ~40 Ma estimated by the apatite fission track method and uplift rate between MIS6 and MIS2 based on elevations and emergent ages of the fluvial terraces. This borehole consists mainly of the Cretaceous Toki granite pluton which is located at the Sanyo Belt in the Inner zone of the South west Japan Arc. The total length of MIZ-1 is about 1,300 mabh (meter along borehole) and Toki granite ranges from 110 to 1,300 mabh. We collected the samples at 159, 449, 751 mabh for multi-OSL-thermochronometry.
Cooling histories of all samples are similar. Their temperatures decreased to the present ambient temperature at each depth before 0.1 Ma and have then been stable. These results correspond to the expected slow denudation rate. Our results indicate that, by using long borehole, multi-OSL-thermochronometry can be applied to slowly-denuded regions.
This study was carried out under a contract with METI (Ministry of Economy, Trade and Industry) as part of its R&D supporting program for advanced research on long-term stability of geological environment.

# Depth condition under which OSL signal of quartz gouge experiences coseismic zeroing

*Yuki Minomo[1], Kiyokazu Oohashi[1], Noriko Hasebe[2], Kazumasa Miura[3]

1. Graduate School of science and Technology for Innovation, Yamaguchi University , 2. Institute of Nature and Environmental Technology, Kanazawa University, 3. Kanazawa University

Attempts to determine the age of faulting recorded on a fault rock have been made using methods such as the K-Ar dating, FT dating, and ESR dating (e.g., Murakami & Tagami, 2004, GRL). Among the proposed methods, the luminescence dating method has an applicable time range of few decades to few hundred thousand years ago, and hence it is suitable for dating an active fault. Early trial demonstrated a successful determination of the latest earthquake event along the active fault in central Japan (Ganzawa et al., 2013, JGSJ). The slip rate dependence of the condition that optically-stimulated luminescence (OSL) signal of quartz gouge resets was experimentally verified, so that the signal start to decrease from the slip rate of 0.25 m/s and becomes zero at slip rate ≧ 0.65 m/s (Minomo et al., 2018, JPGU). Here we show the clear reduction (zeroing) of OSL signal of quartz gouge after the laboratory experiments and estimate depth condition required to occur age resetting in natural fault zones. In the experiments, we used quartz powder with a particle size of <150 μm which is extracted from Tsushigawa granite, located in Awaji island, Hyogo Prefecture. We irradiated 400 Gy of gamma-ray for the quartz powder before the experiments to simulate natural radiation damage. Friction experiments were conducted under the following conditions in darkroom environment using a rotary-shear, high-velocity friction apparatus in Yamaguchi University; normal stress of 0.5–5.0 MPa and slip rate of 0.65 m/s (constant from starts to finish). To eliminate the effect of crushing on OSL signal, we measured coarse grains (75–150 μm) extracted from recovered sample.As a result of the measurement, OSL signal intensity start to decrease from the normal stress of 0.5 MPa. We found “partial resetting” which is characterized by coexistence of both particles with signal and without signal at normal stress of 0.5 and 1.0 MPa, and then frequency of the signal intensity for each aliquot is bimodal distribution.On the other hand, complete resetting of the signal was observed in all particles at normal stress ≧ 2.0 MPa.. Assuming a coseismic fault slip rate of 0.6 m/s, depth conditions required for operating partial and complete resetting of OSL age expected to be 18~36 m and 72 m respectively.

# Result of age determination of samples from Hokuriku Group

*Noriko Hasebe[1], Ryo Kamiguchi[2]

1. Institute of Nature and Environmental Technology, Kanazawa University, 2. Department of Earth Sciences, Kanazawa University

The Hokuriku Group is distributed from the southern part of Ishikawa Prefecture to the eastern part of Toyama prefecture and deposited in the Neogene period (about 25 Ma to 2.5 Ma). This study reports zircon fission track (ZFT) and U-Pb ages from several volcanic rocks distributed in the Tsurugi district, the southern part of Ishikawa Prefecture, Kanazawa University district, and Uozu area in Toyama prefecture. The Iozen Formation in Tsurugi district show ZFT ages between 12.2 ±1.9 to 15.7 ±2.8 Ma (error, 2 sigma) and U-Pb ages between 17.2 ±0.5 to 21.0 ±0.9 Ma. U-Pb ages coincide with the Japan Sea opening event, and eruption age by ZFT is about 5 mys after zircon crystallization. One sample from Otogawa Formation shows an equivalent age with the Iozen Formation, suggesting a rapid volcanic sedimentation for both formations. The sample from a quarry, which we thought is from TR1 (Ohkubo, 1999), therefore estimated age is about 4.4 Ma (Tamura and Yamazaki, 2004) by the correlation, shows much older age of ZFT 33.2 ±4.6 Ma and U-Pb 65.3 ±2.0 Ma, and further investigation, especially on the sample identification, is necessary. For Uozu area, ZFT ages of 3.4 ±0.7 to 9.7 ±1.4 Ma and U-Pb ages of 2.9 ±0.8 to 71.7 ±2.8 Ma are obtained, and eruption ages are equivalent to tephra found in Yatsuo district (Sumii, 1986)

Keywords: Hokuriku Group, TR1 tephra, Tng tephra

## [S-GL27] Geochronology and Isotope Geology

convener:Takahiro Tagami(Graduate School of Science, Kyoto University), Yuji Sano(Division of Ocean and Earth Systems, Atmosphere and Ocean Research Institute, University of Tokyo), Chairperson:Yuji Sano, Takahiro Tagami

Reliable reconstruction of geohistory is of primary importance to better envision the present and future of the Earth. Geochronology and isotope geology play major roles in the reconstruction. This session offers an opportunity to present the results of fundamental studies, including the developments / improvements of analytical methods and age calibration, as well as applications to the Earth and planetary materials. We particularly focus on: (1) radiometric dating, bio-stratigraphy, magneto-stratigraphy and stable isotopic time series that provide the age information, (2) radioisotopes and stable isotopes widely employed for analyzing the Earth and planetary systems and (3) hypothesis and numerical modeling that utilize / assimilate the age and isotopic data. We also welcome contributions that integrate a variety of relevant disciplines.

# Geochemical origin/cycle analysis with isotopologues and isotopomers

*Naohiro Yoshida[1]

1. Department of Chemical Science and Engineering, Earth-Life Science Institute, Tokyo Institute of Technology

Since the 1950's, the stable isotope composition of natural samples has proved to be a unique tool for the study of geological and biological processes, their evolution and effect on Earth's surface environment. However, due to technical and conceptual limitations, the complete set of information potentially contained in the different modes of isotopic substitution remains largely unexplored. In this study, using new methodological developments that allow analysis of more isotopically substituted molecules, we are developing new tracers in 3 modes of isotopic substitution, fully integrated in the study of geological, biological and anthropogenic processes which affect the origin and evolution of the Earth's surface environment.

3 modes of substitution of stable isotopes in a single molecular species are;

1) Position specific isotope abundance (PSIA): Our group has pioneered PSIA of $N_2O$[1,2] and organic molecules using classic isotope mass spectrometry[3] and nuclear magnetic resonance[4,5]. We have shown that PSIA of hydrocarbons and organic acids allows to distinguish between biological and non-biological processes[4,6].

2) Mass-independent fractionation (MIF): The discovery of MIF of sulfur and oxygen in terrestrial samples has revolutionized environmental geochemistry and our understanding of the evolutionary history of the Earth's environment and life[7-9].

3) Clumped isotopes (i.e. isotopologues and isotopomers with 2 minor isotopes) provide unique information about the temperature history of molecules such as carbonates[10] or organic compounds[11-13].

We are currently developing new and improved tracers of environmental and biogeochemical processes and applying them to the environmental diagnosis. We are establishing and standardizing new methods for the analyses of every 3 complex modes of isotopic substitution, and unifying them to develop ultimate environmental diagnosis.

The development and application of these new isotopic tools to the environment evolution, in modern and more ancient eras, represents an important conceptual advance in Earth and life sciences. This will open new areas of research about, for example, the geological production of some atmospheric gases, metabolic processes and the biological fixation of atmospheric $CO_2$, the production and cycling of pollutant gas by industrial processes. As a whole, these new tracers will be integrated together for diagnosis of the Earth's environment.

# Estimation of Paleoenvironment by sedimentary rocks in Labrador, Cacada

*katsutaka sudo[1], Yuji Sano[1], Tsuyoshi Komiya[1], Bakert David[2], Michael Broadley[2], Bernard Marty[2]

1. University of Tokyo, 2. CRPG-CNRS, Université de Lorraine

In the previous research, we reported isotopic compositions of graphite and carbonate in the 3.95Ga metasedimentary rocks from northern Labrador, Canada (Tashiro et al., 2017). Based on the isotopic shift of 20-30‰, we claimed a carbonate fixation by the Earth’ s earliest life. In this work, we picked up graphite from the very old rocks collected in Labrador and Nuvvuagittuq, and measured volatile isotope compositions by the step-wise heating method. We analyzed nitrogen isotopes to investigate whether the organic carbon was producted by cyanobacteria or methanobacteria, and noble gas (argon, krypton, xenon) isotopes to determine the age of rocks. We have used two types of gas mass spectrometer; VG3600 for nitrogen, Helix-MC for noble gases. The obtained data together with experimental method will be given in the presentation.

# Hf-W dating of zircons from mesosiderites with high-pressure sintered sample

*Yuta Koyama[1], Naoto Takahata[1], Yuji Sano[1], Naoji Sugiura[1], Mizuho Koike[2], Makiko K. Haba[3], Sakata Shuhei[4], Hideharu Kuwahara[5], Tetsuo Irifune[5]

1. the University of Tokyo, 2. Japan Aerospace Exploration Agency, 3. Tokyo Institute of Technology, 4. Gakushuin University, 5. Geodynamics Research Center, Ehime University

Hf-W dating is a chronometer based on the decay of $^{182}$Hf to stable $^{182}$W with a half-life of 8.9 Myr (Vockenhuber et al., 2004). This radiometric dating method is important for discussing the timing of core formation in protoplanets and meteorites' parent bodies because hafnium is a lithophile element while tungsten is a siderophile one. In-situ analysis of Hf/W ratio on zircon ($ZrSiO_4$) mineral shows several difficulties, whereas meteoritic zircons have been often used to acquire the information of the early solar system due to their high resistance to thermal metamorphism and great aptitude for U-Th-Pb chronology. Generally, in-situ analysis needs standard materials which have well documented concentrations of target elements and the same matrix as the sample in order to avoid the change of sensitivity depending on major components (matrix effects) during an analysis using a secondary ion mass spectrometer (SIMS). There are no available standard zircons which include abundant and homogeneous tungsten because of its incompatibility with zircon crystal. Therefore, the previous studies determining the relative sensitivity factor (RSF) of Hf and W (Hf/W) for Hf-W dating of zircons using SIMS have been based on several assumptions (e.g., Ireland & Bukovanská,2003; Koike et al., 2017). These methods for measuring Hf/W ratios are indirect ways in terms of lacking standard zircons with known amount of W. In this study, we created new standard zircons which have abundant Hf and W concentrations. High purity zircon powder was mixed with hafnium and tungsten oxide. They were well crushed and mixed by a high energy ball mill and solidified by high-pressure sintering method with multi-anvil apparatus (ORANGE-3000, Geodynamics Research Center, Ehime University) in order to establish the direct way to determine the RSF of Hf/W ratio on zircons for in-situ analyses. Moreover, we applied these standards to Hf-W dating of zircons from a couple of mesosiderites with NanoSIMS (Atmosphere and Ocean Research Institute, the University of Tokyo) at approximately 30 $\mu$m scale. As a result of these analyses, we obtained the Hf-W age consistent with Koike et al. (2017) for the mesosiderite Asuka 882023.

# Radiometric ages *vs.* astrophysical ages -with regard to the numerical age in the International Stratigraphic Chart

*Ichiro Kaneoka[1]

1. Earthquake Research Institute, University of Tokyo

In July, 2018, ICS(International Stratigraphy Commission) of IUGS published the new International Stratigraphic Chart (ISC: v.2018/07). The author drew an attention to the public about some issues to be cautioned on the usage of numerical ages in the ISC based on the 2009 version(v.2009/08) at the JpGU before (Kaneoka, 2016). The essential points do not change between the two versions of ISC, but there are some differences in the representation of numerical ages in the new ISC. Here, the author comments some points about them and discuss issues of astrophysical and radiometric ages used in the ISC.

# Research report on long-term stability of geological environments and LA-ICP-MS-based age dating

*Tatsunori Yokoyama[1], Takehiro Mitsucuchi[1], Shigeru Sueoka[1]

1. Japan Atomic Energy Agency

In recent years, it has become possible to carry out high-precision microscale age dating of geological samples (with a spatial resolution of less than several tens of micrometers) using developed micro-analytical techniques such as secondary ion mass spectrometry (SIMS), laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), etc. Application of LA-ICP-MS-based microscale U-Pb dating is extending from U-rich heavy minerals such as zircon, apatite and monazite to U-depleted minerals such as calcite. This kind of method enables age determination of several types of mineral grains (and their internal zoning structures) occurring within rock bodies, and thereby reveals chronological changes in chemical composition of source materials from which the minerals were crystallized, with some cases in which thermal history of the crystal formation system can be reconstructed.

For research and development of geological disposal techniques for high-level radioactive wastes, we develop and facilitate geochronological dating techniques for evaluation of long-term stability in geological environments, at Tono Geoscience Center, Japan Atomic Energy Agency. Elucidating past long-term variations of geological environments leads to predicting the future of the environments and is essential for the geological disposal, because the radioactive wastes need to be buried in deep underground and isolated far from the human living sphere for more than tens of thousands of years. Geochronological dating techniques are necessary for this purpose. LA-ICP-MS U-Pb dating of zircon provides reliable information about igneous activities such as magmatic differentiation and is also useful for provenance analysis if the mineral is found in sediments. Additionally, dating techniques using $^{10}Be$ and $^{26}Al$, which are generated by cosmic rays reaching the ground, can be applied to quantitative estimation of the amount of uplift and erosion. Combining these various dating methods has great potential to elucidate past long-term variations of geological environments.

In our presentation, we introduce the current status of our development for research on long-term stability of geological environments, U-Pb dating of calcite, U-Pb dating of young zircon and trace element analysis by using LA-ICP-MS.

This study was carried out under a contract with METI as part of its R&D supporting program for developing geological disposal technology.

# U-Pb detrital zircon age dating from the Aileu Formation of Timor-Leste; Estimate depositional age and provenance of the sediment

*Jovita Elisa Fatima da Costa[1], Shoichi Kiyokawa[1], Yukiyasu Tsutsumi[2]

1. Kyushu University, 2. National Museum of Nature and Science

The Aileu Formation is a part of allochthonous metamorphic complexes distributed a 110km long and 40 km wide in Timor-Leste. It occupies most of the north-west of Timor-Leste and crops out along the north coast from Manatutu to the West Timor border and passing through to the south (Audley Charles, 1968). It is considerable lithological variation and metamorphic grade varies between lower greenschist to upper amphibolite facies (Beery and Grady, 1981). Our research area is affected by greenschist metamorphism and comprises an extensive succession of mostly terrigenous metasedimentary rock. The previous study of the north coast suggests that detrital zircon U-Pb from metasandstone, shows three groups at 270-440Ma, 860-1240, and 1480-1870Ma, and the metamorphic age also identified by 40Ar/39Ar of hornblende cooling ages of 10–6 Ma (Elly et al, (2014)). The Aileu Formation contain east-west foliation and north-south widely distributed. However, it's not a well-known south area of metasedimentary origin and depositional age. This study, we collect 3 samples of meta-sandstone transect north-south about 20 km wide. We analyzed U-Pb detrital zircon by using LA-ICP-MS.

Petrographically the 3 samples composed majorities of fine, fine medium grain of quartz-rich sandstone weakly deform and foliated. The three samples composed less than 2% muscovite, biotite, plagioclase, and another accessory mineral include zircon. Texturally immature characterized by sub-angular to sub-rounded and fresh of mica. These three samples are almost consisting of the same morphological characteristic of zircon grain.

The U-Pb age distribution of detrital zircon result from the concordant dataset reflected similar characteristic for all three samples and shows 270-420 Ma 900-1300Ma and 1400-1900 Ma. Grain younger than 270 Ma and older than 1900 Ma makes up 4% of the population. The most significant age peak, at 283-290 Ma indicated that the distribution of sediment coming from early Permian source rocks. The youngest zircon and main peaks are 239.87 Ma and 283-290 Ma, we consider this for maximum deposition age in the south which is the same as the north area. We suggest that the Sedimentation age of the south area of Aileu Formation after middle Triassic. These age from the previous study (north coast) and this study (north-south) shows the similarity characteristic for all samples. The Aileu Formation might be formed a fold and thrust belt and resemble sequences stacked north to south. Source sediment for Aileu Formation is compatible with a sediment source located in South East Asia as part of the now fragmented Sula Spur (Ely 2014). Sula spur is containing a Paleozoic granite and metamorphic basement which is extending from west of New Guinee and include the Bangai and Sula island.

# Petrological, geochemical, and geochronological characteristics of the Oritate travertine from Unazuki area, Toyama, Japan: possibility of U-Pb geochronology of carbonates with high common Pb.

*Mayuko Fukuyama[1], Masatsugu Ogasawara[2]

1. Graduate School of Engineering Science, Akita University, 2. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

U-Pb dating of carbonate minerals can be widely applied to understand the timing of vein-type mineralization, fault movements, and other geological events forming calcites, which are difficult to be dated by other methods. Reference materials for U-Pb dating of calcite, such as WC-1 (254.4 ±6.4 Ma, Roberts *et al.*, 2017) and ASH-15D (3.001 ±0.012 Ma, Mason *et al.*, 2013; Vaks *et al.*, 2013), are available from several laboratories. However, it is often difficult to obtain reliable estimated ages of calcite because calcite usually contains high common Pb content.

In this study, we present the petrological, geochemical, and geochronological characteristic of the Oritate travertine from Unazuki area, Toyama, Japan. Typically, travertines are formed by a precipitation of carbonate minerals from hot spring. Thus, the U-Pb dating of calcite provides the timing of hydrothermal fluid activity. The Oritate travertine is called as ‘Onyx Marble’ by its texture. It shows layered texture with different colors from gray, white, to brown. It consists of aragonite and calcite. The chondrite normalized REE patterns of travertines show the flat and positive Eu anomalies which are different characteristics from oceanic limestones.

High initial $^{238}U/^{204}Pb$ ($\mu$) content is requirement for precise U-Pb dating of calcite (Rasbury & Cole, 2009), because calcite generally contains significant amount of common Pb. It is also better to contain high U in the order of several tens of ppm for U-Ob dating. U/Pb ratio of the Oritate travertines range from 1.1 to 2.2. The U and Pb concentration of Oritate travertines are very low which is less than 1 ppm. The brownish colored layers in travertines contain relatively high U concentrations. Although the chemical compositions of Oritate travertine imply the difficulty to apply U-Pb method, we examined U-Pb dating of calcite with high common Pb. We analyzed travertines with relatively high U/Pb ratio and U contents parts of the travertines for U-Pb dating. U-Pb dating was attempted with the solution ICP-MS as well as the LA-ICP-MS utilize a New Wave Research 193UC excimer laser ablation system, coupled to a Nu Instruments Nu Plasma II multi-collector ICP-MS or Agilent 7700 quadru-pole ICP-MS at Akita University. We discuss and evaluate the U-Pb dating method for calcite with high common Pb.

# Zircon U-Pb age and tectonics of shirakamidake granitic complex

*Hiroki Sato[1], Koji Umeda[1]

1. Hirosaki University

The Shirakamidake granitic complex in the Southwest of Aomori prefecture, is divided into the East, Central and West bodies. The East body and the Central bodies are mainly composed of coarse to medium grained hornblende biotite granodiorite and coarse to medium grained granite, respectively. The West body consists of schistose medium to coarse grained hornblende biotite granodiorite and light color schistose medium to coarse grained hornblende biotite granodiorite with mylonite zone (hujimoto, 2010). A large number of petrological studies have investigated the cooling history of the Shirakamidake granitic complex. Apatite (U-Th)/He age of 4.2±2.0 Ma, biotite K-Ar age of 86-100 Ma, amphibole K-Ar age of 89-94 Ma and whole-rock Rb-Sr age of 110.1±6.0 Ma have been reported. Generally, the ages of the West body are younger than those of the East body.

In this study, we describe geological and petrological features each bodies by polarizing microscopy, XRF spectrometry and EPMA analysis. We also present geochronological data utilizing laser ablation ICP mass spectrometry technique on the zircons that provides zircon U-pb age of 107.7±1.4Ma.
Thermochronological data suggests two distinctive cooling stages for the Shirakamidake granitic complex; 1) a first rapid cooling stage in which the granitic magma was cooled to the temperature of host rock soon after intrusion, and 2) second slow cooling stage associated with the uplift and subsequent erosion of the granite intrusion after ~90 Ma.

Keywords: The Shirakamidake granitic complex , Zircon, U-Pb age

# Zircon U-Pb dating of plutonic rocks from Yamizo Area, northeast Japan

*Terumi Ejima[1,2], Yoshiaki Kon[2], Daisuke Araoka[2], Shigenori Kawano[3], Yutaka Takahashi[2]

1. Shinshu University, 2. Geological Survey of Japan, 3. Tochigi Prefectural Museum

To investigate the timing of the tectonothermal events of Yamizo plutonic suite, U-Pb dating of zircon was carried out using laser ablation inductively coupled plasma mass spectrometry combined with cathodoluminescence imaging on zircon grains separated from the Yamizo plutons.

In the Yamizo mountain areas, K-Ar ages of Ozasa (67.5Ma), Fukuroda (101 Ma), Iwafune (64.5 Ma), Kamehis (64.9 Ma) and Ooyamada plutons (71.8 Ma and 108 Ma) have been reported by Shibata et al. (1973). Basically, the K-Ar ages are sometimes younger than actual intrusive ages because the closure temperature of K-Ar ages are lower than that of the solidus of granitic rocks. The closure temperature of the U-Pb age of zircon was higher than that of K-Ar age and more suitable for investigating intrusive age of magma.

Nagasaka, Hatajyuku, Yamagiwa, Nomisawa, Ozasayama, Kizami, Kamehisa and Hanatatetouge plutons are distributed in the northern part of the Yamizo area. Zircon U-Pb ages of these plutons were 69–63 Ma. In the southern part of the Yamizo area, Ooyamada, Fukuroda and Korofuji plutons are distributed. The zircon U-Pb ages of these plutons were 104–102 Ma.

According to the results in this study, U-Pb ages correspond to the K-Ar ages previously reported. This result indicated that cooling rates after intrusion of the plutons in the Yamizo area were relatively fast. Moreover, U-Pb ages of plutons in the southern part of the Yamizo area were same as those of the Bato pluton (109–106 Ma: Ejima et al., 2017) and of Abukuma plutons (121–97 Ma: Kon and Takagi, 2012; Ishihara and Orihashi, 2015; Kon et al., 2015; Takahashi et al., 2016). On the other hand, U-Pb ages of plutons in the northern part of the Yamizo area were same as those of plutons around Tsukuba mountain (80 Ma, 63–58 Ma: Koike and Tsutsumi, 2018).

# Denudation history of the Higher Himalayan Crystallines in West-Central Nepal: insights from zircon fission-track dating and thermokinematic modeling

*Nakajima Toru[1], Harutaka Sakai[1], Hideki Iwano[2], Tohru Danhara[2], Takafumi Hirata[3]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, 2. Kyoto Fission-Track Co., Ltd., 3. Geochemical Research Center, The University of Tokyo

Zircon Fission-Track (FT) dating and thermochronological inverse calculation were used to indentify the denudation history of the Higher Himalayan Crystalline (HHC) in west-central Nepal. We newly obtained 17 zircon and 4 apatite FT ages from Higher Himalayan Crystallines (HHC), the overlying Tibetan Tethys Sediments (TTS) and the underlying Lesser Himalayan Sediments (LHS) along 80km long transect across the Himalaya.
The ZFT age from the underlyng sediments displayed northward younging linear distribution of the oldest age in the frontal part of the Lesser Hilamaya (13.4 ±1.0 Ma) to the youngest age in the root zone near the Main Central Thrust (1.5 ±0.2 Ma). On the other hand, the ZFT ages from the HHC and the overlying sediments ranged from 10.9 ±0.8 Ma to 1.7 ±0.4 Ma, and showed southward younging distribution. The ZFT age distribution along NNE-SSW transect displayed a concave upward pattern with the youngest FT age located near the Main Central Thrust (MCT). This distribution pattern is well corresponded to present uplift rate, indicating that the FT age distribution pattern reflects the tectonically driven exhumation.
Thermochronological invert calculation showed two rapid cooling (<100 ℃/Myr) phases of the HHC and the LHS in the late Miocene and the Pleistocene. With respect to this result, rapid exhumation is not only suggested in the Pleistocene, but also in the late Miocene. The former implies rapid exhumation of the HHC accompanied by reactivation of the MCT in the late Miocene, the latter implies rapid denudation accompanied by overthrusting of the hanging wall of the Main Himalayan Thrust (MHT).
Thermo-kinematic calculation results also suggest that the distribution of FT ages is well explained by exhumation process accompanied by the activity of the MHT. Furthermore, the kinematic model considering reactivation of the MCT in the late Miocene yields a better fit between predicted and observed ages than the model without reactivation, indicating agreement with reactivation of the MCT in late Miocene.

# Thermochronology on the fore-arc side of Northeast Japan Arc

*Yuya Kajita[1], Shigeru Sueoka[2], Shoma Fukuda[1], Noriko Hasebe[3], Akihiro Tomoaki[4], Tomoaki Morishita[4], Barry P. Kohn[5], Tatsunori Yokoyama[2], Takahiro Tagami[1]

1. Graduate School of Science, Kyoto University , 2. Japan Atomic Energy Agency, 3. Institute of Nature and Environmental Technology, Kanazawa University, 4. Department of Sciences, Kanazawa University, 5. School of Earth Sciences, University of Melbourne

An arc trench system is composed of a topographically high land and a trench along a subduction zone. An arc trench system is grouped into continental arc and island arc. The latter has a back-arc basin. Island arcs are tectonically active regions where a lot of volcanic activities and earthquakes occur, providing keys to solve the formation and evolution processes of orogenic zones and continents (Toriumi et al., 2018).

Northeast (NE) Japan is one of the best regions to study tectonics of island arc because NE Japan has comparatively obvious island arc components, i.e., fore-arc, volcanic front, back-arc and back-arc basin. Therefore, many studies have focused on the tectonic evolution of NE Japan (e.g. Amano and Sato, 1989; Sato, 1992; Nakajima, 2013). However, there are a few quantitative investigations of the mountain uplift and denudation histories which are important for estimating tectonics of island arcs.

For measuring uplift or denudation rates, some techniques are available (e.g., GPS survey, elevation of terraces, and thermochronology). To estimate million-year-scale mountain uplift and denudation rates, thermochronology is among the most appropriate methods. Thermochronology can reconstruct the time-temperature relationship of rock/mineral samples, based on radiometric ages and closure temperatures specific to the combination of radiometric dating methods and target minerals. Furthermore, some assumptions enable discussion of mountain uplift and denudation histories. Although thermochronology has been successfully applied to orogens worldwide (Hermam et al., 2013), a small number of thermochronometric studies have been attempted in NE Japan (e.g. Sueoka et al., 2017, Fukuda et al., in press). Moreover, these previous studies focused on the denudation histories of the across-arc scale rather than individual geologic component, namely fore-arc, Ou backbone range and back-arc.

In this study, we focus on fore-arc side of NE Japan, i.e., Kitakami Mountains and Abukuma Mountains, at which granitic rocks are distributed extensively, providing preferable study areas to apply thermochronology. We adopted apatite fission-track (AFT), apatite (U-Th-Sm)/He (AHe) and zircon (Zr) U-Pb analyses. AFT ages were estimated at 66.8-39.1 Ma in Kitakami and 61.0-40.5 Ma in Abukuma. AHe ages were obtained at 51.2-36.1 Ma in Kitakami and 75.9-60.1 Ma in Abukuma. Zr U-Pb ages were calculated at 110.3-104.3 Ma in Abukuma. With our results and the ages obtained by the previous studies, we discuss age trend and denudation history.

In Kitakami Mountains, AFT ages become younger to the east. On the other hand, all AHe ages are approximately comparable with each other except for the oldest age obtained at the westernmost locality. In Abukuma Mountains, both AFT and AHe age trends change across Hatagawa fault zone (HFZ); the ages were younger at the west side of HFZ than at the east side. Assuming that geothermal gradient is uniform at all localities, westerly tilting uplift and subsequent change of the uplift style were suggested in Kitakami Mountains. In Abukuma Mountains, our age data can constrain the faulting history of HFZ.

As future subjects, we are planning to conduct 1) improvement of accuracy and precision by further analyzing, 2) increasing number of sampling localities and employing other methods (e.g., cosmogenic nuclides analysis and ESR thermochronology), 3) applying thermal inverse modeling of AFT data to estimate more detailed thermal histories, 4) discussion of geothermal gradient, uplift model and tectonics model in Kitakami Mountains and Abukuma Mountains.

# Argon diffusion in rocks - classical approach in view of heating and relaxation

Horst Zwingmann[1], *Hironobu Hyodo[2]

1. KUEPS, Kyoto University, 2. Research Institute of Natural Sciences, Okayama University of Science

Since the development of the conventional K-Ar and subsequent 40Ar-39Ar dating methods fundamental noble gas diffusion processes in rocks were investigated including complex multi-scale and multi-path aspects in polyphase materials. Traditional models interpret the loss of radiogenic Argon due to an increase of temperatures. Hyodo (2017) proposed a new approach investigating the relaxation time and temperature relation within an “unclosure temperature” model. This model regards duration of a heating event as time for relaxation in a diffusion system at specific temperature. The model applies a functional form of mathematical approximation on fractional loss by diffusion. It allows fractional loss of certain amount of radiogenic 40Ar as long as the step heating model spectra in 40Ar-39Ar dating (plateau) maintains its original age within its age error. This new model approach is compared to a classical heating diffusion model (Huon et al., 1993) focusing on clay minerals (<10 and <2 μm) and larger muscovite grains (200 and 100 μm). The classical diffusion heating models applies three main parameters comprising a. grainsize (μm), b. temperature range (°C) and c. time scale (Ma). The obtained results provide a unique insight to compare an active heating versus passive cooling time and temperature path of clay minerals and muscovite with applications for general earth sciences and economic geology such as hydrocarbon exploration.

# $^{4}$He/U-Th dating of pore waters from Quaternary sediments in Switzerland: potential and challenges

*Yama Tomonaga[1], Edith Horstmann[1], Gaudenz Deplazes[2], Rolf Kipfer[1]

1. Swiss Federal Institute of Aquatic Science and Technology (Eawag), 2. National Cooperative for the Disposal of Radioactive Waste (Nagra)

Dating based on the $^{4}$He/U-Th method is used to estimate the residence time of pore waters in very low-permeable rocks and consolidated sediments. The residence time is inferred from the time necessary to accumulate radiogenic $^{4}$He measured in the pore water being produced by the decay of U and Th in the sediment matrix [1].
In the Jurassic Opalinus Clay, the pore water still contains remnants of the original marine formation water that was entrapped during sediment deposition. The pore water composition was altered only by diffusive processes [2,3]. The fact that even ~100-Ma-old water signatures can be preserved in their original pore space suggests that such preservation might also be possible in much younger dense glacial deposits. The $^{4}$He concentrations measured in the pore waters of glacial tills were translated into mean residence times of 15-25 kyrs [4] that agree rather well with the expected depositional ages of 25-31 kyrs [5]. These observations, as well as evidence from lacustrine sediments [6,7], suggest that, if the solute transport in the pore space is sufficiently attenuated, even unconsolidated sediments can "store" and host "old" pore waters.
In the present work we investigate if the $^{4}$He/U-Th dating of pore waters can be used as a novel tool to complement the luminescence dating of unconsolidated Quaternary sediments. We applied the $^{4}$He/U-Th method to date pore waters in the time range of 10 to 100 thousands of years which covers the age range of the sedimentary depositions targeted by the Quaternary drillings (QBOs) managed by the National Cooperative for the Disposal of Radioactive Waste (Nagra) in Switzerland. In particular, we focus on fine-grained lacustrine sediment layers that might provide low-permeability conditions suitable for the preservation of radiogenic $^{4}$He concentrations in the pore space.
We report the preliminary results of the $^{4}$He/U-Th dating based on the measurements conducted in sediment samples from the first QBOs, highlighting potential and challenges of the method with respect to the studied glaciofluvial sediments of the Swiss Midland.

# Compound-specific radiocarbon analysis of lipid biomarkers in surface sediment from Lake Kawaguchi, central Japan

*Shinya Yamamoto[1], Yosuke Miyairi[2], Yusuke Yokoyama[2], Hisami Suga[3], Nanako O. Ogawa[3], Naohiko Ohkouchi[3]

1. Mount Fuji Research Institute, Yamanashi Prefectural Government, 2. Atmosphere and Ocean Research Institute, The University of Tokyo, 3. Japan Agency for Marine-Earth Science and Technology

Lake sediment in volcanic regions contains valuable information on past eruptive history, as well as environmental consequences that took place in the catchment along with volcanisms. In this study, we performed compound-specific radiocarbon analysis (CSRA) of lipid biomarkers in surface sediment from Lake Kawaguchi situated northern proximal to Mount Fuji, central Japan, including short-chain ($C_{16}$) and long-chain ($C_{24}$, $C_{26}$ and $C_{28}$) fatty acids. The results are compared with the $^{14}C$ content of TOC, plant macrofossils (plant leaf and wood) and lake surface water in order to access their potential for dating tool in the lake sediment. The $^{14}C$ concentration of the long-chain ($C_{24}$, $C_{26}$ and $C_{28}$) fatty acids ranged from −43 to −183‰, corresponding to $^{14}C$ ages between 288 to 1554 years BP. This indicates that these acids contain substantial pre-aged materials in addition to those emitted from contemporary plant leaf waxes. In contrast, the short-chain ($C_{16}$) fatty acids showed a good agreement with the $^{14}C$ concentration of lake surface water, suggesting that they are most likely derived from primary producers (diatom) in the present lake and have a potential to improve chronologies in the sedimentary sequence in which the occurrence of fossil leaves is rather limited.

# Reestablishment of the Mesozoic and Cenozoic Stratigraphic Events of the Fergana Basin, Uzbekistan

*OTABEK ULUGBEK OGLI ANVAROV[1], Ken-ichiro Hisada[1], Teruyuki Maruoka[1], Junichiro Kuroda[2], Sherzod Makhmudov[3]

1. UNIVERSITY OF TSUKUBA, 2. Atmosphere and Ocean Research Institute, the University of Tokyo , 3. State Comittee of Geology and Mineral Resources of Uzbekistan

Despite the fact that the Fergana Basin is being the important geologic and tectonic region in Central Asia, for more than a century of research represented that different views have been formed on its geological structure and history of development. Although, it is the least studied intermountain depressions within the Tien-Shan, and lies at the northeastern part of Uzbekistan, covering the 22.000 km $^2$ area. The first attempts on the basins geological investigations dates back to 1916’ s research by A.D. Arkhangelskiy which he started the descriptions of the preliminary stratigraphy of the Cretaceous deposits of the basin and adjacent areas. So far, the scientific debates got interrupted after the explorations of the important industrial resources as oil, gas, gold, uranium and so on, from the 50’ s during the Soviet Period, where all geological investigations concentrated only on broad explorations of resources. Yet, after the collapse of the Soviet Union, the studies still remained as minor and all works were referenced back to the old data, where the most studies were lack of the reliability. The purpose of this study is to reconstruct the stratigraphy of the Fergana Basin.

Generally, three stratigraphic units are involved in the stratigraphy of the basin. The lower one is represented by the Paleozoic formations. The second unit includes Mesozoic to Paleogene sediments. The third is composed of a thick unit of the Cenozoic molasses and the Quaternary sediments covering them. Five geological sections around Chust City, northern part of the Fergana Basin at the foothills of Northwestern Tien-Shan and Chatkal-Kurama Mountain Ranges in the Republic of Uzbekistan were selected and preliminary observations were carried out. The study area were represented by very well exposed deposits starting from the Permian andesites, trachytes and tuffs, the Triassic trachytes, the Cretaceous red beds of conglomerates, paleosols and sandstone shell beds of oyster and bivalve fossils, and the Paleogene grey limestones, sandstones and conglomerates with oyster fossils. At the sections from the Cretaceous to Paleogene, the transitions from terrestrial to marine environment were observed with alluvial, lagoon and costal-marine deposits. But, at the Cretaceous deposits the Upper Cretaceous sections were not observed, where documented as observable by the study of Abduazimova et al. (2012).

The preliminary results showed that the analyzed samples from the Cretaceous, just boundary to the Paleogene beds were the Aptian age of the Lower Cretaceous, therefore this study does not agree with Abduazimova et al. (2012), which documented the existence of the Upper Cretaceous deposits. The Paleogene samples showed the Eocene time. Therefore, the preliminary results of this study can suggest that the existence of disconformity between the Cretaceous and Paleogene sections, which suggests the Paleogene regression following the Late Cretaceous transgression.

[J] Poster | S (Solid Earth Sciences)：S-GL Geology

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_22

## [S-GL27] Geochronology and Isotope Geology

convener:Takahiro Tagami(Graduate School of Science, Kyoto University), Yuji Sano(Division of Ocean and Earth Systems, Atmosphere and Ocean Research Institute, University of Tokyo)

Reliable reconstruction of geohistory is of primary importance to better envision the present and future of the Earth. Geochronology and isotope geology play major roles in the reconstruction. This session offers an opportunity to present the results of fundamental studies, including the developments / improvements of analytical methods and age calibration, as well as applications to the Earth and planetary materials. We particularly focus on: (1) radiometric dating, bio-stratigraphy, magneto-stratigraphy and stable isotopic time series that provide the age information, (2) radioisotopes and stable isotopes widely employed for analyzing the Earth and planetary systems and (3) hypothesis and numerical modeling that utilize / assimilate the age and isotopic data. We also welcome contributions that integrate a variety of relevant disciplines.

# Research report on long-term stability of geological environments and LA-ICP-MS-based age dating

*Tatsunori Yokoyama[1], Takehiro Mitsucuchi[1], Shigeru Sueoka[1]

1. Japan Atomic Energy Agency

In recent years, it has become possible to carry out high-precision microscale age dating of geological samples (with a spatial resolution of less than several tens of micrometers) using developed micro-analytical techniques such as secondary ion mass spectrometry (SIMS), laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS), etc. Application of LA-ICP-MS-based microscale U-Pb dating is extending from U-rich heavy minerals such as zircon, apatite and monazite to U-depleted minerals such as calcite. This kind of method enables age determination of several types of mineral grains (and their internal zoning structures) occurring within rock bodies, and thereby reveals chronological changes in chemical composition of source materials from which the minerals were crystallized, with some cases in which thermal history of the crystal formation system can be reconstructed.

For research and development of geological disposal techniques for high-level radioactive wastes, we develop and facilitate geochronological dating techniques for evaluation of long-term stability in geological environments, at Tono Geoscience Center, Japan Atomic Energy Agency. Elucidating past long-term variations of geological environments leads to predicting the future of the environments and is essential for the geological disposal, because the radioactive wastes need to be buried in deep underground and isolated far from the human living sphere for more than tens of thousands of years. Geochronological dating techniques are necessary for this purpose. LA-ICP-MS U-Pb dating of zircon provides reliable information about igneous activities such as magmatic differentiation and is also useful for provenance analysis if the mineral is found in sediments. Additionally, dating techniques using $^{10}Be$ and $^{26}Al$, which are generated by cosmic rays reaching the ground, can be applied to quantitative estimation of the amount of uplift and erosion. Combining these various dating methods has great potential to elucidate past long-term variations of geological environments.

In our presentation, we introduce the current status of our development for research on long-term stability of geological environments, U-Pb dating of calcite, U-Pb dating of young zircon and trace element analysis by using LA-ICP-MS.

This study was carried out under a contract with METI as part of its R&D supporting program for developing geological disposal technology.

# U-Pb detrital zircon age dating from the Aileu Formation of Timor-Leste; Estimate depositional age and provenance of the sediment

*Jovita Elisa Fatima da Costa[1], Shoichi Kiyokawa[1], Yukiyasu Tsutsumi[2]

1. Kyushu University, 2. National Museum of Nature and Science

The Aileu Formation is a part of allochthonous metamorphic complexes distributed a 110km long and 40 km wide in Timor-Leste. It occupies most of the north-west of Timor-Leste and crops out along the north coast from Manatutu to the West Timor border and passing through to the south (Audley Charles, 1968). It is considerable lithological variation and metamorphic grade varies between lower greenschist to upper amphibolite facies (Beery and Grady, 1981). Our research area is affected by greenschist metamorphism and comprises an extensive succession of mostly terrigenous metasedimentary rock. The previous study of the north coast suggests that detrital zircon U-Pb from metasandstone, shows three groups at 270-440Ma, 860-1240, and 1480-1870Ma, and the metamorphic age also identified by 40Ar/39Ar of hornblende cooling ages of 10–6 Ma (Elly et al, (2014)). The Aileu Formation contain east-west foliation and north-south widely distributed. However, it's not a well-known south area of metasedimentary origin and depositional age. This study, we collect 3 samples of meta-sandstone transect north-south about 20 km wide. We analyzed U-Pb detrital zircon by using LA-ICP-MS.

Petrographically the 3 samples composed majorities of fine, fine medium grain of quartz-rich sandstone weakly deform and foliated. The three samples composed less than 2% muscovite, biotite, plagioclase, and another accessory mineral include zircon. Texturally immature characterized by sub-angular to sub-rounded and fresh of mica. These three samples are almost consisting of the same morphological characteristic of zircon grain.

The U-Pb age distribution of detrital zircon result from the concordant dataset reflected similar characteristic for all three samples and shows 270-420 Ma 900-1300Ma and 1400-1900 Ma. Grain younger than 270 Ma and older than 1900 Ma makes up 4% of the population. The most significant age peak, at 283-290 Ma indicated that the distribution of sediment coming from early Permian source rocks. The youngest zircon and main peaks are 239.87 Ma and 283-290 Ma, we consider this for maximum deposition age in the south which is the same as the north area. We suggest that the Sedimentation age of the south area of Aileu Formation after middle Triassic. These age from the previous study (north coast) and this study (north-south) shows the similarity characteristic for all samples. The Aileu Formation might be formed a fold and thrust belt and resemble sequences stacked north to south. Source sediment for Aileu Formation is compatible with a sediment source located in South East Asia as part of the now fragmented Sula Spur (Ely 2014). Sula spur is containing a Paleozoic granite and metamorphic basement which is extending from west of New Guinee and include the Bangai and Sula island.

# Petrological, geochemical, and geochronological characteristics of the Oritate travertine from Unazuki area, Toyama, Japan: possibility of U-Pb geochronology of carbonates with high common Pb.

*Mayuko Fukuyama[1], Masatsugu Ogasawara[2]

1. Graduate School of Engineering Science, Akita University, 2. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

U-Pb dating of carbonate minerals can be widely applied to understand the timing of vein-type mineralization, fault movements, and other geological events forming calcites, which are difficult to be dated by other methods. Reference materials for U-Pb dating of calcite, such as WC-1 (254.4 ±6.4 Ma, Roberts *et al.*, 2017) and ASH-15D (3.001 ±0.012 Ma, Mason *et al.*, 2013; Vaks *et al.*, 2013), are available from several laboratories. However, it is often difficult to obtain reliable estimated ages of calcite because calcite usually contains high common Pb content.

In this study, we present the petrological, geochemical, and geochronological characteristic of the Oritate travertine from Unazuki area, Toyama, Japan. Typically, travertines are formed by a precipitation of carbonate minerals from hot spring. Thus, the U-Pb dating of calcite provides the timing of hydrothermal fluid activity. The Oritate travertine is called as ‘Onyx Marble’ by its texture. It shows layered texture with different colors from gray, white, to brown. It consists of aragonite and calcite. The chondrite normalized REE patterns of travertines show the flat and positive Eu anomalies which are different characteristics from oceanic limestones.

High initial $^{238}U/^{204}Pb$ ($\mu$) content is requirement for precise U-Pb dating of calcite (Rasbury & Cole, 2009), because calcite generally contains significant amount of common Pb. It is also better to contain high U in the order of several tens of ppm for U-Ob dating. U/Pb ratio of the Oritate travertines range from 1.1 to 2.2. The U and Pb concentration of Oritate travertines are very low which is less than 1 ppm. The brownish colored layers in travertines contain relatively high U concentrations. Although the chemical compositions of Oritate travertine imply the difficulty to apply U-Pb method, we examined U-Pb dating of calcite with high common Pb. We analyzed travertines with relatively high U/Pb ratio and U contents parts of the travertines for U-Pb dating. U-Pb dating was attempted with the solution ICP-MS as well as the LA-ICP-MS utilize a New Wave Research 193UC excimer laser ablation system, coupled to a Nu Instruments Nu Plasma II multi-collector ICP-MS or Agilent 7700 quadru-pole ICP-MS at Akita University. We discuss and evaluate the U-Pb dating method for calcite with high common Pb.

# Zircon U-Pb age and tectonics of shirakamidake granitic complex

*Hiroki Sato[1], Koji Umeda[1]

1. Hirosaki University

The Shirakamidake granitic complex in the Southwest of Aomori prefecture, is divided into the East, Central and West bodies. The East body and the Central bodies are mainly composed of coarse to medium grained hornblende biotite granodiorite and coarse to medium grained granite, respectively. The West body consists of schistose medium to coarse grained hornblende biotite granodiorite and light color schistose medium to coarse grained hornblende biotite granodiorite with mylonite zone (hujimoto, 2010). A large number of petrological studies have investigated the cooling history of the Shirakamidake granitic complex. Apatite (U-Th)/He age of 4.2±2.0 Ma, biotite K-Ar age of 86-100 Ma, amphibole K-Ar age of 89-94 Ma and whole-rock Rb-Sr age of 110.1±6.0 Ma have been reported. Generally, the ages of the West body are younger than those of the East body.

In this study, we describe geological and petrological features each bodies by polarizing microscopy, XRF spectrometry and EPMA analysis. We also present geochronological data utilizing laser ablation ICP mass spectrometry technique on the zircons that provides zircon U-pb age of 107.7±1.4Ma.
Thermochronological data suggests two distinctive cooling stages for the Shirakamidake granitic complex; 1) a first rapid cooling stage in which the granitic magma was cooled to the temperature of host rock soon after intrusion, and 2) second slow cooling stage associated with the uplift and subsequent erosion of the granite intrusion after ~90 Ma.

Keywords: The Shirakamidake granitic complex , Zircon, U-Pb age

# Zircon U-Pb dating of plutonic rocks from Yamizo Area, northeast Japan

*Terumi Ejima[1,2], Yoshiaki Kon[2], Daisuke Araoka[2], Shigenori Kawano[3], Yutaka Takahashi[2]

1. Shinshu University, 2. Geological Survey of Japan, 3. Tochigi Prefectural Museum

To investigate the timing of the tectonothermal events of Yamizo plutonic suite, U-Pb dating of zircon was carried out using laser ablation inductively coupled plasma mass spectrometry combined with cathodoluminescence imaging on zircon grains separated from the Yamizo plutons.

In the Yamizo mountain areas, K-Ar ages of Ozasa (67.5Ma), Fukuroda (101 Ma), Iwafune (64.5 Ma), Kamehis (64.9 Ma) and Ooyamada plutons (71.8 Ma and 108 Ma) have been reported by Shibata et al. (1973). Basically, the K-Ar ages are sometimes younger than actual intrusive ages because the closure temperature of K-Ar ages are lower than that of the solidus of granitic rocks. The closure temperature of the U-Pb age of zircon was higher than that of K-Ar age and more suitable for investigating intrusive age of magma.

Nagasaka, Hatajyuku, Yamagiwa, Nomisawa, Ozasayama, Kizami, Kamehisa and Hanatatetouge plutons are distributed in the northern part of the Yamizo area. Zircon U-Pb ages of these plutons were 69–63 Ma. In the southern part of the Yamizo area, Ooyamada, Fukuroda and Korofuji plutons are distributed. The zircon U-Pb ages of these plutons were 104–102 Ma.

According to the results in this study, U-Pb ages correspond to the K-Ar ages previously reported. This result indicated that cooling rates after intrusion of the plutons in the Yamizo area were relatively fast. Moreover, U-Pb ages of plutons in the southern part of the Yamizo area were same as those of the Bato pluton (109–106 Ma: Ejima et al., 2017) and of Abukuma plutons (121–97 Ma: Kon and Takagi, 2012; Ishihara and Orihashi, 2015; Kon et al., 2015; Takahashi et al., 2016). On the other hand, U-Pb ages of plutons in the northern part of the Yamizo area were same as those of plutons around Tsukuba mountain (80 Ma, 63–58 Ma: Koike and Tsutsumi, 2018).

Keywords: Yamizo area, U-Pb age of zircon, plutons

# Denudation history of the Higher Himalayan Crystallines in West-Central Nepal: insights from zircon fission-track dating and thermokinematic modeling

*Nakajima Toru[1], Harutaka Sakai[1], Hideki Iwano[2], Tohru Danhara[2], Takafumi Hirata[3]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, 2. Kyoto Fission-Track Co., Ltd., 3. Geochemical Research Center, The University of Tokyo

Zircon Fission-Track (FT) dating and thermochronological inverse calculation were used to indentify the denudation history of the Higher Himalayan Crystalline (HHC) in west-central Nepal. We newly obtained 17 zircon and 4 apatite FT ages from Higher Himalayan Crystallines (HHC), the overlying Tibetan Tethys Sediments (TTS) and the underlying Lesser Himalayan Sediments (LHS) along 80km long transect across the Himalaya.
The ZFT age from the underlyng sediments displayed northward younging linear distribution of the oldest age in the frontal part of the Lesser Hilamaya (13.4 ±1.0 Ma) to the youngest age in the root zone near the Main Central Thrust (1.5 ±0.2 Ma). On the other hand, the ZFT ages from the HHC and the overlying sediments ranged from 10.9 ±0.8 Ma to 1.7 ±0.4 Ma, and showed southward younging distribution. The ZFT age distribution along NNE-SSW transect displayed a concave upward pattern with the youngest FT age located near the Main Central Thrust (MCT). This distribution pattern is well corresponded to present uplift rate, indicating that the FT age distribution pattern reflects the tectonically driven exhumation.
Thermochronological invert calculation showed two rapid cooling (<100 ℃/Myr) phases of the HHC and the LHS in the late Miocene and the Pleistocene. With respect to this result, rapid exhumation is not only suggested in the Pleistocene, but also in the late Miocene. The former implies rapid exhumation of the HHC accompanied by reactivation of the MCT in the late Miocene, the latter implies rapid denudation accompanied by overthrusting of the hanging wall of the Main Himalayan Thrust (MHT).
Thermo-kinematic calculation results also suggest that the distribution of FT ages is well explained by exhumation process accompanied by the activity of the MHT. Furthermore, the kinematic model considering reactivation of the MCT in the late Miocene yields a better fit between predicted and observed ages than the model without reactivation, indicating agreement with reactivation of the MCT in late Miocene.

# Thermochronology on the fore-arc side of Northeast Japan Arc

*Yuya Kajita[1], Shigeru Sueoka[2], Shoma Fukuda[1], Noriko Hasebe[3], Akihiro Tomoaki[4], Tomoaki Morishita[4], Barry P. Kohn[5], Tatsunori Yokoyama[2], Takahiro Tagami[1]

1. Graduate School of Science, Kyoto University , 2. Japan Atomic Energy Agency, 3. Institute of Nature and Environmental Technology, Kanazawa University, 4. Department of Sciences, Kanazawa University, 5. School of Earth Sciences, University of Melbourne

An arc trench system is composed of a topographically high land and a trench along a subduction zone. An arc trench system is grouped into continental arc and island arc. The latter has a back-arc basin. Island arcs are tectonically active regions where a lot of volcanic activities and earthquakes occur, providing keys to solve the formation and evolution processes of orogenic zones and continents (Toriumi et al., 2018).

Northeast (NE) Japan is one of the best regions to study tectonics of island arc because NE Japan has comparatively obvious island arc components, i.e., fore-arc, volcanic front, back-arc and back-arc basin. Therefore, many studies have focused on the tectonic evolution of NE Japan (e.g. Amano and Sato, 1989; Sato, 1992; Nakajima, 2013). However, there are a few quantitative investigations of the mountain uplift and denudation histories which are important for estimating tectonics of island arcs.

For measuring uplift or denudation rates, some techniques are available (e.g., GPS survey, elevation of terraces, and thermochronology). To estimate million-year-scale mountain uplift and denudation rates, thermochronology is among the most appropriate methods. Thermochronology can reconstruct the time-temperature relationship of rock/mineral samples, based on radiometric ages and closure temperatures specific to the combination of radiometric dating methods and target minerals. Furthermore, some assumptions enable discussion of mountain uplift and denudation histories. Although thermochronology has been successfully applied to orogens worldwide (Hermam et al., 2013), a small number of thermochronometric studies have been attempted in NE Japan (e.g. Sueoka et al., 2017, Fukuda et al., in press). Moreover, these previous studies focused on the denudation histories of the across-arc scale rather than individual geologic component, namely fore-arc, Ou backbone range and back-arc.

In this study, we focus on fore-arc side of NE Japan, i.e., Kitakami Mountains and Abukuma Mountains, at which granitic rocks are distributed extensively, providing preferable study areas to apply thermochronology. We adopted apatite fission-track (AFT), apatite (U-Th-Sm)/He (AHe) and zircon (Zr) U-Pb analyses. AFT ages were estimated at 66.8-39.1 Ma in Kitakami and 61.0-40.5 Ma in Abukuma. AHe ages were obtained at 51.2-36.1 Ma in Kitakami and 75.9-60.1 Ma in Abukuma. Zr U-Pb ages were calculated at 110.3-104.3 Ma in Abukuma. With our results and the ages obtained by the previous studies, we discuss age trend and denudation history.

In Kitakami Mountains, AFT ages become younger to the east. On the other hand, all AHe ages are approximately comparable with each other except for the oldest age obtained at the westernmost locality. In Abukuma Mountains, both AFT and AHe age trends change across Hatagawa fault zone (HFZ); the ages were younger at the west side of HFZ than at the east side. Assuming that geothermal gradient is uniform at all localities, westerly tilting uplift and subsequent change of the uplift style were suggested in Kitakami Mountains. In Abukuma Mountains, our age data can constrain the faulting history of HFZ.

As future subjects, we are planning to conduct 1) improvement of accuracy and precision by further analyzing, 2) increasing number of sampling localities and employing other methods (e.g., cosmogenic nuclides analysis and ESR thermochronology), 3) applying thermal inverse modeling of AFT data to estimate more detailed thermal histories, 4) discussion of geothermal gradient, uplift model and tectonics model in Kitakami Mountains and Abukuma Mountains.

# Argon diffusion in rocks - classical approach in view of heating and relaxation

Horst Zwingmann[1], *Hironobu Hyodo[2]

1. KUEPS, Kyoto University, 2. Research Institute of Natural Sciences, Okayama University of Science

Since the development of the conventional K-Ar and subsequent 40Ar-39Ar dating methods fundamental noble gas diffusion processes in rocks were investigated including complex multi-scale and multi-path aspects in polyphase materials. Traditional models interpret the loss of radiogenic Argon due to an increase of temperatures. Hyodo (2017) proposed a new approach investigating the relaxation time and temperature relation within an “unclosure temperature” model. This model regards duration of a heating event as time for relaxation in a diffusion system at specific temperature. The model applies a functional form of mathematical approximation on fractional loss by diffusion. It allows fractional loss of certain amount of radiogenic 40Ar as long as the step heating model spectra in 40Ar-39Ar dating (plateau) maintains its original age within its age error. This new model approach is compared to a classical heating diffusion model (Huon et al., 1993) focusing on clay minerals (<10 and <2 μm) and larger muscovite grains (200 and 100 μm). The classical diffusion heating models applies three main parameters comprising a. grainsize (μm), b. temperature range (°C) and c. time scale (Ma). The obtained results provide a unique insight to compare an active heating versus passive cooling time and temperature path of clay minerals and muscovite with applications for general earth sciences and economic geology such as hydrocarbon exploration.

# $^{4}$He/U-Th dating of pore waters from Quaternary sediments in Switzerland: potential and challenges

*Yama Tomonaga[1], Edith Horstmann[1], Gaudenz Deplazes[2], Rolf Kipfer[1]

1. Swiss Federal Institute of Aquatic Science and Technology (Eawag), 2. National Cooperative for the Disposal of Radioactive Waste (Nagra)

Dating based on the $^{4}$He/U-Th method is used to estimate the residence time of pore waters in very low-permeable rocks and consolidated sediments. The residence time is inferred from the time necessary to accumulate radiogenic $^{4}$He measured in the pore water being produced by the decay of U and Th in the sediment matrix [1].
In the Jurassic Opalinus Clay, the pore water still contains remnants of the original marine formation water that was entrapped during sediment deposition. The pore water composition was altered only by diffusive processes [2,3]. The fact that even ~100-Ma-old water signatures can be preserved in their original pore space suggests that such preservation might also be possible in much younger dense glacial deposits. The $^{4}$He concentrations measured in the pore waters of glacial tills were translated into mean residence times of 15-25 kyrs [4] that agree rather well with the expected depositional ages of 25-31 kyrs [5]. These observations, as well as evidence from lacustrine sediments [6,7], suggest that, if the solute transport in the pore space is sufficiently attenuated, even unconsolidated sediments can "store" and host "old" pore waters.
In the present work we investigate if the $^{4}$He/U-Th dating of pore waters can be used as a novel tool to complement the luminescence dating of unconsolidated Quaternary sediments. We applied the $^{4}$He/U-Th method to date pore waters in the time range of 10 to 100 thousands of years which covers the age range of the sedimentary depositions targeted by the Quaternary drillings (QBOs) managed by the National Cooperative for the Disposal of Radioactive Waste (Nagra) in Switzerland. In particular, we focus on fine-grained lacustrine sediment layers that might provide low-permeability conditions suitable for the preservation of radiogenic $^{4}$He concentrations in the pore space.
We report the preliminary results of the $^{4}$He/U-Th dating based on the measurements conducted in sediment samples from the first QBOs, highlighting potential and challenges of the method with respect to the studied glaciofluvial sediments of the Swiss Midland.

# Compound-specific radiocarbon analysis of lipid biomarkers in surface sediment from Lake Kawaguchi, central Japan

*Shinya Yamamoto[1], Yosuke Miyairi[2], Yusuke Yokoyama[2], Hisami Suga[3], Nanako O. Ogawa[3], Naohiko Ohkouchi[3]

1. Mount Fuji Research Institute, Yamanashi Prefectural Government, 2. Atmosphere and Ocean Research Institute, The University of Tokyo, 3. Japan Agency for Marine-Earth Science and Technology

Lake sediment in volcanic regions contains valuable information on past eruptive history, as well as environmental consequences that took place in the catchment along with volcanisms. In this study, we performed compound-specific radiocarbon analysis (CSRA) of lipid biomarkers in surface sediment from Lake Kawaguchi situated northern proximal to Mount Fuji, central Japan, including short-chain ($C_{16}$) and long-chain ($C_{24}$, $C_{26}$ and $C_{28}$) fatty acids. The results are compared with the $^{14}C$ content of TOC, plant macrofossils (plant leaf and wood) and lake surface water in order to access their potential for dating tool in the lake sediment. The $^{14}C$ concentration of the long-chain ($C_{24}$, $C_{26}$ and $C_{28}$) fatty acids ranged from −43 to −183‰, corresponding to $^{14}C$ ages between 288 to 1554 years BP. This indicates that these acids contain substantial pre-aged materials in addition to those emitted from contemporary plant leaf waxes. In contrast, the short-chain ($C_{16}$) fatty acids showed a good agreement with the $^{14}C$ concentration of lake surface water, suggesting that they are most likely derived from primary producers (diatom) in the present lake and have a potential to improve chronologies in the sedimentary sequence in which the occurrence of fossil leaves is rather limited.

Dynamics of interaction between lithosphere and asthenosphere in their boundary zones (LABZ) plays an important role in transferring heat, material, and momentum from the earth’ s interior to the surface. Orogenic peridotites provide direct and high-resolution information for better understanding mantle processes taking place in the boundary zone. However, their exhumation obscure the information on dynamics operating in LABZ, while they could be driven and affected by processes taking place in and beneath the LABZ. This issue leads to ambiguity in the link between magmatism, relevant to whole-rock chemical characteristics, and exhumation of peridotite complexes, relevant to deformation and subsolidus reactions. Bodinier et al. (2008) actually pointed out two possible formation scenarios for plagioclase peridotites in orogenic peridotite complexes: subsolidus reaction from spinel peridotites and open magmatic processes in the plagioclase peridotite facies in the shallow mantle. In the context of lithosphere-asthenosphere interaction, it is crucial to discriminate these two possibilities. Spatial and temporal changes of pressure and temperature within an orogenic peridotite complex can be used to better constrain its history of decompression and magmatism. By exploiting the advantage of size of orogenic peridotite complexes, these data may provide valuable constraints on the LABZ dynamics.

Here, we examine internal variations of thermal and decompression history of three orogenic peridotite complexes: Ronda, Pyrénées, and Horoman. They exhibit diverse geological and petrologic characteristics providing an excellent chance of comparative study. The common feature of these orogenic peridotites is decompression from the garnet peridotite facies deeper than ~50km. In this study, we focus on garnet-related reaction microstructures, which are powerful tools to resolve pressure-temperature history because of their high hysteresis as compared with suppressed hysteresis of chemical zoning in minerals. Garnet and its breakdown products show contrasting features among the three. (1) Garnet was completely decomposed in both peridotite and pyroxenite lithologies in Horoman with formation of symplectite in slightly depleted peridotites; garnet rarely remains in both peridotite and pyroxenite lithologies with extensive formation of symplectite and kelyphite in Ronda; and garnet is completely decomposed into two-pyroxene spinel symplectite in peridotites but well preserved with partial formation of kelyphite rim and veinlets in pyroxenites in Pyrénées. (2) Coarse-grained granular olivine-plagioclase assemblage in both fertile peridotite and pyroxenites is common in Horoman; formation of olivine-plagioclase assemblage forming fine-grained intergrowth in fertile peridotites and pyroxenites is common with its extent being spatially variable in Ronda; and formation of olivine-plagioclase assemblage rarely in pyroxenites and very rarely in fertile peridotites in Pyrénées. These contrasts suggest: (1) high-temperature decompression path all through its ascent in Horoman; (2) low-temperature in deeper levels but relatively high-temperature decompression path in shallower levels in Ronda; and (3) high-temperature decompression path in deeper levels followed by rapid cooling in shallower levels in Pyrénées. Combined with pressure-temperature path deduced from chemical zoning and microstructure related to exsolution and dissolution in pyroxenes, we propose that the shallow high-temperature decompression of Ronda was caused by heating in the plagioclase peridotite facies and that the

©2019. Japan Geoscience Union. All Right Reserved. 

high-temperature decompression of Horoman by heating over a wide depth range deeper than the plagioclase peridotite facies. Pyrénées is probably intermediate of these two cases. The contrasting modes of thermal perturbation may imply different mechanisms of lithosphere-asthenosphere interaction, such as active upwelling vs. passive upwelling.

# Hydration and Ca-metasomatism in Mantle Wedge: An evidence from the Alag Khadny Accretionary Wedge, Western Mongolia

*OTGONBAYAR DANDAR[1], Atsushi Okamoto[1], Masaoki Uno[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University

Hydration and metasomatic reactions of mantle wedge play important roles on global material circulation and changes in physical properties along the plate interface within the subduction zone. Metasomatism is caused by specific components of fluids such as silica; however, our understanding on the relationship between hydration and metasomatism in mantle wedge is still limited. In this study, we report outstanding alteration textures of orthopyroxene as an evidence for significant Ca metasomatism within the mantle wedge, and its relation to the hydration processes.

The Alag Khadny accretionary wedge is located in the Chandman area, western Mongolia, Central Asian Orogenic Belt. The accretionary wedge is subdivided into northern and southern belts. The northern belt is consisted of orthogneiss bodies with layers of mica schists and paragneisses, including amphibolized eclogite, marble, and serpentinite bodies. The southern belt is composed mainly of serpentinized peridotite with minor ophicarbonates and limestone layer including lenses of epidote amphibolites. The ultramafic body mainly consists of harzburgite and lherzolite with minor dunite and its origin is interpreted as mantle wedge.

We collected 17 samples from the ultramafic body in southern belt of the Alag Khadny accretionary wedge in the Chandman area. The peridotites contain primary olivine (Ol), orthopyroxene (Opx), clinopyroxene (Cpx), and spinel. The peridotites were suffered from various extents of metasomatism and hydration. P-Olivine was replaced by antigorite with various extent, whereas primary Cpx was preserved without reactions. One of the notable features that is common in the peridotite is intense replacement of orthopyroxene (>60 vol.% was replaced). The mineralogy of the orthopyroxene replacement is divided into three types: secondary Cpx (S-Cpx) + tremolite (Tr), S-Cpx + tremolite (Tr) + S-olivine, S-Cpx. S-olivine shows lower Mg# (0.85-0.91) than the primary ones (Mg#=0.90-0.91), and S-Cpx shows the lower Al content and higher Mg# than the primary Cpx. Mass-balance calculation for the Opx pseudomorph showed the gains of Ca and water, and losses of silica, Mg and Fe. Due to the lack of Ca source in the primary minerals, significant amount of Ca metasomatism occurred induced by infiltration of the external fluids. The products of Ca metasomatism (S-Cpx, Tr) are commonly cut by antigorite veins, indicating that main hydration (antigorite formation) occurred after Ca metasomatism. The stability field of mineral assemblage of the Opx replacement was consistent with the P-T conditions of eclogite bodies in the Chandman area (T= 590-630 ˚C and P=11-16 kbar), implying that the hydration and metasomatism were caused by mantle wedge due to a supply of fluids derived from dehydration of the subducting slab.

Distinguishing serpentine minerals antigorite, chrysotile and lizardite from a thin section can be challenging due to the similarity of their optical properties and chemical composition. Infrared spectroscopy (IR) is a method based on the characteristic absorption of infrared radiation by different chemical bonds. Since each serpentine mineral has a distinct crystal structure, infrared spectroscopy can be applied in serpentine mineral identification. Infrared radiation is also particularly strong in polar bonds making IR spectroscopy a powerful tool in studying serpentine mineral hydroxyl groups. Transmission infrared spectroscopy is the most widely used IR method but it requires time-consuming and arduous sample preparation. Using a newer method known as attenuated total reflection infrared spectroscopy (ATR-IR) can significantly reduce the sample preparation time since the measurements can be made directly from the surface of a normal thin section.

We applied the ATR-IR method to characterize antigorite, chrysotile and lizardite from samples from Mt. Shiraga serpentinite body, located in central Shikoku, SW Japan. The ATR-IR method proved to be a reliable and simple method to measure the infrared spectrum of serpentine minerals as there were clear differences in the absorbance band positions of the three serpentine minerals. However, we observed notable differences in the absorbance band positions and absorbance intensities of serpentine minerals between the ATR-IR measurements and transmission IR measurements published in previous studies. These results reflect the fact that the ATR-IR method is susceptible to spectral distortions that are caused by the dependence of absorbance intensity to wavelength and by anomalous dispersion of infrared radiation. On the other hand, spectral mapping is much more convenient in the ATR-IR method as measurements can be done from normal thin sections. We also used the ATR-IR method to map a sample with three co-existing serpentine minerals with interesting reaction textures.

ATR-IR spectroscopy, and especially ATR-IR mapping, has a lot of potential in the field of mineral spectroscopy and it could be applied in the study of a wide variety of serpentinite microstructures, such as veining and faulting. One possible research avenue would be to combine ATR-IR mapping of serpentinite microstructures to quantitative analysis of serpentine mineral hydroxyl group absorbance intensities.

# Fabric and petrological characteristics of sheared peridotites in Marion transform fault, Southwest Indian Ridge

*Kakihata Yuki[1], Katsuyoshi Michibayashi[2], Henry Dick[3]

1. Shizuoka University Graduate School of Science, 2. Nagoya University Graduate School of Environmental Studies, 3. Woods Hole Oceanographic Institution

The ultraslow spreading (14 mm/yr) Southwest Indian Ridge (SWIR) lies between the Bouvet and Rodriguez Triple Junctions. The SWIR is volcanically inactive, possibly reflecting poor advection of heat and intensive conductive cooling. Accordingly, there are only partly thin basaltic crusts, and peridotites exposed to the sea floor. Dredge surveys have been performed along the SWIR, and basalt, gabbro and peridotite specimens have been derived since 1980s.

In this study, we studied the microstructural development of 7 peridotite samples obtained from Marion Fracture Zone of the SWIR by the PROTEA cruise Leg.5 in 1983. The peridotites consisted of olivine, orthopyroxene and clinopyroxene with amphibole, plagioclase and chlorite, as well as secondary minerals such as serpentine and magnetite. The peridotites were classified into two groups based on their microstructures: 2 ultramylonites consisting of extremely fine grains (3-5 $\mu$m) with several porphyroclasts (~15 $\mu$m) and 5 heterogeneous tectonites consisting of deformed coarse-granular textures with subsequently developed fine-grained textures. In both types of peridotites, some of olivine grains had subgrain boundaries, whereas phase mixing occurred. These textural features suggest that heterogeneous textures of tectonites had been developed as lowering temperature and decreasing grain size, and subsequently became to ultramylonites.

Major element compositions of olivine and spinel indicated that these peridotites had fertile to moderately depleted mantle composition. Amphibole grains have the chemical compositions of tremolite, magnesio-hornblende and pargasite.

The ultramylonites have intensely deformed amphibole grains, whereas the heterogeneous tectonites have amphibole ranging from undeformed to highly deformed grains, indicating that amphibole formed before and/or during intensive shearing in the mantle. Moreover, olivine crystal-fabrics within the deformed amphibole bearing peridotites have B and E types developed under hydrous conditions. Consequently, the petrophysical characteristics of peridotites indicate that the uppermost mantle below the Marion transform fault has been hydrated during shearing.

Fine olivine grains in heterogeneous tectonites showed weak crystallographic preferred orientation (CPO) patterns. In contrast, those in the ultramylonites exhibited strongly concentrated CPOs. Furthermore, olivine grains were distorted more strongly in the ultramylonites than in the tectonites. These textural characteristics imply that fine-grained textures within the tectonites were deformed by mainly grain boundary sliding/diffusion creep under relatively low differential stress, whereas the ultramylonites were mainly deformed by dislocation creep under high differential stress.

# Structure and formation mechanism of lithosphere-asthenosphere boundary decoded from Ichinomegata peridotite xenoliths

*Yuto Sato[1], Kazuhito Ozawa[1]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

Lithosphere-asthenosphere boundary (LAB) is one of the largest discontinuities in mantle where heat transfer mechanisms change from conduction to convection (Sleep, 2005, 2006). Various formation mechanisms of LAB have been proposed and still controversial (Green et al., 2010; Hirschmann, 2010; Hirth & Kohlstedt, 1996; Karato, 2010, 2012; O' Reilly & Griffin, 2006). Mantle xenoliths are fragments of mantle material (Nixon, 1987) and could have derived from the LAB zone and are useful to reconstruct its internal structure and to understand the ultimate cause of LAB zone and dynamic processes operated there. We have examined spinel peridotite xenoliths from Ichinomegata maar located in the back-arc side of NE Japan to address this issue (Sato & Ozawa, submitting to Ame. Min.; Sato & Ozawa, 2017, 2018, JpGU meeting; Sato & Ozawa, 2016, 2017, AGU fall meeting). We succeeded in reconstructing the structures and clarifying the formation mechanism of the LAB zone beneath Ichinomegata.

Ichinomegata maar is a latest Pleistocene andesitic-dacitic volcano yielding spinel peridotite xenoliths (Katsui et al., 1979). Diversities of thermal, chemical, rheological, and petrological features of the xenoliths have been documented by previous studies (e.g., Kuno, 1967; Kuno & Aoki, 1970; Takahashi 1980, 1986; Koyaguchi, 1986; Tanaka & Aoki, 1981; Abe et al., 1992, 1998; Abe & Yamamoto, 1999; Satsukawa & Michibayashi, 2014; Satsukawa et al., 2017). Despite the numerous data, the derivation depths of the xenoliths have never been seriously examined. We devoted our effort to geothermobarometry of spinel peridotite xenoliths, and successfully estimated derivation pressures and temperatures ranging 0.7-1.6 GPa and 828-1081 ˚C for 8 of the 9 examined xenoliths by examining the time scale of development of every chemical zoning to identify minerals, mineral portions, and chemical species attaining equilibrium as close as possible just before the xenolith extraction.

Various depth variations were clarified. The shallow mantle, ranging from 28 to 32 km, is characterized by low temperature, granular, and plagioclase- and amphibole-bearing mantle, and the deep mantle, from 41 to 55 km, by high temperature, porphyroclastic, and plagioclase- and amphibole-free and melt-bearing mantle. It is notable that the sample-derived solidus condition coincides with the depth of change of deformation microstructures. This indicates that the wet solidus controls rheological LAB zone beneath Ichinomegata. We infer that the shallow zone corresponds to lithospheric mantle and the deep zone to LAB zone.

Intimate correlations between the depth variations of absence or presence of plagioclase and amphibole and geochemical data obtained by previous studies (e.g., Tanaka & Aoki, 1981; Abe et al., 1998) enable us to reconstruct geochemical depth variation; clinopyroxene and whole-rock of plagioclase- and amphibole-bearing shallower peridotites are characterized by light rare earth element (LREE) depleted patterns, low $^{87}Sr/^{86}Sr$ ratios (~0.7027-0.7030), and high $^{143}Nd/^{144}Nd$ ratios (~0.5133-0.5134); in contrast, those of plagioclase- and amphibole-free and melt-bearing deeper peridotites by LREE enriched patterns, high $^{87}Sr/^{86}Sr$ ratios (~0.7033-0.7047), and low $^{143}Nd/^{144}Nd$ ratios (~0.5125-0.5130).

Previous studies attributed geochemical diversity to local magma-related processes beneath MOHO (e.g., Takahashi, 1980; Abe et al., 1992). However, the systematic depth variations of geochemistry indicate a

©2019. Japan Geoscience Union. All Right Reserved. 

larger-scale stratification of the upper mantle beneath Ichinomegata. We infer that the shallower geochemically depleted mantle represents oceanic lithosphere formed during Japan Sea opening and that the deeper enriched mantle represents LAB zone which formed recently through lithosphere thinning by asthenospheric upwelling. A similar scenario was proposed by Ohki et al. (1994) on the basis of temporal variations of Nd-Sr isotopes from Middle Miocene.

# Metasomatic banding and deformation instability in the metamorphic rocks

*mitsuhiro toriumi[1]

1. Japan agency of marine science and technology

Low grade metamorphic rocks formed in the plate boundary commonly show mineral bands composed of albite, amphiboles, chlorite and epidote in basic schists, and of chlorite, albite and quartz in pelitic schists. These bands are almost monomineralic and bimineralic and parallel to subparallel against schistosity plane. Judging from the orientation of bands nearly normal to the maximum stress direction, it seems that the banding is derived from compaction banding/porosity banding induced from the non-linearity of microcrack plasticity (Toriumi and Hara, 1995), elastic modulus (Fortin et al., 2009) and preferred orientation growth of chlorite and actinolite.
In this model, the low grade metamorphic rocks deform accompanied with progressive banding of low porosity and with migration of water vertical to the banding, and it induces stability change of solution and metamorphic minerals. Chlorite may favor the compaction bands but albite does porous bands. This type of yielding shoud lower the yield stress and then the deformation instability may occur in the metasomatic process in the plate boundary rocks.

## [S-VC34] Connecting magma dynamics in vent-conduit system with surface expression of volcanic eruption

convener:Takahiro Miwa(National research institute for earth science and disaster prevention), Nobuo Geshi(Geological Survey of Japan, The National Institute of Advanced Industrial Science and Technology), Chairperson:Takahiro Miwa, Jacopo Taddeucci

Magma dynamics within a shallow conduit system control the diversity of behavior of volcanic eruptions. Recent advancements in geophysical, airborne and ground-based observation techniques provide quantitative data about the dynamic behavior of volcanic eruptions. New analytical methods of the macro and microtextures of eruptive products also open new insights on detailed dynamics of magmas within conduit. The aim of this session is the integration of these new techniques to approach the dynamics of magma ascending from a shallow part of conduit to vent. This session seeks submissions that explore magma dynamics controlling the behaviors of volcanic eruption by integrated investigation of 1) degassing, outgassing, crystallization, and fragmentation of ascending magma, 2) emission and recycling of eruptive product, and 3) morphological characterization of the vent-conduit system. We encourage contributions based on textural-petrological analyses of eruptive product, experimental study reproducing magma in the conduit, geophysical observation on surface expression of volcanic eruption, and related numerical modeling.

In recent years, mitigating the impact of volcanic ash emissions has risen up political and research agendas. Despite intense research efforts, challenges remain as to the detection and forecasting of emissions, and subsequent interactions in the earth system. Monitoring instruments and ash dispersal models usually require the input of volcanic ash properties in order to operate effectively, however forensic methods are poorly suited to volcanic eruptions where near-real-time data is required, and default values are commonly used. Here, we take an experimental approach to demonstrate that the surface composition and the initial size and shape distribution of volcanic ash particles depends upon (i) the initial rock texture, chemistry and mineralogy and (ii) the fragmentation processes that produced the particles.

We compare natural pyroclasts produced during recent eruptive activity at Volcán de Colima, Mt Etna, Santiaguito, Mt Agung and Tungurahua, with particles produced in fragmentation experiments using fresh rock samples from Volcán de Colima and Mt Etna. Sets of experiments were conducted under varying conditions in shock tube, tumbling and fault friction apparatuses to simulate natural eruption processes. Using QEMSCAN, an SEM-based automated mineralogy technique, we produce micron-scale maps showing the size, shape and phase distribution of thousands of ash particles in each sample. We measure particle size-, shape- and phase distribution in each sample and show that particle sizes and shapes show characteristic variation between different experimental methods and eruptive activity. Some phases, particularly groundmass glass (or tachylite), feldspars and pyroxenes are found to vary significantly at particles boundaries compared to the bulk. The pattern of enrichment and depletion of phases is shown to relate to the fragmentation mechanism and the rock texture at the macro- and micro-scale, and correlations between experimental and natural samples indicate a robust signal.

Volcanic ash presents unique hazards to aviation, health and the environment and better constraints on ash particle properties immediately following activity may improve estimations of the intensity and spatial extent of ash-related hazards. Our results may benefit local hazard management, monitoring and forecasting efforts at the case study volcanoes.

# Vapor transport in shallow intruded magmas: insights from diktytaxitic texture

*Ryosuke Sakurai[1], Michihiko Nakamura[2], Satoshi Okumura[2], Mayumi Mujin[2], Takayuki Nakatani[2]

1. Division of Earth and Planetary Materials Science, Faculty of Science, Tohoku University, 2. Division of Earth and Planetary Materials Science, Department of Earth Science, Graduate School of Science, Tohoku University

Volcanic ashes from Vulcanian explosions derived from shallow-intruded magmas and dome lavas often include microporous and glass-free groundmass in which lath-shaped plagioclase microlites form angular voids. Such texture, generally described as diktytaxitic texture, is known to control the permeability of bulk rock significantly when the connected porosity of bubbles and cracks is small (Kushnir et al., 2016). How and under what conditions diktytaxitic texture is formed is, however, not precisely known. In this study we simulated the formation of diktytaxitic groundmass through a series of isobaric-isothermal (IBIT) crystallization experiments in order to clarify its formation kinetics. As a result, diktytaxitic texture was formed at 850 and 900℃ and at 10 and 20 MPa, and almost entire groundmass became diktytaxitic (i.e. glass-free) in the experiment kept at 850℃ and 20 MPa for 189 h. At 850℃ and 10 MPa for >24 h, interstitial melt completely disappeared to form the groundmass composed of feldspar microlites with angular voids. Cristobalite crystals were found in the groundmass and on the interior walls of capsules. The glass compositions form liner trends between the plagioclase microlites and the precipitated silica on the $SiO_2$-$Al_2O_3$ diagram. These observations indicate that evaporation of $SiO_2$-rich melt and condensation of cristobalite are the dominant process for the formation of microporous groundmass characteristic of dixtytaxitic texture. The wide range of $K_2O$ contents in the glass can be explained as a result of vapor-phase growth of ~10 $\mu$m K-feldspar microlites in the diktytaxitic groundmass. Hence, we conclude that diktytaxitic texture is formed through (1) enrichment of silicon and potassium in the melt by microlite crystallization, (2) evaporation of $SiO_2$-rich constituents from the melt accompanied by breakage of Si-O covalent bond, and (3) precipitation of cristobalite and K-feldspar from vapor. The present study indicates that the late stage magma crystallization in shallow intrusions and lava domes proceeds dominantly through a vapor phase.

# First observation of nanolites and ultrananolites in alkaline volcanic glasses (Eifel, Germany)

*Marija Putak Juricek[1], Michihiko Nakamura[2], Mayumi Mujin[2], Hans-Ulrich Schmincke[3], Mari Sumita[3], Nobuyoshi Miyajima[1]

1. BGI, 2. Tohoku Univ., 3. GEOMAR

Nanolites are the smallest, less than <1 μm wide, crystals observed in groundmass of volcanic rocks. They are believed to be the last solid phases that crystallize from the melt during eruptions. Understanding mechanisms of nucleation and subsequent growth of nanolites could potentially provide information about the physiochemical conditions of magma just prior to eruption.

Since nanolite studies are scarce in literature and experimental observation of crystal nucleation and growth is challenging, few constraints on kinetics of nanolite crystallization are available at present. Furthermore, previous studies have investigated nanolites from exclusively calc-alkaline volcanic products. Since melt composition may have a significant effect on crystal nucleation and growth, detailed and systematic descriptions of nanolites occurring in eruptive products of different magma series are required.

The purpose of this study is to present a preliminary overview of nanolite nucleation and growth mechanisms in alkaline melts. Due to high concentrations of network modifying Na and K atoms and considerable volatile budgets, alkaline magmas have very low viscosities. As chemical diffusion is highly dependent on viscosity, nucleation and growth of nanolites in alkaline melts may be governed by different mechanisms from those observed in previous studies.

Variously differentiated samples produced by different eruption styles were collected from West and East Eifel Volcanic Fields (Germany). Samples were observed using a combination of polarized microscopy, FE-SEM and TEM.

Preliminary observation suggests that average nanolite nucleation density in mafic and ultramafic Eifel samples is noticeably higher in comparison to calc-alkaline rocks. In general, nanolites in alkaline eruptive products display a wide range of morphologies with a tendency towards acicular and dendritic habits. Examples of both homogeneous and heterogeneous nucleation were observed. The most abundant phase in the nanolite population of mafic and ultramafic samples is magnetite. The only highly differentiated sample, a phonolitic glass, contained very few nanolites.

In a recently published experimental study it was suggested that precipitation of magnetite nano-crystals may increase magma viscosity by modifying the melt composition. Considering the abundance of magnetite nanolites in Eifel scoria fragments, these magmas may have experienced a severe viscosity increase at shallow crustal levels. We suspect that the presence of extensive interconnected networks of acicular and dendritic magnetite nanolites may have mechanically impeded magma flow as well, contributing to the explosive nature of Eifel eruptions that was previously attributed to magma-water mixing.

# Textural Study of Pumice Clasts from The Youngest Toba Tuff Eruption

*Gabriela Nogo Retnaningtyas Bunga Naen[1], Atsushi Toramaru[1], Tomoharu Miyamoto[1], Haryo Edi Wibowo[2]

1. Department Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, Nishiku, 744, Motooka, Fukuoka, 819-0395, Japan, 2. Geological Engineering Department, Universitas Gadjah Mada, 55284, Yogyakarta, Indonesia

Toba Caldera Complex, North Sumatra, Indonesia is well known as the largest Quaternary caldera (87×33 km) that formed by four major eruptions with magnitude of VEI 8 among which the biggest one is the latest eruption of the Youngest Toba Tuff (YTT) about 74,000 years ago. The conduit dynamics of Toba caldera forming eruption is still poorly understood. Bubbles in pumice, which are produced by an explosive eruption possibly record dynamic processes in the conduit during eruption. This textural study aims to estimate the decompression rate of the biggest event of Toba eruption (YTT) by using textural data from Bubble Number Density (BND) together with geochemical, petrographical, grain size distribution (GSD), and bulk density data. In general, only a few data of decompression rate from caldera forming eruption events are available because the products were mostly welded and the original texture has been erased. Meanwhile, Toba eruption produced non-welded to welded deposit. Therefore, we focus on the nonwelded part of the biggest Quaternary caldera forming eruption localized on the northern part of the caldera in order to extract the original condition of the bubble formation. Samples from three different locations were employed for the analyses. Whole rock geochemical data of pumices were obtained by XRF. Petrography analysis for 21 thin sections were conducted using optical microscope. Bulk density measurement for 338 individual pumices with the size range of 4-8 mm and 8-16 mm were conducted using Laser 3D scanner. Textural analysis was carried out for 6 particles of 3 selected thin sections using microphotographs taken by SEM and further analyzed using image processing software. Geochemical data showed that the YTT magma is rhyodacitic to rhyolitic in whole rock compositions with the narrow range of $SiO_2$ (69.15 - 72.17 wt. %). Phenocrysts are plagioclase, biotite, quartz, and sanidine, most of which are fractured. The vesicle has a variety in size from 2.5 $\mu$m to 97 $\mu$m and in shape from rounded, elongated, to complex. GSD for each location are dominated by fine size (phi=1). Bulk density of individual pumice ranges from 0.4 to 1.1 $gcm^{-3}$. BND calculation were done in carefully selected area where is uniform in size of bubbles to represent samples in estimating the decompression rate in the conduit. BND value ranges from $10^5$ - $10^7$ $mm^{-3}$ showing a wide range of BND magnitude. Qualitatively, higher magnitude of BND is correlated with higher silica content, higher frequency of crystal fracture, complex vesicle shape, smaller vesicle size, and lower bulk density, and vice versa . The decompression rate was calculated using the BND decompression rate meter from Toramaru (2006). The result showed that Toba caldera forming eruption has high decompression rate ranging from $10^7$ –$10^8$ Pa/s. Those fact shows that Toba experienced with rapid decrease of pressure in the conduit. Moreover, this idea could be an important factor to reveals the conduit dynamic system of YTT super eruption.

# Oomurodashi volcano: Past effusive and phreatomagmatic activity revealed by submarine and subaerial deposits

*Iona McIntosh[1], Kenichiro Tani[2], Alexander Nichols[3], Qing Chang[1], Jun-Ichi Kimura[1]

1. Japan Agency for Marine-Earth Science and Technology, Yokosuka, 2. National Museum of Nature and Science, Tsukuba, 3. University of Canterbury, Christchurch, New Zealand

Oomurodashi is a recently discovered active, shallow (~140 mbsl), silicic submarine volcano in the northern Izu-Bonin arc, only 60 km from the entrance to Tokyo Bay. Past activity at Oomurodashi spans a wide range of eruption styles and includes small lava effusions, submarine pumice, and subaerial tephra deposits on nearby Izu-Oshima and Toshima islands. Here we present volatile and textural data that reveal contrasting degassing, quench and fragmentation processes occurring in the shallow conduit and overlying water column.

$H_2O$ data for pumiceous pyroclasts and lavas were obtained using new Fourier Transform Infrared spectroscopy (FTIR) analytical techniques for vesicular and hydrated glasses. Although the Oomurodashi glasses are extensively hydrated, the interconversion of $H_2O$ species (i.e. molecular water, $H_2O_m$, and hydroxyl groups, OH) stops at the glass transition temperature, and low temperature hydration occurs via diffusive addition of $H_2O_m$ only, leaving OH contents unchanged. OH data can therefore be interpreted according to the known pressure-dependence of $H_2O$ solubility and temperature dependence of $H_2O$ speciation.

Pumice clasts within the subaerial tephra layer have OH contents that are consistent with quench fragmentation at depths of ~60 –150 m depth within the shallow edifice. Moreover, the majority of this tephra deposit consists of ‘mosslike’ particles formed by annealing of extremely fine-grained material, which are typically formed by explosive phreatomagmatic activity. We therefore propose that this tephra represents the distal deposits from the explosive formation of the shallow (~100 m depth) summit crater by a shallow submarine, phreatomagmatic maar-type eruption.

By contrast, two in situ submarine lavas have lower OH contents than expected for their current water depths. Comparison with past sea level variation suggests that these effusive eruptions occurred at ~8-9 and ~12 ka during times of lower sea level. Loose submarine pumice also sampled from the edifice has a range of OH contents and vesicularities, reflecting different quench depths and dispersal histories within the water column.

# Mechanism of volatile transport from mafic to silicic magma upon mixing

*Shumpei Yoshimura[1], Akiko Matsumoto[1], Mitsuhiro Nakagawa[1]

1. Department of Earth and Planetary Sciences, Hokkaido University

Introduction
Deep-derived, high-temperature mafic magma often injects into shallow-stored, low-temperature silicic magma, producing either well-mixed intermediate magma or mafic enclaves floating in host magma. Volatile transport from mafic to silicic magma accompanies magma mixing, and it may control volcanic activity (e.g., Roberge et al., 2009). However, the detailed mechanism of such volatile transport is unclear. In this study, we investigated how the gas was generated in mafic magma and transported to the silicic magma based on S and Cl analysis of Atchiyama rhyolitic lava that contains abundant basaltic enclaves.

Method
We observed Atchiyama biotite-rhyolite lava that erupted 1600 BP in Niijima Island (Isshiki, 1997), and analysed compositions of host rhyolite and basaltic enclaves. Cl mapping analysis was also performed on the area of enclave-host boundary to track the volatile transfer paths.

Results and discussion
Basaltic enclaves exhibited fine-grained groundmass composed of dendritic crystals, rhyolitic interstitial melt, and bubbles. The interstitial melt, which was compositionally distinguishable from the host rhyolite, was S-free (<50 ppm) and Cl-rich (1200 ppm). Melt inclusion analysis showed that the initial basaltic melt before mixing was S-rich (~4000 ppm) and Cl-poor (~430 ppm). These observations indicate that the basaltic magma cooled and crystallised rapidly upon injection, and the interstitial rhyolitic melt was produced as a result of crystallisation fractionation. Crystallisation-induced vesiculation (second boiling) occurred and S degassed completely, while Cl was concentrated in the interstitial melt.
Groundmass glass of host rhyolite was S-free and Cl-poor (~800 ppm). However, Cl mapping analysis revealed that the Cl content increased to 1200 ppm near the enclave margin. In addition, finger-like veins containing vapour-phase crystals developed from the enclave to far afield in host rhyolite, and the Cl content was also high near such veins. All these observations indicate that S- and Cl-rich gas was generated in crystallising enclave, and it was transported to the host rhyolitic magma via gas flow and diffusion.

## [S-VC34] Connecting magma dynamics in vent-conduit system with surface expression of volcanic eruption

convener:Takahiro Miwa(National research institute for earth science and disaster prevention), Nobuo Geshi(Geological Survey of Japan, The National Institute of Advanced Industrial Science and Technology), Chairperson:Nobuo Geshi(GSJ/AIST), Adrian Hornby(Ludwig-Maximilians-University Munich)

Magma dynamics within a shallow conduit system control the diversity of behavior of volcanic eruptions. Recent advancements in geophysical, airborne and ground-based observation techniques provide quantitative data about the dynamic behavior of volcanic eruptions. New analytical methods of the macro and microtextures of eruptive products also open new insights on detailed dynamics of magmas within conduit. The aim of this session is the integration of these new techniques to approach the dynamics of magma ascending from a shallow part of conduit to vent. This session seeks submissions that explore magma dynamics controlling the behaviors of volcanic eruption by integrated investigation of 1) degassing, outgassing, crystallization, and fragmentation of ascending magma, 2) emission and recycling of eruptive product, and 3) morphological characterization of the vent-conduit system. We encourage contributions based on textural-petrological analyses of eruptive product, experimental study reproducing magma in the conduit, geophysical observation on surface expression of volcanic eruption, and related numerical modeling.

# The in-flight grain size distribution of lapilli and bombs from Strombolian explosions

*Jacopo Taddeucci[1], Piergiorgio Scarlato[1], Elisabetta Del Bello[1], Tullio Ricci[1], Ulrich Kueppers[2], Bruce Houghton[3]

1. Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy, 2. Department of Earth and Environmental Sciences. Ludwig-Maximilians-Universität (LMU). Munich, Germany, 3. Department of Earth Sciences, University of Hawai ʻi at Mānoa, Honolulu, USA

Grain size distribution is one of the fundamental physical parameters of pyroclastic deposits, key to understanding both magma fragmentation and tephra emplacement processes during an explosive eruption. Most commonly, the grain size distribution of pyroclasts from one eruption is obtained from field sampling and analysis of the resulting tephra deposit; integration of multiple analyses gives a total grain size distribution. In this process it is often assumed that the grain size distribution of the deposit reflects that of the assemblage of pyroclasts that left the eruptive vent. However, observations suggest that multiple processes may act to change the size of erupted pyroclasts during their emplacement, so that the grain size distribution of a deposit may differ, to a variable degree, from that at the vent. Here, we use high-speed imaging to measure the in-flight grain size distribution of pyroclasts for the first tens of meters above an eruptive vent.

We focus on lapilli and bombs from Strombolian- explosions at Stromboli volcano (Italy) in September 2018. At that time, multiple, well-collimated jets with incandescent pyroclasts and no visible ash erupted from a vent about one meter in diameter and in plain view. The activity was recorded by using a high-speed camera filming with a temporal and spatial resolution of 500 frames per second and 0.012 m/pixel, respectively. The high-speed videos were pre-processed for background subtraction, then thresholded for gray level intensity, and finally the individual particles measured for their 2-D size and shape by using image processing. Particle velocity and size was also measured using particle tracking algorithms.

In a parametric study, the effect of different thresholding levels and frame sampling has been investigated. The results define the best parameters and the most effective truncation limits of the measured grain size distributions. Modal values of the grain size are broadly centered around the phi -4 to -5 size classes (16-32 mm) by particle number and the phi -5 to -6 size classes (32 to 64) by particle mass, respectively. The grain size distribution of erupted pyroclasts shifts considerably over time, with smaller clasts being ejected at the beginning of an explosion, and larger median diameters recorded at instants of higher pyroclast volume fluxes.

These results highlight the complexity and variability of the erupted size distributions at the vent, but also the need for a careful assessment of analytical error and methodological limitations.

# Pyrrotite oxidation as a proxy for air entrainment in eruption columns

*Keiko Matsumoto[1], Michihiko Nakamura[2]

1. Geological Survey of Japan, The National Institute of Advanced Industrial Science and Technology, 2. Faculty of Science, Tohoku University

Entrainment of air by turbulent mixing into eruption columns is a primary control of explosive eruption styles. Pyrrhotite (Po; $Fe_{1-x}S$) in erupted materials is oxidized to form magnetite (Mt) and hematite (Hm) at the oxygen fugacity ($fO_2$) on the Earth's surface and at magmatic temperature. Degree of Po breakdown has been proposed as a proxy for magma oxidation and cooling by entrained air through examination of the Plinian pumice and lavas from the 1914 eruption at Sakurajima volcano (VEI4). To verify and further investigate the potential use of Po oxidation for estimating eruption intensities from pyroclasts, we have examined the pumice clasts from three andesitic explosive eruptions with similar magmatic temperature and different eruption intensity: the 1783 Plinian eruption of the Asama volcano (VEI4), the 2011 sub-Plinian eruption of the Shinmoedake volcano (VEI2) and the 2010 Vulcanian explosion of the Sakurajima volcano (VEI1).

Mineral phases of magmatic sulfide and occurrence of pseudomorph (Mt and Hm) are different among the three eruption samples. Po is observed in the groundmass of the pumice from the Asama 1783 eruption and the Sakurajima 2010 eruption, whereas the sulfide in the Shinmoedake 2011 groundmass is intermediate solid solution (iss; $Cu_{1-x}Fe_{2+y}S_{2-z}$). Po is sometimes replaced to form pseudomorph, while iss shows no replacement. The porous texture of the Po pseudomorph, which indicates a reaction of Po with air, is similar to that observed for the oxidation product having columnar microstructure reported in the pumice from the Sakurajima 1914 eruption (Matsumoto and Nakamura, 2017). Approximately half of the Po grains are partly or entirely replaced by the pseudomorph in the Asama 1783 pumice, as observed in the Sakurajima 1914 samples. On the other hand, proportion of the pseudomorphic Po grains is less than 20% in the Sakurajima 2010 pumice. This difference indicates that the Asama 1783 pumice, together with the Sakurajima 1914 pumice, has been more efficiently oxidized than the Sakurajima 2010 pumice. The preservation of iss in the Shinmoedake 2011 pumice is probably due to the difference in oxidation mechanism between iss and Po. The efficient oxidation of Po during the two Plinian eruptions (i.e., the Asama 1783 and the Sakurajima 1914 eruptions) can be attributed to the longer duration in which temperature of pumice were kept high in the eruption columns than that in the Vulcanian column. These results underscore the potential use of Po oxidation for the purpose of constraining the temperature and $fO_2$ of eruption columns that reflect eruption intensity of explosive eruptions.

# Thermal signals in volcano monitoring: combining MODIS-MIROVA data with ground-based measurements at Aso Volcano, Japan

*Corrado CIGOLINI[1], Akihiko Yokoo[2], Diego Coppola[1], Marco Laiolo[1]

1. Department of Earth Sciences, University of Torino, Italy, 2. Aso Volcanological Laboratory, Institute for Geothermal Sciences, Kyoto University, Japan

Active volcanoes bearing crater lakes are rather challenging targets for thermal monitoring since their anomalies are rather small when compared to lava flows and/or domes. Thus, we have combined satellite data with ground-based measurements at Aso Volcano during its recent activity.
The thermal signals of Aso Volcano (Nakadake) during unrest episodes have been analyzed by means of the MODIS-MIROVA data set and high resolution images (LANDSAT 8 OLI and Sentinel 2) cross-checked with ground-based thermal observations. The Volcanic Radiative Power (VRP) detected by nighttime satellite data during the time span considered was mainly below 3 MW. This value is a thermal threshold that marks the transition from high fumarole activity (HFA) to Strombolian eruptions (SE). Periods with the occurrence of sporadic phreatic eruptions (PE, eventually bearing phreatomagmatic episodes), is the dominant phase during unrest episodes, with VRP values around 0.5 MW. However, during sustained Strombolian phases (November-December 2014) the radiative power was higher than 4 MW, reaching peak values up to 15.6 MW (on December 7, 2014, 10 days after the major Strombolian explosion of November 27). Ground-based measurements, recorded by FLIR T440 Thermo-camera on the fumarole field of the South Area, shows that the heat-flux stabilized around 2 MW until February 2015. Apparent temperatures measured on the fumarole field were around 490-575˚C before the major Strombolian explosive event, whereas those recorded at the active vent (Central Pit) reached their maxima around 600 ˚C. In the following days they both exhibited a decreasing trend. However, during the Strombolian phase the crater lake dried out and was then replenished by early July, 2016. Then volcanic activity shifted back to phreatic-phreatomagmatic and the eruptive cycle was completed; in this period ground measurements were fluctuating around 1 MW. Following the major phreatic explosion of October 8, 2016 satellite VRP were moderately above 2 MW and then progressively decreased. During 2018, they were essentially below 1 MW (with a mean of 0.75 Mw and few peaks above 1 MW).
We estimated the total amount of Magma Equivalent Volume (MEV) responsible for satellite thermal anomalies during the Strombolian phase (from the end of November 2014 to May 2015). The cumulative volume involved in this phase reached 4.5 x $10^5$ $m^3$, which is two order of magnitude lower than the total volume of magma undergoing degassing (estimated by means of the petrologic models based on $SO_2$ degassing). This indicates that thermal anomalies during the Strombolian phases detect the magma that is reaching the surface and through a feeder dike, or conduit, connected at depth with a major reservoir.

# Magma transfer processes in the NE Japan arc: insights from crustal ambient noise tomography combined with volcanic eruption records

*Georg F Zellmer[1], Kai-Xun Chen[2], Yuancheng Gung[2], Ban-Yuan Kuo[3], Takeyoshi Yoshida[4]

1. Massey University, Palmerston North, New Zealand, 2. National Taiwan University, Taipei, Taiwan, 3. Academia Sinica, Taipei, Taiwan, 4. Tohoku University, Sendai, Japan

Subduction zone magmatic budgets and crustal growth processes depend on poorly constrained intrusive : extrusive ratios of arc magmas. Published ambient noise tomography data from northeast Japan reveal upper crustal low-$V_S$ bodies, indicating elevated temperatures of plutonic rocks, beneath most sites of active arc-front volcanoes, with the exception of Zao volcano. Strikingly, when small eruptions (VEI 1 to VEI 3) from arc-front volcanoes in the last 2 kyr are considered, Zao has erupted most frequently and has produced a more than three times greater tephra volume than any of the other volcanoes. We propose that the frequent low-volume volcanism at Zao is fed by dikes that traverse the crustal section rapidly, fracturing through brittle lithologies. Beneath the other volcanoes, hotter and more ductile plutonic bodies have developed through repeated intrusive activity, hindering magma transport to the surface. This positive feedback mechanism ultimately results in cataclysmic caldera-forming events. We show that the number of late Cenozoic calderas is higher above the imaged low-$V_S$ crust, consistent with this interpretation. We propose that generation of plutonic bodies is facilitated by volcaniclastic materials buried in a Miocene rift graben, which dampen fracture propagation and promote repeated sill intrusion. In contrast, transcurrent faulting has moved cold Cretaceous basement of the fore-arc range into the arc-front beneath Zao. These brittle rocks instead provide fracture pathways explored by magmas rapidly rising to the surface. The combined data imply that millions of years of crustal growth and tectonic history have a direct control on present-day volcanic eruption style.

# STRATIGRAPHY RENEWAL, MAGMA CHAMBER STRATIFICATION, AND CONDUIT PROCESS OF THE 1815 TAMBORA CALDERA FORMING ERUPTION

*Indranova Suhendro[1], Atsushi Toramaru[1], Yasuo Miyabuchi[2], Tomoharu Miyamoto[1]

1. Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, Japan, 2. Faculty of Advanced Science and Technology, Kumamoto University, Kurokami 2-40-1, Chuo-ku, Kumamoto 860-8555, Japan

The 1815 eruption of Tambora volcano was initiated by two precursory Plinian falls and terminated by pyroclastic density current (PDC) deposits. Although the occurrence of fall deposits and pumice rich PDC has been well-described by previous researchers, we discover scoria rich PDC deposits. However, the presence and relationship of scoria rich PDC with another well-described 1815 eruption deposit has never been discussed in detail. Moreover, several aspects of the magma chamber and conduit dynamics are still poorly understood. In order to that, we conducted petrography by optical microscope, chemical anlyses by XRF, SEM-EDS, and FE-EPMA, and textural analyses of BND and MND. Systematic change in the phenocryst, vesicle, microlite, and chemical compositions also observed through the stratigraphic position. Plinian fall units are characterized by relatively low crystal abundance and small average phenocryst size (0.44 - 0.52 mm) with higher silica content (56.8-58.05 wt.% $SiO_2$). In contrast, PDC deposits are characterized by relatively higher crystal abundance and greater average phenocryst size (0.53 - 0.59 mm) with lower silica content (56.5-57.5 wt.% $SiO_2$). There is no evidence of magma mixing because no bimodal distribution in anorthite content and no reverse zoning pattern in plagioclase phenocryst. Large phenocrysts (>1 mm) have less variation than small phenocrysts (<1 mm) in chemistry. Core compositions of large phenocrysts are $An_{70}$-$_{90,}$ while those of small phenocrysts are $An_{40}$-$_{95}$. The correlation between crystal size, chemical composition, and stratigraphic position suggests that stratification of crystals and chemical compositions in the magma chamber was established prior to 1815 eruption. Juveniles from Plinian eruption are composed of higher BND and lower MND value, compared to juveniles from PDC. As a result, we explained negative correlation of BND and MND by the control of decompression rate ($dP/dt$). Namely, high decompression rate will induce high nucleation rate of bubble thus facilitate magma to ascent rapidly and limiting the growth of microlite. The increase of lithic population from precursory Plinian towards PDC can be regarded as vent-widening process. Therefore, the decrease of decompression rate accompanied by conduit widening during the early to later phase has shifted the eruption style, from buoyant Plinian column to PDC. Finally, rapid and voluminous magma withdrawal from the chamber has led to the formation of caldera.

## [S-VC34] Connecting magma dynamics in vent-conduit system with surface expression of volcanic eruption

convener:Takahiro Miwa(National research institute for earth science and disaster prevention), Nobuo Geshi(Geological Survey of Japan, The National Institute of Advanced Industrial Science and Technology)

Magma dynamics within a shallow conduit system control the diversity of behavior of volcanic eruptions. Recent advancements in geophysical, airborne and ground-based observation techniques provide quantitative data about the dynamic behavior of volcanic eruptions. New analytical methods of the macro and microtextures of eruptive products also open new insights on detailed dynamics of magmas within conduit. The aim of this session is the integration of these new techniques to approach the dynamics of magma ascending from a shallow part of conduit to vent. This session seeks submissions that explore magma dynamics controlling the behaviors of volcanic eruption by integrated investigation of 1) degassing, outgassing, crystallization, and fragmentation of ascending magma, 2) emission and recycling of eruptive product, and 3) morphological characterization of the vent-conduit system. We encourage contributions based on textural-petrological analyses of eruptive product, experimental study reproducing magma in the conduit, geophysical observation on surface expression of volcanic eruption, and related numerical modeling.

To evaluate the effect of melt viscosity on bubble nucleation, we newly formulate homogeneous nucleation rate of water bubbles to explicitly include melt viscosity. The viscosity appears in the pre-exponential factor of the nucleation rate in terms of the Péclet number: the ratio of bubble growth timescale by molecular diffusion and viscous relaxation timescale. The pre-exponential factor linearly decreases with increasing viscosity (or decreasing Péclet number) under a given supersaturation. We numerically solve the evolution of bubble nucleation and growth processes in ascending magmas by using the new formula of nucleation rate and a precise approximation of moment equations of bubble size distribution function. In high viscosity or high decompression rate region, the effect of melt viscosity reduces bubble number density by several orders of magnitude compared with the previous study. Because of the lack of experimental data in this high-viscous regime, the reality of this regime will be verified by future experiments.

# Kinetic delay of crystal growth controls plagioclase-basaltic melt apparent disequilibrium

*Ryoya Oida[1], Hidemi Ishibashi[1], ATSUSHI YASUDA[2], Natsumi Hokanishi[2]

1. Faculty of Science, Shizuoka University, 2. Earthquake Research Institute, University of Tokyo

Plagioclase-melt compositional relations sensitively depend on temperature, T, and water content, $X_W$, of melt. Therefore, the relations are formulated as functions of T and $X_W$ and used as geothermohygrometer (e.g., Putirka, 2008). Plagioclase-melt equilibrium is postulated for applying the thermohygrometer models. However, validity of the assumption is unobvious for microlite crystallization driven by degassing and/or cooling during eruption. Can we apply the thermohygrometers to the plagioclase-melt pairs formed by dynamic crystallization? To examine the issue, the cooling crystallization experiments of the high-Al basaltic melt were carried out and textural and chemical analyses were performed the run samples.

We used the high-Al basalt lava from Waianae, Hawaii Oahu as the starting material for the cooling crystallization experiments. This experiment was conducted using the 1atm $fO_2$-controlled furnace at University of Hawaii at Manoa. After 3 hours pre-heating at 1180℃, ~30K higher than the liquidus, the samples were cooled at cooling rates, $R_c$, of 0.1, 0.3, 1, 3, and 10K/min, and then quenched in water at four target temperatures, $T_q$, of 1150, 1120, 1090, and 1060℃. We used FE-EPMA (JEOL-JXA-8530FPlus) and EPMA (JEOL8800R) at Earthquake Research Institute, University of Tokyo, for textural and chemical analyses of the run samples.

As $R_c$ and/or $T_q$ increase, the abundance and size of plagioclase crystals decrease. As $R_c$ increases, the shape of plagioclase changes from euhedral to dendritic. The $R_c$-dependent shape change is more obvious at lower $T_q$. Pyroxene crystallization was suppressed in the run samples coolied at higher $R_c$. In addition, melt boundary layers are observed around pyroxene in the samples cooled at 0.3-1K/min, quenched at 1090℃ and cooled at 0.3-3K/min, quenched at 1060℃, and around plagioclase in the samples cooled at >3K/min, quenched at <1120℃. Lower diffusivity of $Al_2O_3$ compared to those of FeO and MgO is responsible for lower threshold cooling rate of melt boundary layer formation around pyroxene.

The maximum An# [=100Ca/(Ca + Na)] of plagioclase was almost the same among all run samples. We applied both plagioclase liquidus and plagioclase-melt An-partitioning thermometers of Putirka (2008) to the pairs of plagioclase rim-boundary layer melt (BLM) and plagioclase rim-far field melt (FFM) to estimate temperatures recorded in their phase compositions. At $T_q$=1150℃, the estimated temperatures well represent $T_q$ for both BLM and FFM. However, at lower $T_q$, both of the thermometers estimate temperatures higher than $T_q$; difference between estimated temperature and $T_q$, $\Delta T$, increases as decreasing $T_q$. The two thermometers estimate similar temperatures for each sample, and the differences between the two estimated temperatures do not depend on $R_c$. These results suggest that the plagioclase-melt partition coefficient of An component does not depend on the $R_c$. Therefore, the increase of $\Delta T$ at lower $T_q$ is not due to the $R_c$-dependence of the partition coefficient. It is attributed to the kinetic delay of the crystal growth at lower temperature. On the other hand, the coincidence between calculated temperatures and $T_q$ at 1150℃ suggests that kinetic delay of plagioclase crystal growth is small at near liquidus temperature.

©2019. Japan Geoscience Union. All Right Reserved. 

Present results show that plagioclase-melt thermometers can be applied regardless of the $R_c$ at higher temperatures, while magmatic temperature tends to be overestimated due to kinetic delay of crystal growth at lower temperature.

# Eruptive trends and dynamics of remote volcanoes detected form space-based thermal data and $SO_2$ emissions: a comparative analysis of Stromboli, Batu Tara and Tinakula volcanoes

*Corrado CIGOLINI[1], Marco Laiolo[1], Francesco Massimetti[1,2], Maurizio Ripepe[2], Diego Coppola[1]

1. Department of Earth Sciences, University of Torino, Italy, 2. Department of Earth Sciences, University of Firenze, Italy

South-Eastern Pacific has a large number of unmonitored volcanoes that may potentially produce large-scale eruptive events capable to affect highly-populated areas. Therefore, forecasting changes in volcanic activity in the light of historical time-series is a rather intriguing challenge for the space-based earth observations.
Batu Tara (Indonesia) and Tinakula (Solomon Island) are two poorly known volcanic islands with morphologies and reported short-term activities rather similar to the ones observed at Stromboli volcano (Italy). However, thanks to over a decade-long satellite data we are able to effectively compare the activity occurring at Stromboli (a unique natural laboratory and “open-vent” system) with those taking place at the above volcanoes.
We process and analyse the radiant flux (thermal activity) coupled with $SO_2$ emissions (degassing activity) at these three volcanoes for over a decade. The combined analysis of Volcanic Radiant Power (from MODIS data) and $SO_2$ burden (from OMI data) reveals different long-term eruptive trends, and contrasting ratio of gas vs. thermal emissions. In fact, the persistent open-vent explosive activity of Stromboli volcano is interrupted by flank effusions that periodically drain the degassed magma stored at shallow levels. On the other hand, the long-lasting exponential decay of both thermal and gas emissions observed at Batu Tara is consistent with the eruption of an “undegassed magma” from a deep, and likely a “closed” magma chamber. Finally, Tinakula volcano exhibits multiple year-long eruptive phases, characterised by evolving gas vs. thermal ratio correlated with an increasing eruptive intensity: thus suggesting the involvement of a volatile-zoned magma chamber with periodic phases of gas/magma accumulations.
Our results suggest that the combined analysis of satellite thermal/gas data is a useful tool for better understanding long-term volcanic dynamics and interpreting volcanic processes occurring at a shorter time-scale. We also stress that large satellite datasets on active volcanoes, available from different platforms, greatly enhance the opportunity to efficiently monitor remote volcanic targets in the attempt to mitigate volcanic risk.

Dipartimento di Scienze della Terra, Sapienza Università di Roma, Rome, Italy

The source depth of an individual explosion during Strombolian-style explosive volcanic activity can be defined as the depth of the region within the volcanic conduit where magma fragmentation occurs and the acceleration of pyroclasts by the expanding gas continuum begins. Source depth is thought to exert a first-order control on the final ejection dynamics of the pyroclasts and the ensuing eruptive styles and hazards. As such, different methods to estimate source depth have been developed in the past.

Here, we used three independent methods to estimate the source depth of some Strombolian explosions from Stromboli and Etna volcanoes (Italy). The first method uses the back-tracking of the trajectories of pyroclasts leaving the vent to infer their minimum release depth. It is a purely geometric method relying on the assumption that pyroclasts follow linear trajectories after fragmentation. The second method uses the time delay between the appearance of pyroclasts at the vent and the arrival of acoustic waves at a recording station at a known distance from the vent. This method relies on several assumptions, including (i) the sound velocity inside the conduit, (ii) the co-location of source depth of pyroclasts and acoustic waves, and (iii) a constant velocity of pyroclasts in the conduit, following the initial acceleration. The third method uses the velocity of pyroclasts progressively exiting the vent. This velocity decays following a non-linear trend which is function of the source depth, as illustrated by previous experimental and theoretical studies. As for the second method, also this last one assumes a constant velocity of pyroclasts rising in the conduit.

For the Etna case, the three methods provide consistent results and a shallow (<20 m) source depth of the explosions. For the Stromboli case, the first and third methods provide shallow (around 6 and 15 m, respectively) source depths while the second method provides depths of around 60 m. The incompatibility of such large depths with the first two methods, and given the relative assumptions, we believe that in the Stromboli case the co-location of the particles and acoustic source is probably the least strong assumption. These results suggest that caution should be used in assessing source depth from a single methodology, and that more investigations are required on the source of acoustic signals from the explosions and on the motion (specifically the acceleration and deceleration) of pyroclasts ascending along the conduit.

# Magmatic aggregate of basaltic ash particles

*Takahiro Miwa[1], Nobuo Geshi[2]

1. National research institute for earth science and disaster prevention, 2. National Institute of Advanced Industrial Science and Technology

Dynamics of volcanic cloud and jet at the vent is largely controled by a grain size of pyroclast. The grain size is considered to be determined by primary fragmentation of magma, and subsequent breakup of pyroclasts due to therir collsions in upper conduit (Dufek et al. 2012). However, whether the breakup occurs or not depend on viscoelastic responce of magma (Dingwell and Webb, 1989).
In this study, we report aggregate of ash particles which is formed in magmatic temperature. We observed basaltic ash samples from Stromboli volcano, Italy, and Aso volcano, Japan. The “magmatic aggretate” shows texture that numerous small guest particles (< 200 $\mu$m) adhere or stick on a host particle (> 1 mm). All the host particles are catergorized to sideromelane having fluidal morphology. The guest particles are on fluidal surface of the host particle, and show fluidal and dense morphology. These characteristics found in the magmatic aggregate can be explaned by collision and aggretation of ash particles in high temperature condition. Here we model formation of the magmatic aggregates as passing of two frying particles bearing viscoelastic nature, by using viscosity of magma estimated ($10^4$-$10^5$ Pa s). When the relative velocity of the two particles falls the critical value, the two particles behave as viscous material, coalsece each other, and then form the magmatic aggregate. The result of calculation demonstrates that the critical relative velocity is approximately $10^{-2}$ m/s, and implies the magmatic aggregation is difficult to occur for silisic magma with highly viscosity. Thus we conclude that the collision can increase average grain size of pyroclast in basaltic system.

# Melt inclusion study on the eruption process of Izu-Omuroyama monogenetic volcano, Japan

Risako Hatada[1], *Hidemi Ishibashi[1], Yusuke Suzuki[2], ATSUSHI YASUDA[3], Natsumi Hokanishi[3]

1. Faculty of Science, Shizuoka University, 2. Izu Peninsula Geopark, 3. Earthquake Research Institute, University of Tokyo

Izu-Omuroyama is one of monogenetic volcanoes in Izu-Tobu volcanic field, which is the largest pyroclastic cone formed by ~4ka eruption with ~450 million tons of tephra and lava (Koyano et al., 1996). Because a monogenetic volcano such as Omuroyama is built by the first eruption of a newly-formed magma plumbing system, phenocrysts and melt inclusions (MIs) in its volcanic products may record information about the initial process of formation of the magma plumbing system. In this study, textural and chemical analyses were performed for phenocrysts and MIs in Strombolian scoria of the Omuroyama eruption to clarify the eruption process of the monogenetic volcano.

According to Koyano et al. (1996), Omuroyama eruption started from sub-plinian phase (stage-A), followed by weak ash-eruption phase (stage-B), and then shifted to the main phase of Strombolian eruption (stage-C). Omuroyama pyroclastic cone was built during the stage-C. In this study, we performed textural and chemical analyses for phenocrysts and MIs in the fall scoria erupted during the stage-C, by using FE-EPMA and EPMA at ERI, Univ. Tokyo, Japan.

The scoria contain ~3.3 vol.% of olivine and ~5.4 vol.% of plagioclase as phenocrysts, and their groundmass include olivine and plagioclase microphenocsyts (MPs) of several tens-100 microns sizes embedded in almost glassy or microlite-rich matrix. Olivine phenocrysts are homogeneous (Fo~74-83 with concentration at 83-84) in each grain except for normal zoned rim. Olivine MPs has compositions similar to Fo-poor phenocrysts. Most of plagioclase phenocrysts show reverse zoning with cores of An~30-60 and rims of An~84 and dusty zones are often found. Plagioclase MPs have compositions identical to those of phenocryst rims. Olivine- and plagioclase-hosted MIs have $SiO_2$ contents of ~52-60 wt.% and 57-78 wt.%, respectively. Compositions of both olivine- and plagioclase-hosted MIs with $SiO_2$~57-60 wt.% are identical with glass in microlite-poor groundmass, indicating that the melt was saturated with olivine and plagioclase. Based on the olivine-plagioclase-melt compositional relation, temperature and $H_2O$ content conditions of the melt is estimated to be ~1080ºC and ~2 wt.% (H2O-saturated depth of ~2km), respectively. Majority of MIs in plagioclase phenocrysts are rhyolitic with SiO2~70-74wt.%. FeO content of host plagioclase crystals are consistent with those in equilibrium with the MIs. $H_2O$ contents of the MIs are estimated by melt-plagioclase hygrometer to be ~6.2-9.2 wt.% ($H_2O$-saturated depth of ~8-14km), under assumption of temperature of 800-850 ºC. In addition, olivine-hosted MIs with $SiO_2 < 57$ wt.% are enriched in $SO_3$ (~0.3-0.5 wt.%), indicating their origin deeper than those of more evolved MIs ($SO_3 < 0.1$ wt.%).

Present results suggest that (1) deep-derived, olivine-bearing mafc melt ascent, captured plagioclase phenocrysts and rhyolitic melt and mixed with them at 11km depth, and crystallized MPs at 2km depth before the eruption, and (2) rhyolitic melt existed at ~11km depth beneath the volcanic field at ca. 800 years before the first eruption of rhyolitic magma at Kawagodaira volcano.

# Time-series variation in the textures of ejecta of the An'ei eruption, Izu-Oshima

*Yuya Ikenaga[1], Fukashi Maeno[1], ATSUSHI YASUDA[1]

1. Earthquake Research Institute, The University of Tokyo

In Izu-Oshima, a large-scale eruption called the An’ ei eruption began in 1777. This eruption lasted for 15 years, and scoria and lava flows were strongly ejected before ash eruption period (Nakamura, 1964; Isshiki, 1984; Koyama and Hayakawa, 1996, Tsukui et al, 2009). As for scoria eruption, the transition of the intensity of eruption was unveiled (Ikenaga et al., 2018). Scoria eruption in the initial stage (Unit A) was somewhat weak and scoria is poor in plagioclase phenocrysts (Pl). After the small-scale scoria eruption (Unit B, rich in Pl), the climax stage (Unit C) occurred. Scoria in Unit C is richest in Pl and eruption column height of this unit is inferred to be approximately 10km. The change in the textures of scoriae among these 3 units, however, has not been investigated yet. It becomes clear in this study that there are differences in the textures of scoriae.

The scoria of Unit A (A-scoria) is rich in microlites and the groundmass glass has low transparency. The surface of bubbles is rough and many bubbles are connected each other. On the other hand, the scoria of Unit C (C-scoria) has almost no microlites and the glass is transparent. The shape of bubbles is spherical or ellipsoid, and the surface of bubbles is smooth. The connectivity of bubbles is low. The characteristics of the scoria of Unit B (B-scoria) are intermediate between those of A- and C-scoria. Considering the transition in the intensity of eruption, magma ascent rate of Unit A is expected to have been low than that of Unit C, and the crystallization of microlites and connection of bubbles in Unit A were probably caused because of low decompression rate.

The compositions of Pl, groundmass glass and melt inclusions in Pl of scoriae were measured using EPMA, and there are no difference in these compositions among 3 units. It is inferred from this result that the change in the intensity of 3 units was not caused by injection of undifferentiated magma into magma chamber, but caused by other processes, such as decompression of magma chamber after the eruption of Unit A. It is a future issue to reveal the cause of the change in intensity.

# The textural analysis of pumice from the Plinian eruption of Taupo volcano: implications for tube pumice

*Masatoshi Ohashi[1], Mie Ichihara[2], Fukashi Maeno[2], Ben Kennedy[3], Darren Gravley[3]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, 2. Earthquake Research Institute, The University of Tokyo, 3. Department of Geological Sciences, The University of Canterbury

Tube pumice is characterized by aligned highly elongated bubbles and is a common product of explosive silicic eruptions. This bubble texture is thought to reflect shear deformations during flow in a conduit (Marti et al., 1999). Therefore, quantitative measurements of tube pumice texture can inform conduit flow models. Recent development in X-ray tomography allows us to measure bubble shapes in 3D pumice accurately (e.g., Dingwell et al., 2016). In addition to the microscopic structures of individual pumices, the abundance of tube and non-tube pumices in the stratigraphy is important in inferring temporal and spatial variations in a conduit flow. This study aims at quantifying micro-structural and stratigraphic features of pumice from the 1.8 ka eruption of Taupo volcano, New Zealand.

The 1.8 ka eruption is the most recent large eruptive event from Taupo volcano. It is characterized by various eruptive styles, including three phreatomagmatic fall deposits (units 1, 3, 4), Hatepe plinian fall deposit (unit 2), Taupo plinian fall deposit (unit 5), and Taupo ignimbrite (unit 6) (Houghton et al., 2010). Since those deposits show chemically uniform pumices and melt inclusions, the great diversity of bubble textures in pumices may reflect purely physical processes in the eruption. We collected samples from the units of the two plinian eruptions (units 2 and 5) and the ignimbrite (unit 6), and measured bubble textures and vesicularities. Among those units, we focused on unit 5 to investigate the transition from plinian fall to ignimbrite. For this purpose, a detailed sampling of unit 5 was conducted at an outcrop about 25 km away from the vent, where the unit consists of a fine lower part (40 cm) and a coarse upper part (180 cm). We sampled clasts from the bottom to top of the unit 5 layer at 20cm interval. The bubble textures of more than 1000 pumice samples were measured by a digital microscope (VHX-1000, Keyence) with variable illumination function. The illumination was optimized to make good luminance contrast between the flat surface and bubbles for image analysis.

The image analysis shows that bubbles in unit 5 are more elongated than those in unit 2 and less elongated than those in unit 6. The average values of bubble elongation in unit 2 and 6 are proportional to those of vesicularity. In contrast, bubble elongation and vesicularity are uniform within unit 5. The component analysis over unit 5 shows that the weight percentage of lithics is also uniform except in the lowest part. The relatively high lithic content in the lowest part suggests vent widened or shifted location at the beginning of the Taupo plinian event.

Previous studies in other volcanoes suggest that bubbles in the pre-ignimbrite phase become more elongated toward the flow stage (Taddeucci and Wohletz 2001, Polacci et al., 2003). The increased amount of tube pumice is thought to reflect a gradual transition from fallout to ignimbrite, and it was interpreted as a result of increased erosive activity near the conduit wall, or a greater conduit area available for shearing (Polacci et al., 2003). In contrast, no such variation of bubble texture is observed in Taupo plinian event (unit 5), which implies that a steady conduit flow was sustained during the pre-ignimbrite fallout eruption. The ignimbrite (unit 6) might not simply be the result of a collapsing plinian eruption column. It is also possible that the topmost part of unit 5 had been eroded by and/or mixed with the pyroclastic flow that deposited the subsequent ignimbrite (unit 6).

[E] Poster | S (Solid Earth Sciences)：S-VC Volcanology

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_23

## [S-VC34] Connecting magma dynamics in vent-conduit system with surface expression of volcanic eruption

convener:Takahiro Miwa(National research institute for earth science and disaster prevention), Nobuo Geshi(Geological Survey of Japan, The National Institute of Advanced Industrial Science and Technology)

Magma dynamics within a shallow conduit system control the diversity of behavior of volcanic eruptions. Recent advancements in geophysical, airborne and ground-based observation techniques provide quantitative data about the dynamic behavior of volcanic eruptions. New analytical methods of the macro and microtextures of eruptive products also open new insights on detailed dynamics of magmas within conduit. The aim of this session is the integration of these new techniques to approach the dynamics of magma ascending from a shallow part of conduit to vent. This session seeks submissions that explore magma dynamics controlling the behaviors of volcanic eruption by integrated investigation of 1) degassing, outgassing, crystallization, and fragmentation of ascending magma, 2) emission and recycling of eruptive product, and 3) morphological characterization of the vent-conduit system. We encourage contributions based on textural-petrological analyses of eruptive product, experimental study reproducing magma in the conduit, geophysical observation on surface expression of volcanic eruption, and related numerical modeling.

1. Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

To evaluate the effect of melt viscosity on bubble nucleation, we newly formulate homogeneous nucleation rate of water bubbles to explicitly include melt viscosity. The viscosity appears in the pre-exponential factor of the nucleation rate in terms of the Péclet number: the ratio of bubble growth timescale by molecular diffusion and viscous relaxation timescale. The pre-exponential factor linearly decreases with increasing viscosity (or decreasing Péclet number) under a given supersaturation. We numerically solve the evolution of bubble nucleation and growth processes in ascending magmas by using the new formula of nucleation rate and a precise approximation of moment equations of bubble size distribution function. In high viscosity or high decompression rate region, the effect of melt viscosity reduces bubble number density by several orders of magnitude compared with the previous study. Because of the lack of experimental data in this high-viscous regime, the reality of this regime will be verified by future experiments.

# Kinetic delay of crystal growth controls plagioclase-basaltic melt apparent disequilibrium

*Ryoya Oida[1], Hidemi Ishibashi[1], ATSUSHI YASUDA[2], Natsumi Hokanishi[2]

1. Faculty of Science, Shizuoka University, 2. Earthquake Research Institute, University of Tokyo

Plagioclase-melt compositional relations sensitively depend on temperature, T, and water content, $X_W$, of melt. Therefore, the relations are formulated as functions of T and $X_W$ and used as geothermohygrometer (e.g., Putirka, 2008). Plagioclase-melt equilibrium is postulated for applying the thermohygrometer models. However, validity of the assumption is unobvious for microlite crystallization driven by degassing and/or cooling during eruption. Can we apply the thermohygrometers to the plagioclase-melt pairs formed by dynamic crystallization? To examine the issue, the cooling crystallization experiments of the high-Al basaltic melt were carried out and textural and chemical analyses were performed the run samples.

We used the high-Al basalt lava from Waianae, Hawaii Oahu as the starting material for the cooling crystallization experiments. This experiment was conducted using the 1atm $fO_2$-controlled furnace at University of Hawaii at Manoa. After 3 hours pre-heating at 1180℃, ~30K higher than the liquidus, the samples were cooled at cooling rates, $R_c$, of 0.1, 0.3, 1, 3, and 10K/min, and then quenched in water at four target temperatures, $T_q$, of 1150, 1120, 1090, and 1060℃. We used FE-EPMA (JEOL-JXA-8530FPlus) and EPMA (JEOL8800R) at Earthquake Research Institute, University of Tokyo, for textural and chemical analyses of the run samples.

As $R_c$ and/or $T_q$ increase, the abundance and size of plagioclase crystals decrease. As $R_c$ increases, the shape of plagioclase changes from euhedral to dendritic. The $R_c$-dependent shape change is more obvious at lower $T_q$. Pyroxene crystallization was suppressed in the run samples coolied at higher $R_c$. In addition, melt boundary layers are observed around pyroxene in the samples cooled at 0.3-1K/min, quenched at 1090℃ and cooled at 0.3-3K/min, quenched at 1060℃, and around plagioclase in the samples cooled at >3K/min, quenched at <1120℃. Lower diffusivity of $Al_2O_3$ compared to those of FeO and MgO is responsible for lower threshold cooling rate of melt boundary layer formation around pyroxene.

The maximum An# [=100Ca/(Ca + Na)] of plagioclase was almost the same among all run samples. We applied both plagioclase liquidus and plagioclase-melt An-partitioning thermometers of Putirka (2008) to the pairs of plagioclase rim-boundary layer melt (BLM) and plagioclase rim-far field melt (FFM) to estimate temperatures recorded in their phase compositions. At $T_q$=1150℃, the estimated temperatures well represent $T_q$ for both BLM and FFM. However, at lower $T_q$, both of the thermometers estimate temperatures higher than $T_q$; difference between estimated temperature and $T_q$, $\Delta T$, increases as decreasing $T_q$. The two thermometers estimate similar temperatures for each sample, and the differences between the two estimated temperatures do not depend on $R_c$. These results suggest that the plagioclase-melt partition coefficient of An component does not depend on the $R_c$. Therefore, the increase of $\Delta T$ at lower $T_q$ is not due to the $R_c$-dependence of the partition coefficient. It is attributed to the kinetic delay of the crystal growth at lower temperature. On the other hand, the coincidence between calculated temperatures and $T_q$ at 1150℃ suggests that kinetic delay of plagioclase crystal growth is small at near liquidus temperature.

©2019. Japan Geoscience Union. All Right Reserved. 

Present results show that plagioclase-melt thermometers can be applied regardless of the $R_c$ at higher temperatures, while magmatic temperature tends to be overestimated due to kinetic delay of crystal growth at lower temperature.

# Eruptive trends and dynamics of remote volcanoes detected form space-based thermal data and $SO_2$ emissions: a comparative analysis of Stromboli, Batu Tara and Tinakula volcanoes

*Corrado CIGOLINI[1], Marco Laiolo[1], Francesco Massimetti[1,2], Maurizio Ripepe[2], Diego Coppola[1]

1. Department of Earth Sciences, University of Torino, Italy, 2. Department of Earth Sciences, University of Firenze, Italy

South-Eastern Pacific has a large number of unmonitored volcanoes that may potentially produce large-scale eruptive events capable to affect highly-populated areas. Therefore, forecasting changes in volcanic activity in the light of historical time-series is a rather intriguing challenge for the space-based earth observations.
Batu Tara (Indonesia) and Tinakula (Solomon Island) are two poorly known volcanic islands with morphologies and reported short-term activities rather similar to the ones observed at Stromboli volcano (Italy). However, thanks to over a decade-long satellite data we are able to effectively compare the activity occurring at Stromboli (a unique natural laboratory and “open-vent” system) with those taking place at the above volcanoes.
We process and analyse the radiant flux (thermal activity) coupled with $SO_2$ emissions (degassing activity) at these three volcanoes for over a decade. The combined analysis of Volcanic Radiant Power (from MODIS data) and $SO_2$ burden (from OMI data) reveals different long-term eruptive trends, and contrasting ratio of gas vs. thermal emissions. In fact, the persistent open-vent explosive activity of Stromboli volcano is interrupted by flank effusions that periodically drain the degassed magma stored at shallow levels. On the other hand, the long-lasting exponential decay of both thermal and gas emissions observed at Batu Tara is consistent with the eruption of an “undegassed magma” from a deep, and likely a “closed” magma chamber. Finally, Tinakula volcano exhibits multiple year-long eruptive phases, characterised by evolving gas vs. thermal ratio correlated with an increasing eruptive intensity: thus suggesting the involvement of a volatile-zoned magma chamber with periodic phases of gas/magma accumulations.
Our results suggest that the combined analysis of satellite thermal/gas data is a useful tool for better understanding long-term volcanic dynamics and interpreting volcanic processes occurring at a shorter time-scale. We also stress that large satellite datasets on active volcanoes, available from different platforms, greatly enhance the opportunity to efficiently monitor remote volcanic targets in the attempt to mitigate volcanic risk.

Centro de Investigación en Gestión de Riesgo y Cambio Climático, Universidad de Ciencias y Artes de Chiapas, Tuxtla Gutiérrez, Mexico, 3. Department of Geosciences, Università degli Studi di Padova, Padua, Italy, 4. Department of Earth and Environmental Sciences. Ludwig-Maximilians-Universität (LMU). Munich, Germany, 5. Dipartimento di Scienze della Terra, Sapienza Università di Roma, Rome, Italy

The source depth of an individual explosion during Strombolian-style explosive volcanic activity can be defined as the depth of the region within the volcanic conduit where magma fragmentation occurs and the acceleration of pyroclasts by the expanding gas continuum begins. Source depth is thought to exert a first-order control on the final ejection dynamics of the pyroclasts and the ensuing eruptive styles and hazards. As such, different methods to estimate source depth have been developed in the past.

Here, we used three independent methods to estimate the source depth of some Strombolian explosions from Stromboli and Etna volcanoes (Italy). The first method uses the back-tracking of the trajectories of pyroclasts leaving the vent to infer their minimum release depth. It is a purely geometric method relying on the assumption that pyroclasts follow linear trajectories after fragmentation. The second method uses the time delay between the appearance of pyroclasts at the vent and the arrival of acoustic waves at a recording station at a known distance from the vent. This method relies on several assumptions, including (i) the sound velocity inside the conduit, (ii) the co-location of source depth of pyroclasts and acoustic waves, and (iii) a constant velocity of pyroclasts in the conduit, following the initial acceleration. The third method uses the velocity of pyroclasts progressively exiting the vent. This velocity decays following a non-linear trend which is function of the source depth, as illustrated by previous experimental and theoretical studies. As for the second method, also this last one assumes a constant velocity of pyroclasts rising in the conduit.

For the Etna case, the three methods provide consistent results and a shallow (<20 m) source depth of the explosions. For the Stromboli case, the first and third methods provide shallow (around 6 and 15 m, respectively) source depths while the second method provides depths of around 60 m. The incompatibility of such large depths with the first two methods, and given the relative assumptions, we believe that in the Stromboli case the co-location of the particles and acoustic source is probably the least strong assumption. These results suggest that caution should be used in assessing source depth from a single methodology, and that more investigations are required on the source of acoustic signals from the explosions and on the motion (specifically the acceleration and deceleration) of pyroclasts ascending along the conduit.

# Magmatic aggregate of basaltic ash particles

*Takahiro Miwa[1], Nobuo Geshi[2]

1. National research institute for earth science and disaster prevention, 2. National Institute of Advanced Industrial Science and Technology

Dynamics of volcanic cloud and jet at the vent is largely controled by a grain size of pyroclast. The grain size is considered to be determined by primary fragmentation of magma, and subsequent breakup of pyroclasts due to therir collsions in upper conduit (Dufek et al. 2012). However, whether the breakup occurs or not depend on viscoelastic responce of magma (Dingwell and Webb, 1989).
In this study, we report aggregate of ash particles which is formed in magmatic temperature. We observed basaltic ash samples from Stromboli volcano, Italy, and Aso volcano, Japan. The “magmatic aggretate” shows texture that numerous small guest particles (< 200 $\mu$m) adhere or stick on a host particle (> 1 mm). All the host particles are catergorized to sideromelane having fluidal morphology. The guest particles are on fluidal surface of the host particle, and show fluidal and dense morphology. These characteristics found in the magmatic aggregate can be explaned by collision and aggretation of ash particles in high temperature condition. Here we model formation of the magmatic aggregates as passing of two frying particles bearing viscoelastic nature, by using viscosity of magma estimated ($10^4$-$10^5$ Pa s). When the relative velocity of the two particles falls the critical value, the two particles behave as viscous material, coalsece each other, and then form the magmatic aggregate. The result of calculation demonstrates that the critical relative velocity is approximately $10^{-2}$ m/s, and implies the magmatic aggregation is difficult to occur for silisic magma with highly viscosity. Thus we conclude that the collision can increase average grain size of pyroclast in basaltic system.

# Melt inclusion study on the eruption process of Izu-Omuroyama monogenetic volcano, Japan

Risako Hatada[1], *Hidemi Ishibashi[1], Yusuke Suzuki[2], ATSUSHI YASUDA[3], Natsumi Hokanishi[3]

1. Faculty of Science, Shizuoka University, 2. Izu Peninsula Geopark, 3. Earthquake Research Institute, University of Tokyo

Izu-Omuroyama is one of monogenetic volcanoes in Izu-Tobu volcanic field, which is the largest pyroclastic cone formed by ~4ka eruption with ~450 million tons of tephra and lava (Koyano et al., 1996). Because a monogenetic volcano such as Omuroyama is built by the first eruption of a newly-formed magma plumbing system, phenocrysts and melt inclusions (MIs) in its volcanic products may record information about the initial process of formation of the magma plumbing system. In this study, textural and chemical analyses were performed for phenocrysts and MIs in Strombolian scoria of the Omuroyama eruption to clarify the eruption process of the monogenetic volcano.

According to Koyano et al. (1996), Omuroyama eruption started from sub-plinian phase (stage-A), followed by weak ash-eruption phase (stage-B), and then shifted to the main phase of Strombolian eruption (stage-C). Omuroyama pyroclastic cone was built during the stage-C. In this study, we performed textural and chemical analyses for phenocrysts and MIs in the fall scoria erupted during the stage-C, by using FE-EPMA and EPMA at ERI, Univ. Tokyo, Japan.

The scoria contain ~3.3 vol.% of olivine and ~5.4 vol.% of plagioclase as phenocrysts, and their groundmass include olivine and plagioclase microphenocsyts (MPs) of several tens-100 microns sizes embedded in almost glassy or microlite-rich matrix. Olivine phenocrysts are homogeneous (Fo~74-83 with concentration at 83-84) in each grain except for normal zoned rim. Olivine MPs has compositions similar to Fo-poor phenocrysts. Most of plagioclase phenocrysts show reverse zoning with cores of An~30-60 and rims of An~84 and dusty zones are often found. Plagioclase MPs have compositions identical to those of phenocryst rims. Olivine- and plagioclase-hosted MIs have $SiO_2$ contents of ~52-60 wt.% and 57-78 wt.%, respectively. Compositions of both olivine- and plagioclase-hosted MIs with $SiO_2$~57-60 wt.% are identical with glass in microlite-poor groundmass, indicating that the melt was saturated with olivine and plagioclase. Based on the olivine-plagioclase-melt compositional relation, temperature and $H_2O$ content conditions of the melt is estimated to be ~1080ºC and ~2 wt.% (H2O-saturated depth of ~2km), respectively. Majority of MIs in plagioclase phenocrysts are rhyolitic with SiO2~70-74wt.%. FeO content of host plagioclase crystals are consistent with those in equilibrium with the MIs. $H_2O$ contents of the MIs are estimated by melt-plagioclase hygrometer to be ~6.2-9.2 wt.% ($H_2O$-saturated depth of ~8-14km), under assumption of temperature of 800-850 ºC. In addition, olivine-hosted MIs with $SiO_2 < 57$ wt.% are enriched in $SO_3$ (~0.3-0.5 wt.%), indicating their origin deeper than those of more evolved MIs ($SO_3 < 0.1$ wt.%).

Present results suggest that (1) deep-derived, olivine-bearing mafc melt ascent, captured plagioclase phenocrysts and rhyolitic melt and mixed with them at 11km depth, and crystallized MPs at 2km depth before the eruption, and (2) rhyolitic melt existed at ~11km depth beneath the volcanic field at ca. 800 years before the first eruption of rhyolitic magma at Kawagodaira volcano.

# Time-series variation in the textures of ejecta of the An'ei eruption, Izu-Oshima

*Yuya Ikenaga[1], Fukashi Maeno[1], ATSUSHI YASUDA[1]

1. Earthquake Research Institute, The University of Tokyo

In Izu-Oshima, a large-scale eruption called the An’ ei eruption began in 1777. This eruption lasted for 15 years, and scoria and lava flows were strongly ejected before ash eruption period (Nakamura, 1964; Isshiki, 1984; Koyama and Hayakawa, 1996, Tsukui et al, 2009). As for scoria eruption, the transition of the intensity of eruption was unveiled (Ikenaga et al., 2018). Scoria eruption in the initial stage (Unit A) was somewhat weak and scoria is poor in plagioclase phenocrysts (Pl). After the small-scale scoria eruption (Unit B, rich in Pl), the climax stage (Unit C) occurred. Scoria in Unit C is richest in Pl and eruption column height of this unit is inferred to be approximately 10km. The change in the textures of scoriae among these 3 units, however, has not been investigated yet. It becomes clear in this study that there are differences in the textures of scoriae.

The scoria of Unit A (A-scoria) is rich in microlites and the groundmass glass has low transparency. The surface of bubbles is rough and many bubbles are connected each other. On the other hand, the scoria of Unit C (C-scoria) has almost no microlites and the glass is transparent. The shape of bubbles is spherical or ellipsoid, and the surface of bubbles is smooth. The connectivity of bubbles is low. The characteristics of the scoria of Unit B (B-scoria) are intermediate between those of A- and C-scoria. Considering the transition in the intensity of eruption, magma ascent rate of Unit A is expected to have been low than that of Unit C, and the crystallization of microlites and connection of bubbles in Unit A were probably caused because of low decompression rate.

The compositions of Pl, groundmass glass and melt inclusions in Pl of scoriae were measured using EPMA, and there are no difference in these compositions among 3 units. It is inferred from this result that the change in the intensity of 3 units was not caused by injection of undifferentiated magma into magma chamber, but caused by other processes, such as decompression of magma chamber after the eruption of Unit A. It is a future issue to reveal the cause of the change in intensity.

# The textural analysis of pumice from the Plinian eruption of Taupo volcano: implications for tube pumice

*Masatoshi Ohashi[1], Mie Ichihara[2], Fukashi Maeno[2], Ben Kennedy[3], Darren Gravley[3]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo, 2. Earthquake Research Institute, The University of Tokyo, 3. Department of Geological Sciences, The University of Canterbury

Tube pumice is characterized by aligned highly elongated bubbles and is a common product of explosive silicic eruptions. This bubble texture is thought to reflect shear deformations during flow in a conduit (Marti et al., 1999). Therefore, quantitative measurements of tube pumice texture can inform conduit flow models. Recent development in X-ray tomography allows us to measure bubble shapes in 3D pumice accurately (e.g., Dingwell et al., 2016). In addition to the microscopic structures of individual pumices, the abundance of tube and non-tube pumices in the stratigraphy is important in inferring temporal and spatial variations in a conduit flow. This study aims at quantifying micro-structural and stratigraphic features of pumice from the 1.8 ka eruption of Taupo volcano, New Zealand.

The 1.8 ka eruption is the most recent large eruptive event from Taupo volcano. It is characterized by various eruptive styles, including three phreatomagmatic fall deposits (units 1, 3, 4), Hatepe plinian fall deposit (unit 2), Taupo plinian fall deposit (unit 5), and Taupo ignimbrite (unit 6) (Houghton et al., 2010). Since those deposits show chemically uniform pumices and melt inclusions, the great diversity of bubble textures in pumices may reflect purely physical processes in the eruption. We collected samples from the units of the two plinian eruptions (units 2 and 5) and the ignimbrite (unit 6), and measured bubble textures and vesicularities. Among those units, we focused on unit 5 to investigate the transition from plinian fall to ignimbrite. For this purpose, a detailed sampling of unit 5 was conducted at an outcrop about 25 km away from the vent, where the unit consists of a fine lower part (40 cm) and a coarse upper part (180 cm). We sampled clasts from the bottom to top of the unit 5 layer at 20cm interval. The bubble textures of more than 1000 pumice samples were measured by a digital microscope (VHX-1000, Keyence) with variable illumination function. The illumination was optimized to make good luminance contrast between the flat surface and bubbles for image analysis.

The image analysis shows that bubbles in unit 5 are more elongated than those in unit 2 and less elongated than those in unit 6. The average values of bubble elongation in unit 2 and 6 are proportional to those of vesicularity. In contrast, bubble elongation and vesicularity are uniform within unit 5. The component analysis over unit 5 shows that the weight percentage of lithics is also uniform except in the lowest part. The relatively high lithic content in the lowest part suggests vent widened or shifted location at the beginning of the Taupo plinian event.

Previous studies in other volcanoes suggest that bubbles in the pre-ignimbrite phase become more elongated toward the flow stage (Taddeucci and Wohletz 2001, Polacci et al., 2003). The increased amount of tube pumice is thought to reflect a gradual transition from fallout to ignimbrite, and it was interpreted as a result of increased erosive activity near the conduit wall, or a greater conduit area available for shearing (Polacci et al., 2003). In contrast, no such variation of bubble texture is observed in Taupo plinian event (unit 5), which implies that a steady conduit flow was sustained during the pre-ignimbrite fallout eruption. The ignimbrite (unit 6) might not simply be the result of a collapsing plinian eruption column. It is also possible that the topmost part of unit 5 had been eroded by and/or mixed with the pyroclastic flow that deposited the subsequent ignimbrite (unit 6).

# Geochemical interpretation of Ulleung Island volcanic rocks: Implication for the new magmatic model for plume-slab interaction in East Asia

*Chungwan LIM[1], Dohyun Kim[1]

1. Kongju National University

Ulleung Island has been considered as an intraplate volcanic island located in the East Sea/Japan Sea. The alkaline tephra originated from Ulleung Island has played an important role in understanding of the intraplate alkaline volcanism during the Quaternary. Ulleung Island on volcanism that occurs far from plate margins is abstruse with the current paradigm of plate tectonics. The Ulleung Island volcanic complex is unlikely to result from a mantle plume rising at the base of the mantle.

Ulleung Island is consisted of basaltic lava, agglomerate succession, and trachytic/phonolitic pumiceous tephra. The analyses of chemical compositions of glass shards in Ulleung tephras is necessary to identify each unit. During the Quaternary, at least six pumiceous tephras (UT-1~6) covered the island for this research. Based on the relationships of $SiO_2$, the $Al_2O_3$, $Na_2O$, $K_2O$, and $Fe_2O_3$ contents of the tephras increase as $SiO_2$ increases and decrease MgO as $SiO_2$ increases in Ulleung tephras. The trace elements in tephra show intra-plate type characteristics. Sr-Nd-Pb isotopic data from the literature of volcanic glass shards suggest that the mix in magma source might have involved EM1 and EM2-components of Quaternary tephras from Ulleung Island, South Korea.

This study has two principal objectives: First, multiple Ulleung tephras are expected to detect and identify the Ulleung Island. In order to accurately identify and correlate the tephras, it is necessary to consider stratigraphic position as well as geochemical characteristics. The chemical composition of volcanic glass shards is a useful tool for evaluating mixtures of multiple layers. The heavy mineral composition can also be used to identify tephra units. In order to reveal the distribution of each tephra unit to a high degree of certainty, characteristics such as heavy mineral and chemical compositions of each unit must be determined in greater detail itself. Second, we propose that the anomaly represents lithospheric mantle that had been accompanied by beneath the sinking lithosphere of the Philippine Sea Plate and was erupted through a slab-tear in the subducting slab. We suggest that this subduction-induced upwelling process produces mantle-upwelling that feeds the Ulleung Island volcanoes. Subduction-induced upwelling may also may explain back-arc volcanism at other subduction zones in East Asia.

# 1D particle model for vertiacal non-uniform bubble coalescence

*Maruishi Takafumi[1]

1. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

Bubble coalescence deeply affects the dynamics of conduit flow during volcanic eruption.

Previously, the theory assuming nonuniform coalescence has been used.(Macini et al., 2016, etc.). However, in the outgassing process, non-uniform bubble coalescence is considered important in the radial direction and vertical direction of the conduit, the model cannot deal with the coalescence process.

In this study, we construct a simple model that describe a bubble as a particle moving on a one-dimensional line, particle coalesces when particles contact with each other, and calculates the bubble size distribution in a nonuniform coalescence process in the vertical direction.

The particles have a speed corresponding to the size (buoyancy), and the size increases with the altitude and time (expansion / growth). Note that this model is equivalent to the model by Meakin (1989) when bubble growth and advection are not considered. The particles are fed to the lower end of the system at a constant rate (foaming).

Numerical calculation was carried out by broadly controlling the time scale of foaming, rising buoyancy, expansion and growth.

As a result, there was a parameter range where foaming and coalescence are balanced, and it was found that the size distribution shows a dynamic scaling rule regardless of the fluctuation of the radius and number of particles to be supplied.

The relational expression between the expansion and growth exponential law and the vertical scaling index is derived from the conservation law under the assumption that the size distribution is self-similar.

# The formation process of a 100m thick basaltic lava flow in the Kitamatsuura basalts, northwestern Kyushu

*Ryotaro Araki[1], Tetsuya Sakuyama[1]

1. Osaka City University

Kita Matsuura basalts cover the Northwest Kyushu Kitamatsuura Peninsula widely and they were the eruption activities of basaltic lavas which were one of the largest in the Cenozoic in Southwest Japan. The volcanic activity of this basaltic rock had erupted sub-alkaline basalt lavas from multiple sources from the late stage of activity, and ended at about 6.5 Ma. There is a mountain composed of basaltic lavas called Senryu Shiradake that was formed at the end of the eruption in the Senryu Area (Matsui et al., 1989; Sakuyama et al., 2009). Although Senryu Shiradake has a specific height of about 100 m, the boundary of the flow unit has not been confirmed (Fukuyama, 1960, 1961; Kurasawa, 1967). The lapilli tuff layers are sandwiched between this basaltic lava and the lower basalt plateau widely cover the upper surface of the lower basalt plateau and are distributed in a narrower area above it (Matsui et al. 1989). It is difficult to think that basaltic lava which are thought to be more robust against weathering and erosion than erosion of the lapilli tuff are selectively eroded, and that valley buried basaltic lava was eroded Selectively, It is unlikely that the mountain body had remained. From this, it can be considered that Senryu Shiradake is a single basaltic lava flow.

The thickness and length of the lava flow forming the volcanoes are systematically varied in general depending on the chemical composition. Basaltic lavas have low viscosity, so the run length of the basaltic lava flows are longer than that of the andesitic and rhyolitic lava flows, and the average thickness is at most about 30 m (Walker et al., 1973). On the other hand, Senryu Shiradake is formed a basaltic lava flow but its height is about 100 m. In this study, we investigated the lava flow that formed the mountain body of Senryu Shiradake from a petrological point of view.

Analysis of whole rock chemical composition of samples taken from Senryu Shiradake was performed by a fluorescent X-ray analyzer. It was confirmed that Senryu Shiradake basaltic lava has $SiO_2$ = 50 to 53 wt%, MgO = 7 to 11 wt%, FeO * / MgO = 0.87 to 1.5, and it is formed of undifferentiated basalt. The phenocrysts are predominant in olivine and contain a small amount of clinopyroxene, orthopyroxene, and the total phenocryst amount was 3 to 15 vol%. There was a correlation between the sampling altitude and the total rock chemical composition. As the height from the foot increased, the total rock SiO2 amount tended to increased and the MgO amount tended to decrease.

First, assuming that only the phenocrysts were crystallized at the time of lava eruption, the viscosity of lava flow was calculated using the model of Pinkerton & Stevenson (1992) for the effect of crystals on magma viscosity and the model of Hui & Zhang (2007) for the influence of the viscosity of melt. Melt composition was estimated using total rock chemical composition, phenocryst mode composition, and mineral composition. We assumed that all the water in the magma was volatilized and the magma temperature at the time of squirting was 1320 K estimated using pyroxene thermometer. the lava flow model used the flow of magma is stopped by solid shell formation by cooling by Griffiths & Fink (1993).

In this study, we investigated the conditions that can explain the thickness and radius of circulation of the basaltic lava of Senryu Shiradake, considering three variables of volume of erupting magma, time change rate of eruption volume and magma temperature. As a result, even if the rate of change of the first eruption amount and the eruption rate were changed, the thickness was only about 20 m at most which did not reproduce 100 m thick lava flow of Senryu Shiradake. Next, the same study as above was carried out assuming that the degree of crystallization at the time of erupting was 50%, but the thickness was about 30 m at most. From this, it is possible that a 100m thick basaltic lava flow was formed by erupting at

# An introduction to the observation method of imaging volcanoes by using cosmic-ray muons

*Seigo Miyamoto[1]

1. Earth Reasearch Institute, University of Tokyo

The purpose of this presentation is widely to inform a method of exploring the density structure inside a gigantic structure such as a volcano, by using high evergy muons included in cosmic rays. It is considered that there are some reasons for low awareness. For example, the history of this method which is applied to Earth and planetary science is still short, knowledge about "Muon" which is one of "cosmic rays" or "elementary particles" is not known widely. To improve such a situation, we will review the fundamental principles to evaluate the internal density of volcanoes using cosmic-ray muons, past and going-on observation examples of volcanoes, and technological developments stories in this presentation.

# Simulation and test observation for omni-directional muography at Omuro-yama

*Shogo Nagahara[1], Seigo Miyamoto[1], Kunihiro Morishima[2], Toshiyuki Nakano[2], Masato Koyama[3], Yusuke Suzuki[4]

1. Earthquake Research Institute,the University of Tokyo, 2. Nagoya University, 3. Shizuoka University, 4. Izu Peninsula Geopark Promotion Council

In the understanding of the eruption of the volcano, the size and the shape of the volcanic vent close to the crater are important. Generally, the size is several to hundreds of meters, and the shape is not simple cylinder. When we consider the largest vent, we need spatial resolution of several tens of meters to measure the shape of vent.

“Muography” is the technique to observe two-dimensional the inner density structure with high spatial resolution. In previous study, they attempted to reconstruct the three-dimensional (3D) density structure by observing the volcano from multiple directions, but they got three-dimensional density structure with only several hundreds of meters spatial resolution because of a few observation points. To improve the spatial resolution, we are planning “omni-directional muography”, putting ten or more observation points to surround the volcano.

We are planning to demonstrate omni-directional muography at Omuro-yama, located in Shizuoka pref., Japan. We have two reasons that we choose this volcano. First, Omuro-yama is a scoria cone formed by a single eruption, so simple structure is expected and it is easy to obtain significant result. Second, there are no objects around near it. In addition, there are no observation of muography at scoria cone.

We carried out the feasibility check of demonstration observation at Omuro-yama by simulation and test observation by using 3 points muography before full observation. In this simulation, we used a method applying Filtered Back Projection. As a result of simulation, it was found that it is necessary to ensure the minimum S / N ratio for the number of muons observed at each observation point. As a result of test observation, it was found that there was a high density part in the west part of crater rim.

In this publication, we will show the detail of simulation of feasibility check and the result of test observation.

# Estimation of pressure source occurring volcanic crustal deformation with FEM considering topography

*Shinya Yamada[1], Tomokazu Kobayashi[1]

1. GSI of Japan

In order to grasp the activity of the volcano and evaluate it, it is necessary to grasp the behavior of the magma and the like. When volcanic disasters such as eruption occurred, we estimated the deformation source assuming volume change of the spherical pressure source or opening displacement of the dike using observation results of crustal deformation obtained by GNSS and InSAR . Conventionally, when calculating the crustal deformation, calculation was carried out based on a model assuming a semi-infinite homogeneous elastic body. However, if there is a deformation source especially in the shallow part of the volcano, the influence of the topography cannot be ignored. In recent years, along with the development of the technology of InSAR, crustal movement at the crater and its surroundings can be observed in a planar manner, and detailed analysis has become possible. Therefore, in order to more accurately estimate the deformation source, it is necessary to estimate with the topography added.

Based on this background, we developed a crustal deformation calculation system that incorporates the Finite Element Method (FEM) that divides elastic bodies into minute meshes and calculates displacement for each mesh. As a result, it became possible to analyze taking model topography and underground structure into account. In this study, we compare the deformation source estimated using the FEM with the deformation source estimated by the conventional method. In this presentation, we mainly examined the eruption of Mt.Ontake in Nagano Prefecture in 2014. We detected about 10cm crustal deformation in the crater and its surroundings with InSAR analysis by ALOS-2 satellite on the eruption (Yamada et al., 2014). Based on this observation result, we estimated the deformation source with a model assuming a conventional semi-infinite homogeneous elastic body, and we obtained the result that the almost vertical crack opened 45 cm. However, since the topography of the region where the crustal deformation was observed by this eruption is steep and it is thought that the deformation is also influenced by the topography, in this presentation we report the results of comparison of the conventional estimation and the estimation considering the influence of the topography.

# Geochemical interpretation of Ulleung Island volcanic rocks: Implication for the new magmatic model for plume-slab interaction in East Asia

*Chungwan LIM[1], Dohyun Kim[1]

1. Kongju National University

Ulleung Island has been considered as an intraplate volcanic island located in the East Sea/Japan Sea. The alkaline tephra originated from Ulleung Island has played an important role in understanding of the intraplate alkaline volcanism during the Quaternary. Ulleung Island on volcanism that occurs far from plate margins is abstruse with the current paradigm of plate tectonics. The Ulleung Island volcanic complex is unlikely to result from a mantle plume rising at the base of the mantle.

Ulleung Island is consisted of basaltic lava, agglomerate succession, and trachytic/phonolitic pumiceous tephra. The analyses of chemical compositions of glass shards in Ulleung tephras is necessary to identify each unit. During the Quaternary, at least six pumiceous tephras (UT-1~6) covered the island for this research. Based on the relationships of $SiO_2$, the $Al_2O_3$, $Na_2O$, $K_2O$, and $Fe_2O_3$ contents of the tephras increase as $SiO_2$ increases and decrease MgO as $SiO_2$ increases in Ulleung tephras. The trace elements in tephra show intra-plate type characteristics. Sr-Nd-Pb isotopic data from the literature of volcanic glass shards suggest that the mix in magma source might have involved EM1 and EM2-components of Quaternary tephras from Ulleung Island, South Korea.

This study has two principal objectives: First, multiple Ulleung tephras are expected to detect and identify the Ulleung Island. In order to accurately identify and correlate the tephras, it is necessary to consider stratigraphic position as well as geochemical characteristics. The chemical composition of volcanic glass shards is a useful tool for evaluating mixtures of multiple layers. The heavy mineral composition can also be used to identify tephra units. In order to reveal the distribution of each tephra unit to a high degree of certainty, characteristics such as heavy mineral and chemical compositions of each unit must be determined in greater detail itself. Second, we propose that the anomaly represents lithospheric mantle that had been accompanied by beneath the sinking lithosphere of the Philippine Sea Plate and was erupted through a slab-tear in the subducting slab. We suggest that this subduction-induced upwelling process produces mantle-upwelling that feeds the Ulleung Island volcanoes. Subduction-induced upwelling may also may explain back-arc volcanism at other subduction zones in East Asia.

# 1D particle model for vertiacal non-uniform bubble coalescence

*Maruishi Takafumi[1]

1. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

Bubble coalescence deeply affects the dynamics of conduit flow during volcanic eruption.

Previously, the theory assuming nonuniform coalescence has been used.(Macini et al., 2016, etc.). However, in the outgassing process, non-uniform bubble coalescence is considered important in the radial direction and vertical direction of the conduit, the model cannot deal with the coalescence process.

In this study, we construct a simple model that describe a bubble as a particle moving on a one-dimensional line, particle coalesces when particles contact with each other, and calculates the bubble size distribution in a nonuniform coalescence process in the vertical direction.

The particles have a speed corresponding to the size (buoyancy), and the size increases with the altitude and time (expansion / growth). Note that this model is equivalent to the model by Meakin (1989) when bubble growth and advection are not considered. The particles are fed to the lower end of the system at a constant rate (foaming).

Numerical calculation was carried out by broadly controlling the time scale of foaming, rising buoyancy, expansion and growth.

As a result, there was a parameter range where foaming and coalescence are balanced, and it was found that the size distribution shows a dynamic scaling rule regardless of the fluctuation of the radius and number of particles to be supplied.

The relational expression between the expansion and growth exponential law and the vertical scaling index is derived from the conservation law under the assumption that the size distribution is self-similar.

# The formation process of a 100m thick basaltic lava flow in the Kitamatsuura basalts, northwestern Kyushu

*Ryotaro Araki[1], Tetsuya Sakuyama[1]

1. Osaka City University

Kita Matsuura basalts cover the Northwest Kyushu Kitamatsuura Peninsula widely and they were the eruption activities of basaltic lavas which were one of the largest in the Cenozoic in Southwest Japan. The volcanic activity of this basaltic rock had erupted sub-alkaline basalt lavas from multiple sources from the late stage of activity, and ended at about 6.5 Ma. There is a mountain composed of basaltic lavas called Senryu Shiradake that was formed at the end of the eruption in the Senryu Area (Matsui et al., 1989; Sakuyama et al., 2009). Although Senryu Shiradake has a specific height of about 100 m, the boundary of the flow unit has not been confirmed (Fukuyama, 1960, 1961; Kurasawa, 1967). The lapilli tuff layers are sandwiched between this basaltic lava and the lower basalt plateau widely cover the upper surface of the lower basalt plateau and are distributed in a narrower area above it (Matsui et al. 1989). It is difficult to think that basaltic lava which are thought to be more robust against weathering and erosion than erosion of the lapilli tuff are selectively eroded, and that valley buried basaltic lava was eroded Selectively, It is unlikely that the mountain body had remained. From this, it can be considered that Senryu Shiradake is a single basaltic lava flow.

The thickness and length of the lava flow forming the volcanoes are systematically varied in general depending on the chemical composition. Basaltic lavas have low viscosity, so the run length of the basaltic lava flows are longer than that of the andesitic and rhyolitic lava flows, and the average thickness is at most about 30 m (Walker et al., 1973). On the other hand, Senryu Shiradake is formed a basaltic lava flow but its height is about 100 m. In this study, we investigated the lava flow that formed the mountain body of Senryu Shiradake from a petrological point of view.

Analysis of whole rock chemical composition of samples taken from Senryu Shiradake was performed by a fluorescent X-ray analyzer. It was confirmed that Senryu Shiradake basaltic lava has $SiO_2$ = 50 to 53 wt%, MgO = 7 to 11 wt%, FeO * / MgO = 0.87 to 1.5, and it is formed of undifferentiated basalt. The phenocrysts are predominant in olivine and contain a small amount of clinopyroxene, orthopyroxene, and the total phenocryst amount was 3 to 15 vol%. There was a correlation between the sampling altitude and the total rock chemical composition. As the height from the foot increased, the total rock SiO2 amount tended to increased and the MgO amount tended to decrease.

First, assuming that only the phenocrysts were crystallized at the time of lava eruption, the viscosity of lava flow was calculated using the model of Pinkerton & Stevenson (1992) for the effect of crystals on magma viscosity and the model of Hui & Zhang (2007) for the influence of the viscosity of melt. Melt composition was estimated using total rock chemical composition, phenocryst mode composition, and mineral composition. We assumed that all the water in the magma was volatilized and the magma temperature at the time of squirting was 1320 K estimated using pyroxene thermometer. the lava flow model used the flow of magma is stopped by solid shell formation by cooling by Griffiths & Fink (1993).

In this study, we investigated the conditions that can explain the thickness and radius of circulation of the basaltic lava of Senryu Shiradake, considering three variables of volume of erupting magma, time change rate of eruption volume and magma temperature. As a result, even if the rate of change of the first eruption amount and the eruption rate were changed, the thickness was only about 20 m at most which did not reproduce 100 m thick lava flow of Senryu Shiradake. Next, the same study as above was carried out assuming that the degree of crystallization at the time of erupting was 50%, but the thickness was about 30 m at most. From this, it is possible that a 100m thick basaltic lava flow was formed by erupting at

# An introduction to the observation method of imaging volcanoes by using cosmic-ray muons

*Seigo Miyamoto[1]

1. Earth Reasearch Institute, University of Tokyo

The purpose of this presentation is widely to inform a method of exploring the density structure inside a gigantic structure such as a volcano, by using high evergy muons included in cosmic rays. It is considered that there are some reasons for low awareness. For example, the history of this method which is applied to Earth and planetary science is still short, knowledge about "Muon" which is one of "cosmic rays" or "elementary particles" is not known widely. To improve such a situation, we will review the fundamental principles to evaluate the internal density of volcanoes using cosmic-ray muons, past and going-on observation examples of volcanoes, and technological developments stories in this presentation.

# Simulation and test observation for omni-directional muography at Omuro-yama

*Shogo Nagahara[1], Seigo Miyamoto[1], Kunihiro Morishima[2], Toshiyuki Nakano[2], Masato Koyama[3], Yusuke Suzuki[4]

1. Earthquake Research Institute,the University of Tokyo, 2. Nagoya University, 3. Shizuoka University, 4. Izu Peninsula Geopark Promotion Council

In the understanding of the eruption of the volcano, the size and the shape of the volcanic vent close to the crater are important. Generally, the size is several to hundreds of meters, and the shape is not simple cylinder. When we consider the largest vent, we need spatial resolution of several tens of meters to measure the shape of vent.

“Muography” is the technique to observe two-dimensional the inner density structure with high spatial resolution. In previous study, they attempted to reconstruct the three-dimensional (3D) density structure by observing the volcano from multiple directions, but they got three-dimensional density structure with only several hundreds of meters spatial resolution because of a few observation points. To improve the spatial resolution, we are planning “omni-directional muography”, putting ten or more observation points to surround the volcano.

We are planning to demonstrate omni-directional muography at Omuro-yama, located in Shizuoka pref., Japan. We have two reasons that we choose this volcano. First, Omuro-yama is a scoria cone formed by a single eruption, so simple structure is expected and it is easy to obtain significant result. Second, there are no objects around near it. In addition, there are no observation of muography at scoria cone.

We carried out the feasibility check of demonstration observation at Omuro-yama by simulation and test observation by using 3 points muography before full observation. In this simulation, we used a method applying Filtered Back Projection. As a result of simulation, it was found that it is necessary to ensure the minimum S / N ratio for the number of muons observed at each observation point. As a result of test observation, it was found that there was a high density part in the west part of crater rim.

In this publication, we will show the detail of simulation of feasibility check and the result of test observation.

# Estimation of pressure source occurring volcanic crustal deformation with FEM considering topography

*Shinya Yamada[1], Tomokazu Kobayashi[1]

1. GSI of Japan

In order to grasp the activity of the volcano and evaluate it, it is necessary to grasp the behavior of the magma and the like. When volcanic disasters such as eruption occurred, we estimated the deformation source assuming volume change of the spherical pressure source or opening displacement of the dike using observation results of crustal deformation obtained by GNSS and InSAR . Conventionally, when calculating the crustal deformation, calculation was carried out based on a model assuming a semi-infinite homogeneous elastic body. However, if there is a deformation source especially in the shallow part of the volcano, the influence of the topography cannot be ignored. In recent years, along with the development of the technology of InSAR, crustal movement at the crater and its surroundings can be observed in a planar manner, and detailed analysis has become possible. Therefore, in order to more accurately estimate the deformation source, it is necessary to estimate with the topography added.

Based on this background, we developed a crustal deformation calculation system that incorporates the Finite Element Method (FEM) that divides elastic bodies into minute meshes and calculates displacement for each mesh. As a result, it became possible to analyze taking model topography and underground structure into account. In this study, we compare the deformation source estimated using the FEM with the deformation source estimated by the conventional method. In this presentation, we mainly examined the eruption of Mt.Ontake in Nagano Prefecture in 2014. We detected about 10cm crustal deformation in the crater and its surroundings with InSAR analysis by ALOS-2 satellite on the eruption (Yamada et al., 2014). Based on this observation result, we estimated the deformation source with a model assuming a conventional semi-infinite homogeneous elastic body, and we obtained the result that the almost vertical crack opened 45 cm. However, since the topography of the region where the crustal deformation was observed by this eruption is steep and it is thought that the deformation is also influenced by the topography, in this presentation we report the results of comparison of the conventional estimation and the estimation considering the influence of the topography.

## [S-VC37] Dynamics of volcanic eruptions and their physical and chemical processes

convener:Yujiro Suzuki(Earthquake Research Institute, The University of Tokyo), Chairperson:Yujiro Suzuki(Earthquake Research Institute, The University of Tokyo), Hiroyuki Shimizu(Earthquake Research Institute, The University of Tokyo)

This session discusses the dynamics of volcanic and igneous activities such as magma accumulation, magma ascent in volcanic conduits, and dispersion of volcanic products. In order to understand such multi-scale phenomena, the researches of microscopic and macroscopic scales and the techniques that combine the different scales are required. We aim to discuss the latest approaches based on the recent observations, laboratory experiments and numerical simulations, from the viewpoint of cross-cutting research.

The existence of a causal link between large earthquakes and volcanic unrest is widely accepted. Recent observations have also revealed counterintuitive negative responses of volcanoes to large earthquakes, including decreased gas emissions and subsidence in volcanic areas. In order to explore the mechanisms that could simultaneously explain both the positive and negative responses of volcanic activity to earthquakes, we here focus on the role played by topography. In the laboratory, we shook a volcanic edifice analogue, made of gel, previously injected with a buoyant fluid. We find that shaking triggers rapid migration of the buoyant fluid upward, downward, or laterally, depending on the fluid’ s buoyancy and storage depth; bubbly fluids stored at shallow depth ascend, while low-buoyancy fluids descend or migrate laterally. The migration of fluids induced by shaking is two orders of magnitude faster than without shaking. Downward or lateral fluid migration may decrease volcanic gas emissions and cause subsidence as a negative response, while upward migration is consistent both with an increase in volcanic activity and immediate unrest (deformation and seismicity) after large earthquakes. The fluid migration is more efficient when the oscillation frequency is close to the resonance frequency of the edifice. The resonance frequency for a 30-km-wide volcanic mountain range, such as those where subsidence was observed, is ~0.07 Hz. Only large earthquakes are able to cause oscillation at such low frequencies.

# Groundmass crystallization experiments of an andesitic pumice under low vapor pressure.

*Yasukawa Hiroki[1], Mayumi Mujin[1], Michihiko Nakamura[1], Shizuka Otsuki[2]

Recently, nanoscale crystals (ultrananolite and nanolite) have been found in groundmass glasses of volcanic rocks. These crystals are thought to crystallize at very shallow part of conduit or inside lava dome. It is suggested that nanoscale crystals recorded information about eruption style transition in shallow conduit. In addition, the eruption style is assumed to be change with viscosity increase due to crystallization of nanoscale crystals. Therefore, it is imoprtant to clarify the nucleation and growth condition of nanoscale crystals for understanding volcanic eruption dynamics . Kinetics of nanoscale crystallization is, however, poorly understood compared to that of microlites. In this study, we performed the series of crystallization experiments that simulate dehydration-induced crystallization in shallow conduit and near surface conditions and investigated the crystallization condition of ultrananolite and nanolite.

As a starting material for the experiments, we used almost microlite-free andesitic pumice clasts from the 1914 (Taisho) Plinian eruption of Sakurajima volcano. The water content in the groundmass glass is approximately 0.5 wt.%. The samples were sealed in a silica glass tube and heated instantaneously to temperatures of 800, 900, 930, and 1000˚C for 3 and 30 minutes, and 2, 8 and 32 hours. When the silica glass tube was evaluated and welded shut, vapor pressure produced via degassing of the starting material is calculated to be of 0.07 (Low Vapor Pressure runs: LVPs). The higher vapor pressures were conducted at 2, 4, and 6 MPa by dehydration of brucite powder.

The mineral assemblage of the crystallized nanolite includes magnetite and pyroxene. The crystallization mode of the groundmass crystals is mostly classified into 5 types; 1) homogeneous nucleation of pyroxene in whole the sample and following growth to the size up to nanolite and occasionally microlite, 2) homogeneous nucleation of ultrananolite in whole the sample, 3) homogeneous nucleation of pyroxene and magnetite crystallization in the vicinity of plagioclase, 4) heterogeneous nucleation of pyroxene on the surface of plagioclase phenocrysts and microlites, and 5) heterogeneous crystallization of pyroxene and magnetite on the bubble surface. Appearance of these types was dependent on the experimental conditions. Magnetite nanolite crystallized under relatively high supercooling, i.e. at low $H_2O$ vapor pressure. Pyroxene nanolite crystallized under wide temperature and pressure conditions. Ultrananolite crystallized in all the runs at 800˚C and at LVP. This indicates that ultrananolite appears under high supercooling. These results on nanoscale crystallization can be used to constrain the pressure-temperature-time paths of volcanic pyroclasts in a shallow conduit.

Keywords: nanolite, ultrananolite

# Decoding pre-eruptive magma evolution and water behavior from plagioclase phenocrysts: Application to the Hoei eruption of Mt. Fuji

*Tsuyoshi Iizuka[1], Chiyo Harada[1], Kenji Shimizu[2], Takayuki Ushikubo[2], Morihisa Hamada[2], Mitsuhiro Yoshimoto[3]

1. University of Tokyo, 2. JAMSTEC, 3. Mount Fuji Research Institute

Explosive eruptions are often accompanied by signs of mixing of felsic and mafic magmas in their eruptive products, suggesting the potential link between explosive eruptions and magma mixing. Yet, the underlying mechanism of such eruptions remains elusive. The key to this debate is understanding pre-eruptive magma evolution including water behavior in the magma and the time lag between the magma mixing and eruption.

Water behavior in pre-eruptive magma has been widely studied using melt-inclusions in phenocrysts. More recently, it has been shown that hydrogen concentration in plagioclase phenocryst can be used as a hygrometer of pre-eruptive magma (Hamada et al., 2013). Furthermore, zoning of hydrogen content in the phenocryst can be used as a high-resolution chronometer, as hydrogen diffusion in plagioclase is sufficiently fast.

Here we report the first study that combines in-situ measurements of the contents of major and trace elements, including hydrogen, in plagioclase phenocrysts using the EPMA, LA-ICP-QMS, and SIMS, respectively. These analyses were carried out on sequential eruptive products of the 1707 Hoei eruption at Mt. Fuji. The Hoei eruption is characterized by its explosivity and wide chemical variation in the eruptive products (e.g., $SiO_2$=50~70 wt%), and the interaction of mafic and felsic magmas has been considered as playing a role in triggering the explosive eruption (Fujii et al., 2002).

We found that the light REE concentrations of plagioclase phenocrysts split in two clusters. These results suggest that there were at least two magma reservoirs underneath Fuji volcano in which magma differentiation had individually proceeded before the Hoei eruption, and also that plagioclase phenocrysts crystallized from these individual magmas were partly mixed before or during the eruption.

Our results further reveal that most melt inclusions have lower water contents than those estimated from hydrogen contents of the host plagioclase phenocrysts and the plagioclase-melt hydrogen partitioning. This suggests that water in melt inclusion could be more easly lost by secondary events than hydrogen in plagioclase phenocryst. Measured hydrogen contents in plagioclase phenocrysts suggest that the early-erupted felsic magma contained water up to 17wt%, whereas the late-erupted mafic magma had lower contents of ~5 wt%. Moreover, the combination of REE and hydrogen contents in the plagioclase phenocrysts (Figure) revealed that the higher water contents, Ce contents, and lower Anorthite contents in the evolved magma can be attributed to fractional crystallization. Moreover, intra-grain chemical variations suggest that rapid crystallization of plagioclase likely driven by decompression accompanied by the exsolution of water occurred in the felsic magma several hours before the explosive eruption. The decompression and water exsolution may result from the convection of the felsic magma caused by the injection of the hot and water-poor mafic magma.

# Probing magmatic processes just prior to historic eruptions at Sakurajima volcano: Toward understanding “magma pre-charge”

*Naoki Araya[1], Michihiko Nakamura[1], Satoshi Okumura[1]

1. Division of Earth and Planetary Materials Science, Department of Earth Science, Graduate School of Science, Tohoku UniversityUniversity

Based on the pressure at which volatiles within phenocryst-hosted melt inclusions and plagioclase rims were finally equilibrated, Araya et al. (2019, Scientific Reports) reported that the magma storage depths immediately prior to the historic Plinian eruptions at the Sakurajima volcano (AD 1471, 1779, 1914) were much shallower (0.9–3.2 km) than those of the present magma reservoirs beneath Aira Caldera (~10 km) and Sakurajima (~4–6 km). They proposed that the Plinian eruptions were fed from a thick shallow conduit pre-charged from the magma reservoirs. How this process, “magma pre-charge”, has occurred is poorly understood because the Sakurajima case is the first report. As magma pre-charge is assumed to have occurred at least a few tens of days before each eruption, probing magmatic processes just prior to the eruptions is a key to prepare for the possible future eruption.

Magnetite is a mineral suitable for investigating short-timescale pre-eruptive processes because of its fast element diffusion (i.e., high time resolution) compared to common phenocrystic silicates. We have analysed chemical compositions of more than 300 magnetite phenocrysts in pumices and lavas from the historic eruptions. The magnetite phenocrysts showed scarce zoning in each crystal (mostly within 1 Usp mol%), while their compositional range is wide (e.g., 27–45 Usp mol% for the 1914–1915 eruption). This indicates that the eruptions had initiated from a magma reservoir heterogeneous in at least either temperature, melt composition, or oxygen fugacity, and that this heterogeneity had not been perturbed prior to the eruptions. Therefore, widely accepted models for eruption trigger, such as new magma injection and overturn of stratified magma reservoir are not likely to apply to these historic Plinian eruptions.

# Magmatic processes prior to the Vulcanian eruptions of Sakurajima volcano: A combined petrologic and geophysical approach

*Sakauchi Nono[2], Michihiko Nakamura[2], ATSUSHI YASUDA[1], Satoshi Okumura[2], Naoki Araya[2], Masato Iguchi[3], Daisuke Miki[3], Nobuo Geshi[4]

1. Earthquake Research Institute, University of Tokyo, 2. Division of Earth and Planetary Materials Science, Department of Earth Science, Graduate School of Science, Tohoku University, 3. Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University, 4. Geological Survey of Japan, The National Institute of Advanced Industrial Science and Technology

We analyzed water contents of phenocryst melt inclusions (= MIs) in the erupted materials of Vulcanian explosions from Sakurajima volcano in a period from October 30, 1975 to February 18, 2015. The 11 typical and characteristic Vulcanian explosions were selected with respect to the seismic and geodetic behaviors prior to the explosions. The water contents of 153 MIs were analyzed with FT-IR micro-reflectance spectroscopy (Yasuda, 2014). We then observed the texture of MIs and analyzed the major chemical element compositions with EMPA.

Most of the MI s have dacitic to rhyolitic compositions. The MIs in lava-type pyroclasts have lower water contents (0–1.9wt.%) than those in the scoria type (0–4.1 wt.%). This is consistent with a general view that the lava-type pyroclasts are derived from degassed and compacted magmas in a very shallow conduit. The MIs with high water contents were quenched and fragmented at deeper parts of the conduit or within short time insufficient for water re-equilibrium with surrounding melt in the shallow conduit.

The MIs in pyroclasts from the Minamidake crater have higher water contents than those from the Showa crater. The average water content of MIs in the samples from the Showa crater is 1.4 wt.%, while that from the Minamidake crater is 0.6 wt.%. This shows that the magma was ejected from the shallower part of conduit or their residence time in the shallow conduit was longer during the activity of the Showa crater, being consistent with the fact that Vulcanian explosions from the Minamidake crater were more vigorous than those from the Showa crater.

The water contents of MIs contained in the pyroclasts erupted on August 24, 1995 from the Minamidake crater were 1.9–4.3 wt.% (2.5 wt.% on average). This range of water contents is similar to those of the three historical Plinian eruptions of Sakurajima (Araya et al., 2019). This indicates that the magma ascended nearly as fast as in the Plinian eruptions, and that magma ascent rate does not solely determine the difference between Vulcanian and Plinian eruptions.

The eruption on August 24, 1995 occurred after approximately 3 months low-activity period. As a precursory phenomenon of the explosion, raid and large intrusion of magma was detected through inflation of the volcanic edifice observed with an extensometer. Five hours after the expansion started (at the time the tiltmeter scaled-out), the eruption began concurrently with the beginning of the BL swarm. In the early stage, the eruption was not accompanied by air shocks, and a fire fountain 100–200 m in height was observed, then later the activity shifted to the Vulcanian explosions with repeated air shocks. The volume of magma intruded prior to the eruption was estimated from the amount of crustal inflation to be more than 5 times as much as that of the average value for the explosions at Minamidake crater. Such a sub-Plinian-like eruption sequence on August 24, 1995 seems to be consistent with the result that the magma ascent rate was close to those of the Plinian eruptions.

# Cyclic degassing behavior accompanying dome-forming lava effusion at Shinmoedake volcano in the 2018 eruption

*Taishi Yamada[1], Hideki Ueda[1], Toshiya Mori[2], Toshikazu Tanada[1]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Geochemical Research Center, Graduate School of Science, The University of Tokyo

Shinmoedake volcano, one of the most active volcanoes in the Kirishima complex in Japan, had a series of eruption in 2018. At the beginning of the eruption sequence in March 2018, Shinmoedake had a dome-forming effusive eruption. Observation networks of the National Institute for Earth Science and Disaster Resilience (NIED, V-net), the Japan Meteorological Agency (JMA), and the Geospatial Information Authority of Japan (GSJ, GEONET) around the Kirishima area detected significant ground deformation accompanying the lava effusion. The deformation can be explained by assuming a pressure source located at the same position (7 km NW from Shinmoedake, depth of 10 km) that is adopted to explain syn-eruptive ground deformation in the 2011 eruption (Ueda, 2018, VSJ). The time series of the magma chamber contraction obtained by geodetic observations provides remarkable insight to constrain the macroscopic behavior of the eruption mechanism. Here, we examine characteristics of volcanic earthquake catalogue, seismic, acoustic, tilt, SO2 gas flux measurement, and visual observation data obtained by observation networks of NIED, JMA, and University of Tokyo, to constrain detail aspects of the effusive eruption such as the magma flow regimes inside the conduit.

Hypocenters of low-frequency earthquakes accompanying the lava effusion are distributed almost vertically in the range of 0.1–3.2 km from the surface. Therefore, we assume vertical elongated conduit geometry. Syn-eruptive seismic waveforms record cyclic tremor signals with a peak frequency of about 0.8 Hz, with a duration of 5–20 minutes as well as repose time. The tremor is accompanied with explosive degassing from the crater, which is recorded by infrasound, SO2 gas flux measurement, and visual camera data. Tilt data with a bandpass filter of 250–2000 s show inflation-deflation cycles of the Shinmoedake edifice accompanying the cyclic degassing. Both inflation and deflation of the filtered tilt data correspond to the repose time and amplitude increasing of the tremor.

Some features of the cyclic degassing at Shinmoedake from our data set are summarized as follows: (1) Inflation of the volcano edifice (2) Beginning of degassing and deflation of the volcano edifice (3) End of degassing and repose time until next inflation. Such an inflation-deflation cycle is reported by Takeo et al. (2013) from observation data of lava effusion in the 2011 eruption. Dome-forming lava effusion at Santiaguito also produces such a cyclic degassing and related ground deformation (Johnson et al., 2014). The inflation prior to the degassing may have similar source physics to that related Strombolian and Vulcanian eruptions. Next our challenge is to quantify the source of those signals to estimate the amount of relating gas or magma, and relationship with the time series of the magma chamber contraction.

## [S-VC37] Dynamics of volcanic eruptions and their physical and chemical processes

convener:Yujiro Suzuki(Earthquake Research Institute, The University of Tokyo), Chairperson:Yujiro Suzuki(Earthquake Research Institute, The University of Tokyo), Taishi Yamada

This session discusses the dynamics of volcanic and igneous activities such as magma accumulation, magma ascent in volcanic conduits, and dispersion of volcanic products. In order to understand such multi-scale phenomena, the researches of microscopic and macroscopic scales and the techniques that combine the different scales are required. We aim to discuss the latest approaches based on the recent observations, laboratory experiments and numerical simulations, from the viewpoint of cross-cutting research.

# Estimation of the amplitude of infrasoundsignal based on sound diffraction

*Kyoka Ishii[1], Akihiko Yokoo[1]

1. Graduate School of Science, Kyoto University

Observation of infrasound signals generated from volcano eruptions provides us with important information directly reflecting explosion processes at the source. How to determine the locations of stations for acquiring clear signals has been one of the most fundamental problems for researchers. The best way to solve this problem should be a numerical simulation of infrasound wave propagation considering the propagation effect of topography (e.g., Kim & Lees, 2011; Lacanna & Ripepe, 2013). However, we have to take time and cost money to perform numerical simulations. In this study, we attempt to estimate the amplitude of infrasound signal by an easier method applying the sound diffraction theory. We replaced the cross-section of topography from the source to the station by an equivalent single screen and calculated the attenuation of the amplitude due to diffraction by the thin screen based on Macdonald's exact solution (1915). Then, our results were compared with the calculated amplitudes from 3D-FDTD simulation (Kim et al., 2015) and the observed amplitudes of 31 explosive events occurring at Showa crater, Sakurajima in September 2017. For comparison, the amplitude value was converted to the amplitude ratio with respect to the amplitude of the KUR station in the line-of-sight with the source. As a result, the amplitude ratios estimated by our method were determined at an accuracy of ±30% of the amplitude from the FDTD simulation at all stations. The amplitude ratio of our method was included in the range of the observed amplitude ratio at five stations. On the other hand, at one station, where the azimuth and distance from the source is almost similar to those of the KUR station, observation results cannot agree with the result of our method. This discrepancy suggests that the infrasound signal is affected by other effects than diffraction, such as reflection at the ground, and further study is required in the future.

# Mechanism and frequency change of pressure oscillation in the laboratory geyser system

*Noriko Teshima[1], Atsushi Toramaru[2]

1. Department of Earth and Planetary Sciences, Graduate School of Sciences, Kyushu University, 2. Department of Earth and Planetary Sciences, Faculty of Sciences, Kyushu University

Geysers are hydrothermal activities seen in volcanic areas, which have the similarities with volcanos in seismicity. It is known that the pressure pulses occurring inside geyser's conduit excite tremors, but the source and mechanism of the pressure pulses are still unclear. Because phenomena of natural geysers are complex due to additional factors such as the influence of atmospheric conditions, and because their interiors are hardly observed directly, simplified laboratory experiments which allow us to directly observe what are happening in the interior may be useful. In this study, we tried to reveal the mechanism of the pressure oscillation and factors controlling its dominant frequency using our fluid oscillation model and pressure and temperature data measured in our laboratory experiments.

We designed an experimental setup which reproduces cyclic eruptions of natural geysers. The setup mainly consisted of a flask and a glass tube, which correspond to natural hot water chamber and conduit, respectively. Heating the flask by the hotplate, we measured pressure and temperature in the flask, and erupted mass of each eruption. We also took video images of flask interior and water surface in the conduit with normal-speed and high-speed video cameras. From the movies of the water surface, we digitalized the vertical water column movement in the conduit using a video analysis software. We examined the effects of experimental conditions on characteristics of pressure oscillation by varying three geometric parameters of the experimental system: (i) inner flask volume, (ii) initial water level in the conduit, and (iii) cross-sectional area of the conduit.

In interpreting experimental results, we used the model proposed by Toramaru et al. (Volcanological Society of Japan 2010 Fall Meeting), in which the frequency of pressure oscillation is represented in terms of geometric parameters of the experimental system and the effective bulk modulus K* of fluid in the flask. In our experiments, it was difficult to determine correctly the effective bulk modulus K* from the movie analysis or another measurement, so we calculated the values of K* using a model to relate the pressure variation in the flask $\Delta P$ and water level in the conduit $\Delta L$, by $AK^*/Vo = \Delta P/\Delta L$, where, A is cross-sectional area of glass tube, Vo is inner flask volume, respectively. The values other than K* were obtained from our experimental measurements. From these expressions, we calculated theoretical values of the resonance frequency and compared it with the measured values of dominant frequency of pressure oscillation.

The results showed that the measured pressure oscillation in the flask consisted of high-frequency pulses and subsequent low-frequency damped oscillation. The damped pressure oscillation had a strong inverse correlation with vertical water column movement in the conduit. From the observation of video images synchronized with pressure record, we found that the bubble formations in the flask bottom caused the pressure pulses. From an eruption to the next eruption, the dominant frequency of pressure oscillation decreased systematically. This monotonic decrease in the dominant frequency was explained by the reduction of K*, as a result of increase in the gas volume in the flask by heating. We found that the dominant frequency of pressure oscillation varied depending on experimental conditions. The variations in temporal behavior of dominant frequency could be interpreted by differences in the setting of

©2019. Japan Geoscience Union. All Right Reserved. 

geometric parameters and in the initial values of K* just after eruptions due to various erupted masses of the preceding eruptions.

In conclusion, the pressure oscillation in the experimental geyser system is caused by bubble formations in the flask and vertical water column movement in the conduit. The dominant frequency of pressure oscillation is controlled by the geometric parameters of the experimental system and the erupted mass of the preceding eruption.

# Effects of temperature on the run-out distance of large-scale pyroclastic density currents: Numerical simulation of a two-layer depth-averaged model

*Hiroyuki A. Shimizu[1], Takehiro Koyaguchi[1], Yujiro J. Suzuki[1]

1. Earthquake Research Institute, The University of Tokyo

During large-scale explosive volcanic eruptions, a mixture of volcanic particles and gas is continuously ejected from the volcanic vent and can flow along the ground surface as a pyroclastic density current (PDC). Understanding the relationship between the run-out distance of PDC (i.e., the extent of PDC deposits) and the eruption conditions (e.g., the magma discharge rate and the temperature of erupted mixture) is desired to mitigate volcanic hazard associated with explosive eruptions. This study aims to clarify the effect of temperature on the run-out distance of large-scale PDCs on the basis of numerical simulations. The effect of temperature is a key issue, because it closely relates to the eruption style; the temperature ranges from less than 500 K for phreatomagmatic eruptions to more than 1000 K for magmatic eruptions.

Generally, the run-out distance of PDC is affected by the vertical stratification of particle concentration in PDC; it is determined by lift-off of the upper dilute part (particle concentrations < 1 vol.%) or deposition of the lower dense part (~ 10—50 vol.%). To reproduce the run-out distance of a density current with a strong density stratification, we have developed a new two-layer depth-averaged model. In order to evaluate the effects of temperature on the PDC dynamics, our model considers entrainment of ambient air into the upper dilute current, and thermal expansion of the entrained air. We assumed that a homogeneous dilute current is steadily supplied during time > 0 from the source vent on a horizontal ground surface. We performed a parametric study for various temperatures of the dilute current at the source (400—1200 K).

The numerical results show that, as a dilute current spreads radially from the source, the current density decreases through particle settling, air entrainment, and thermal expansion of the entrained air. When the frontal region of the dilute current becomes lighter than the ambient air to reverse buoyancy and lift off, the dilute current stops forward propagation and converges to a steady state (the distance between whose front position and the source position is referred to as $r_{\infty U}$). Particles settling from the base of the dilute current form a thin dense current, which also spreads radially. As the radial mass flux of the dense current at the front balances the basal deposition rate, the dense current stops forward propagation and converges to a steady state (the distance between whose front position and the source position is referred to as $r_{\infty L}$). The result of the parametric study shows that the relative magnitude between $r_{\infty U}$ and $r_{\infty L}$ depends on the temperature: $r_{\infty U}$ is shorter than $r_{\infty L}$ in high-temperature cases (> 600 K) whereas $r_{\infty U}$ is longer than $r_{\infty L}$ in low-temperature cases (< 600 K). This variation comes from the fact that the lift-off distance of the dilute current (i.e., $r_{\infty U}$) significantly increases as the temperature decreases, because thermal expansion of entrained air is suppressed with the decreasing temperature. The results of the low-temperature cases (i.e., $r_{\infty U} > r_{\infty L}$) explain the observation that stratified surge deposits originated from dilute PDCs are widely observed in the deposits of phreatomagmatic eruptions.

# Total grain-size distribution of pumice fallout deposits (Kj-P1) from 54 ka plinian eruption at Kuju Volcano

*Tomohiro Tsuji[1], Kishimoto Hiroshi[2], Fujita Kouji[2], Chisato Nakamura[3], Nagata Tomohiro[3], Kimura Kazunari[3], Michiharu Ikeda[1], Naoki Nishizaka[4], Kozo Onishi[4]

1. Shikoku Research Institute Inc., 2. Asia Air Survey Co. Ltd., 3. Naiba, 4. Shikoku Electric Power Co. Inc.

Constraining physical parameters (e.g. Total grain-size distribution; TGSD) of tephra dispersion and deposition from explosive volcanic eruptions have been studied using observation and analyses of deposits of recent eruptions. However, TGSD of old tephra deposit is a significant challenge and has been rarely studied, because of the difficulty of measuring grain size of altered pumice particles and lack of observation. In this study, to estimate TGSD of VEI5 dacitic plinian explosive eruption occurred at 54 ka at Kuju volcano, we conducted geological survey and grain size analyses for the Kj-P1 pumice fall deposit.

Based on grain-size distribution, maximum pumice size and components, Kj-P1 pumice fall deposit is divided into finer lower and coarser upper layer. We analyzed each grain-size distribution for the lower and upper layers.

Generally, sieving and laser-diffraction analysis have been used for measuring grain-size of tephra and we also used these methods. However, because the upper layer of Kj-P1 has been altered and lumped, it can be hardly separated. In addition, because the altered pumice particle could be broken into finer particles under water, we cannot measure accurate grain sizes. Then, we challenged a new method, image analysis, outlining pumice particles on photographs of outcrops and measure the sizes and area ratio of each pumice particles. We combined the results of the image analyses, sieving and laser-diffraction analyses at 15 and 20 localities for the lower and the upper layers. Using volonoi distribution, Md phi and sigma phi are calculated to be -1.5 and 2.5 for the upper layer and 0.5 and 2.6 for the lower layer. The result fit the observation of altered pumice particles at the outcrops better than the result without the image analyses. To verify this method, analytical methods such as numerical simulation are needed.

# Estimating ashfall volumes for the 2018 Shinmoedake eruptions using the Ellipse Approximated Isopach (EAI) method - How to quantify ashfall volumes from limited ashfall observation locations

*Yasuhisa Tajima[1], Setsuya Nakada[2], Masashi NAGAI[2], Fukashi Maeno[3], Jun Oikawa[3], Teruki Oikawa[4], Yasuo Miyabuchi[5], Toshiaki Hasenaka[5], Masataka Kawaguchi[5]

1. NIPPON KOEI CO.,LTD., 2. NIED, 3. ERI, the Univ. Tokyo, 4. Geological Survey of Japan, AIST, 5. Kumamoto Univ.

A volcanic ash eruption began on March 3, 2018 at the Shinmoedake Volcano, in the Kirishima Volcanoes Group. Eruption activity increased to March 5, and lava flow was observed on March 6. Eruptions continued until June 27. We observed volcanic ashfall amounts around the Shinmoedake Volcano and analyzed volcanic ashfall volumes for each eruption using the EAI method (EAI ashfall volume) proposed by Tajima et al. (2013). The EAI method can be used in four different ways. Firstly, ashfall volume is estimated based on one ashfall deposit data point. Second, the estimation is undertaken using two ashfall deposit data points. Third, the estimation is based on three ashfall deposit data points. Fourth, the estimation is based over four ashfall deposit data points.

Tajima et al. (2013) suggest that if an accurate calculation axis and an accurate aspect ratio of a distribution are determined, we can calculate the total volume of ashfall deposit using the EAI method using only one ashfall deposit data point. The calculation axis for the ellipse must be accurate, but it is difficult to determine an accurate calculation axis from the observation. Tajima et al. (2013) determined the lower threshold of detectable ashfall as 0.1 $g/m^2$ for an eruption of the Sakurajima Volcano. This lower threshold of detectable ashfall value is used in this calculation. The EAI method is used based on one data point calculation, and we have taken a suitable aspect ratio of the ellipse which is fitted between the EAI isopach from 0.1 $g/m^2$ and a limit location of detectable ashfall. We calculated ashfall deposit volumes for the period of eruption from 11 am on March 1 to 7 am on March 2.

Next, we demonstrate a calculation using two data points. Tajima et al. (2013) suggest, if an accurate axis of the ellipse distribution is determined, we can calculate an EAI ashfall volume of the deposit using two ashfall data points. In this case, we would need a limit location of a detectable ashfall deposit, because it is difficult to determine an accurate calculation axis. In this case we select two ashfall deposit data points for the EAI calculation, then we determine a suitable axis which is fitted between the EAI isopach as 0.1 $g/m^2$ and a limit location of visible ashfall. In this way, we estimated the EAI ashfall volume of the eruption at 15:58 pm on March 9. For comparison, we observed a limit location of visible ashfall on a car.

We show a calculation procedure for three ashfall deposit data points. This is a normal calculation case shown by Tajima et al (2013). We select two ashfall deposit data values for the EAI calculation, and determine a suitable axis to fit the observation points and the calculated distribution. However, sometimes it is take the over or under estimated volume from the calculation, because estimation of EAI ashfall volume can be influenced by environmental variables, such as wind direction changes, depositional conditions of ash-fall, and other research conditions. Lastly, we demonstrate the estimation of ashfall deposit volumes using four ashfall deposit data points. In this case, we select two ash-fall values for the EAI calculation. We determined a suitable axis which best fits the observation points and the calculated distribution. Using four ashfall deposit data points improves accuracy.

©2019. Japan Geoscience Union. All Right Reserved. 

It is determined the EAI ashfall volumes of over 10 eruptions of the 2018 Shinmoedake eruptions. We assume that the eruption rate of each volumes per an hour increased before the lava flow producing. We will discuss the accuracy of the EAI method and the practical applications of this method.

# Optical disdrometer measurement of tephra fall: Constraints on radar parameters for eruption cloud observations

*Tomofumi Kozono[1], Masato Iguchi[2], Takahiro Miwa[3], Masayuki Maki[4], Takeshi Maesaka[3], Daisuke Miki[2], Takeshi Nishimura[1]

1. Department of Geophysics, Graduate School of Science, Tohoku University, 2. Sakurajima Volcano Research Center, Disaster Prevention Research Institute, Kyoto University, 3. National Research Institute for Earth Science and Disaster Resilience, 4. Research and Education Center for Natural Hazards, Kagoshima University

A tephra fallout process during a volcanic eruption has mainly been investigated by geological method such as based on measurement of mass and grain size distribution on tephra deposits. Recently, a combination of the tephra fallout deposit data with numerical simulations of tephra dispersal and fallout contributes to understanding the detail of the eruption dynamics. In order to further promote the combination between the simulations and the observations, we need multi-parameter observations of the eruptive phenomena with high-time resolution which is comparable with the timescale of the eruption. One of the methods for the high-resolution observations is to apply techniques already used in other fields, such as precipitation measurements by weather radar and disdrometer in meteorology. In this study, we investigated the main characteristics of tephra fall from the eruptions at Sakurajima volcano in southern Kyushu, Japan by using a laser based optical disdrometer, Parsivel.

The disdrometer measurements were carried out for two years at one station located 2.5 km south of Showa crater of Sakurajima volcano, and made it possible to detect 76 tephra fall events, in which particle size and fall velocity were simultaneously measured with one-minute sampling interval. We found that the tephra fall can be easily distinguished from precipitation because of a notable feature of the tephra fall that both the particle size and the fall velocity gradually decrease with time during each event. The detected events were compared with the information about the direction of eruption cloud which is reported in eruption list by JMA, and it was found that the detection rate of the tephra fall during the eruptions with south-directed eruption cloud is about 7 times higher than that with other directions. Furthermore, the feature of the temporal changes in the size and the velocity was also most obvious in the case of south-directed eruption cloud. These indicate that the disdrometer can successfully measure the tephra fall directly reaching from the crater location to the station, and that the disdrometer measurements at multiple stations covering all directions may provide valuable information about the tephra dispersion and eruption cloud dynamics.

By using the tephra fall events, we obtained a quantitative relationship between the particle size and fall velocity. The cumulative weight of the tephra fall during one event was also measured by digital electric scale set close to the disdrometer, which enabled us to calculate the density of the particles. On the basis of the size-velocity relationship and the particle density data, we can estimate morphological parameters of volcanic particles in models of terminal fall velocity in previous studies. Furthermore, the tephra size and fall velocity data enabled us to calculate a particle size distribution per unit volume and size class, and we found that this distribution is well explained by exponential distribution. In the case of precipitation, the value of exponent is modeled as a function of the amount of rain fall. When we estimate the exponent as a function of the amount of the tephra fall using the same manner as precipitation, it was found that the exponent is smaller than that for precipitation. Because the size-velocity relationship and the particle size distribution are important parameters for radar analysis, the formulation and parametrization for its relationship and distribution in this study can be utilized for eruption cloud observations by weather radar.

Summary and Considerations about Borehole Stress Meter for Continuous Observation

We will explain the following items
1. Stress Meter can Observe both Stress and Strain
2. Stress unlike Strain can be Derived without Knowing an Elastic Constant
3. Why is Observed Elastic Invariants Similar with Vertical Component ?
4. How High Resolution Does a Stress Meter Have ?
5.How Wide Observation Range Does a Stress Meter Have ?

# Seismic monitoring by an autonomous robotic float equipped with a hydrophone: MERMAID

*Masayuki Obayashi[1], Hiroko Sugioka[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Department of Planetology, Kobe University

Seismic monitoring in the oceans has been limited to rather localized experiments such as ocean bottom seismometers (OBSs) and moored hydrophones. Because about 70% of the Earth is covered by water, advances in seismic monitoring depend on the development of radically new instruments, capable of providing seismic data all over the ocean. Recently a new instrument, named MERMAID (Mobile Earthquake Recording in Marine Areas by Independent Divers), was developed to measure acoustic signals converted from seismic waves at the seafloor. The MERMAID is an autonomous robotic float equipped with a hydrophone and drifts passively at 1,500 −2,000 m depth until an earthquake signal is detected. If this is identified as a strong P wave, the MERMAID ascends at speed of 10 cm/s for transmission of the recorded waveform within time window of a hundred seconds before and after the P wave arrival as well as its global positioning system coordinates at the surface. After transmitting the data via satellite links, the MERMAID descends at speed of 5 cm/s to monitor earthquake signals at 1,500 −2,000 m depth again. Therefore we are able to obtain seismograms from the ocean in quasi-real time. Under an international project collaborated among Japan, France, United States and China, we planed to deploy more than 40 drifting buoys with hydrophone to image the detail of the South Pacific mantle plume that is one of two huge mantle plumes from the base of the mantle. As part of this project, we deployed drifting floats in the South Pacific during the 1st leg of MR18-06 cruise. We will show the obtained seismograms and discuss their quality.

# Earthquake observation in a borehole over 250 ˚C using high temperature optical fiber and DAS technology

*Tsunehisa KIMURA[1]

1. Schlumberger

DAS (Distributed Acoustic Sensing) technology has been used to meet the demands of pipeline monitoring and intrusion detection in Oil & Gas business since 2011. The latest optical fiber sensing technology using differential phase data called “hDVS” (heterodyne Distributed Vibration Sensing), now enables DAS to record seismic signal including VSP (Vertical Seismic Profiling)[1)]. Three-dimensional imaging can also be performed by a 3DVSP method[2)]. We have introduced the observation of natural earthquakes and waves, targeting the tsunami detection, using the hDVS device at recent meetings of JpGU and the seismological society of Japan (SSJ)[3)].

Late 2018, we conducted an experiment of natural earthquake observation using the hDVS system at the geothermal well in Japan. A high temperature optical fiber logging cable with 300 ˚C rating was run in a deviated well having a maximum depth of about 1,600 m and connected the third generation hDVS acquisition system to the optical fiber (single mode fiber) and recorded natural earthquake events for 5 days. The maximum temperature recorded at a depth of about 900 m was more than 250 ˚C. Under such a high temperature environment, almost all electronic, electric and magnetic sensors including seismometers cannot operate for a long time. Even with the use of DAS equipment, there is no precedent as far as I know, at least it is the first attempt in Japan.

A weight of 2 m length and 25 kg weight was attached to the high temperature optical fiber logging cable, and the observation was started by lowering the weight to the depth of 977 m inside the casing in order to avoid the weight becoming stuck in the open hole section of the well. With continuous recording with 60 seconds as one file, data of 975 m section from the surface was recorded for 5 days. In this paper, we report on the result of verifying how much observation of natural earthquake waves can be performed by using continuous measurement data.

During the observation period, we succeeded in capturing six natural earthquake events. Two of them were medium-scale earthquakes published in the earthquake information of the Japan Meteorological Agency (JMA). An example of this was recorded as follows.

**(21st of November, 2018 04:09:49.9 Latitude 30˚24.0'N Longitude 130˚9.0'E 123km depth M5.2)**

Earthquake data recorded by hDVS is shown in Fig. 1.

The arrival time of the P-wave analyzed from the waveform is 4:10:12.2 JST on 21st of November at the deepest part of the borehole and 4:10:12.5 JST near surface. Measurement parameters were gauge length 4 m, spatial sampling 1 m, and sampling period 1 msec. We also conducted reprocessing to change the gauge length and confirmed that data with higher S/N can be obtained. Reprocessing the raw data for an optimized gauge length is a capability that is unique to hDVS amongst the available DAS techniques.

We also compared it with continuous seismometer records by NIED (Hi-net). The nearest Hi-net station

from the wellsite (just about 4km away), is compared with the recorded hDVS data, and it was found that they match well. For small earthquake events, S/N was higher in the measurement data of hDVS in some cases, which will be shown during the presentation.

It was confirmed that hDVS/DAS system can be used to monitor natural earthquake events while monitoring the reservoir or other purpose under very high-temperature condition such as geothermal well or very deep well that reaches a mantle, if the condition of the optical fiber is good.

Acknowledgements: JMA and NIRD data are used as a reference earthquake data for comparison. We thank these organizations.

# Distributed Acoustic Sensing measurement by using seafloor optical fiber cable system off Sanriku for dense seismic observation

*Masanao Shinohara[1], Tomoaki Yamada[1], Takeshi Akuhara[1], Kimihiro Mochizuki[1], Takeo Kasajima[2], Takahiro Arioka[2], Masayuki Hamakawa[3], Shunsuke Kubota[4]

1. Earthquake Research Institute, University of Tokyo, 2. Fujitsu Laboratories Ltd., 3. Fujitsu Limited, 4. YK Giken Co., Ltd.

Recently Distributed Acoustic Sensing (DAS) measurement which utilizes an optical fiber itself as a sensor becomes popular for security surveillance, monitoring of oil pipe line system. etc. In addition, DAS measurement begins to be applied to seismic prospecting such as vertical seismic profiling for an exploration of energy resources. As DAS measurement is thought to be useful for earthquake observation, there is a trial to observe an earthquake using a seafloor optical fiber. DAS measurement is one of optical fiber sensing technologies. A coherent laser pulse with short duration is transmitted continuously to a single mode optical fiber, and backscattered light is observed. When a small deformation of a fiber occurs by a vibration near fiber, a pattern change of the backscattered light is observed. Travel time of light and pulse length correspond to distance of measurement point and spatially resolution, respectively. Spatially resolution is 1 - 20 m in the highest case. From these characteristics, DAS measurement enables a linear array seismic observation. A length of the array with short sensor interval corresponds to that of a deployed optical fiber. Using the present technology, the maximum length of a DAS measurement reaches more than 70 km. On the other hand, development of data processing is needed because the principle of measurement by the DAS differs from that of conventional seismic measurement using a pendulum. In 1996, a seafloor seismic tsunami observation system using an optical fiber cable was deployed off Sanriku by Earthquake Research Institute, the University of Tokyo. The system still continues the observations experiencing an interruption by a damage of the 2011 Tohoku-oki earthquake. The system has six spare (dark) optical fibers for future extension. The length of dark fibers is about 120 km without a repeater. The dark fibers are suitable for DAS measurement due to dispersion shifted single mode fiber. Therefore we start development of a seafloor seismic observation system by the DAS technology with Sanriku cable observation system as a next generation of marine seismic observation system. The observation system using the DAS measurement can increase spatial resolution on seafloor seismic observation. In February 2019, we made a pilot observation of DAS measurement using a dark fiber of Sanriku seafloor observation system. An interrogator was installed in the landing station temporarily, data were recorded continuously for 100 km length with spatial resolution of 10 m or 40 m and sampling frequency of about 500 Hz. As a result, earthquakes including small local earthquakes occurring near the cable system, deep earthquakes were recorded. We will develop data processing using the obtained data.

# Proposal of the low cost seismometer network system

*Takamori Ito[1], Takashi Akazawa[2], Koichi Kusunoki[3], Masato Yazawa[4]

1. aLab Inc., 2. Geo-Research Institute, 3. ERI, The University of Tokyo, 4. MAD Lab.

In the IT strong-motion seismometer (Takano et al. 2004), we aimed at realizing "the earthquake disaster prevention information system which can be offered for grassroots organizing" at first. The development as the general-purpose seismometer network does not advance. One of these causes is that operative cost of the whole system including a network was not low conventionally. We regarded a method to build a seismometer network in a low price as VPS(virtual private server) using VPN(virtual private network) and began examination use.
http://itk.seism.jp/
We use WIN system as a telemeter system. It is a stable system and is used widely. However, the transfer method of the WIN system is weak to use it on the Internet. The VPN router to deal with it is expensive. We can cut the cost of this part by realizing VPN by usable free software. In the WIN system, X-Window is used in display basically and is difficult to approach other than some researchers. In the prototype IT strong-motion seismometer, we realized display via the Web using CGI and Java applet. Because support of the Java applet was broken off, we realized waveform display by the Web using a JavaScript.
We use VPS of the SAKURA Internet Inc. for a core server. Virtual machine with a fixed global IP address is offered in 685 yen / month. We use OpenVPN as VPN. We use RaspberryPi for other construction apparatuses. The global addresses are unnecessary for them. The seismometer can raise a low price by connecting ADXL355 of the MEMS acceleration sensor of Analog Devices, Inc. to RaspberryPi. Because WIN system is carried out on RaspberryPi, existing win output logger can do this network connection through RaspberryPi.
We continue examination use and will push forward development of the application that made use of this network in future.

# Experimental observation toward the realization of low-cost and high-density strong-motion observation network

*Takashi Akazawa[1], Takamori Ito[2]

1. Geo-Research Institute, 2. aLab Inc.

After the 1995 Kobe earthquake, high-density strong-motion observation network without parallel in the world has been improved in Japan. For example, the National Research Institute for Earth Science and Disaster Resilience (NIED) built K-NET (Kyoshin network), which consists of more than 1,000 seismic observation stations distributed every 20 km uniformly covering Japan. In Kansai area, together with the network, The Committee of Earthquake Observation and Research in the Kansai Area (CEORKA) has built one’ s own strong-motion observation network since 1994. However, under the existing observation density, there is a limit to comprehend the seismic ground motion. To solve the problem, there is a method of increasing the number of seismic observation station furthermore. However, the method requires a huge amount of money.
We developed a prototype of a low-cost ITK sensor, which is composed of Raspberry Pi (small single-board computer) and ADXL355 (MEMS acceleration sensor), corresponded to the IT strong-motion seismometer and began experimental observation using the sensor for evaluating the performance as a strong-motion seismometer, in parallel with the experimental operation of the low-cost seismometer network using VPS (Virtual Private Server) and VPN (Virtual Private Network) (Ito et al. (2019)). We will continue the experimental observation and will conduct further examination toward the realization of low-cost and high-density strong-motion observation network.

# Comparison of noise levels of the JMA and F-net broadband seismographs / strong motion velocity-type seismographs in long-period range for the purpose of magnitude estimation of tsunami earthquakes

*Masayuki Tanaka[1], Akio Katsumata[1]

1. Meteorological Research Institute

Slow tsunami earthquakes generate tsunamis higher than those expected from conventional magnitude such as surface wave magnitude $M_s$ or the Japan Meteorological Agency (JMA) magnitude $M_J$ (Kanamori, 1972). The 1992 Nicaragua earthquake ($M_s$ :7.2, $M_w$ :7.6) is considered as a typical slow tsunami earthquake because the rupture duration exceeded 100 seconds (e.g., Satake *et al.*, 1993). Therefore, the observation data from the broadband seismograph is very promising in the analyses of mechanism and the magnitude estimation of such an earthquake. In Japan, data from the Full Range Seismograph Network of Japan (F-net) operated by the National Research Institute for Earth Science and Disaster Resilience is utilized. The broadband seismographs are susceptible to temperature changes. Seismometers of the F-net are installed in vaults. According to previous studies, the strong motion velocity-type seismograph of F-net would be helpful for estimating size of tsunami earthquakes (e.g., Tanaka and Katsumata, 2017 SSJ Fall Meeting, Tanaka and Katsumata, JpGU Meeting 2018, Tanaka and Katsumata, 2018 SSJ Fall Meeting). The JMA also installed the broadband seismographs and the strong motion velocity-type seismographs, but it is not necessarily together at the same site. However, the observation environments of the JMA stations are not as good as these of the F-net stations, for example they are not installed in the vaults. We examined the background noise level from the observed continuous waveform data of JMA and F-net. The power spectral densities are calculated for the 1-day length time-window data with moving it with a step of the half day (e.g., McNamara and Buland, 2004). From the results, we investigate whether the broadband seismographs and the strong motion velocity-type seismograph of the JMA can be used for magnitude estimation of tsunami earthquakes. Figure 1 shows the power spectral densities of the vertical component of the strong motion velocity-type seismograph at the Nemuro Toyosato station of the JMA (Red line) and the nearby F-net Nemuro station (Blue line). The period is one hour from 00:00 January 1, 2019. The noise levels of the two recordings are approximately the same.

Acknowledgment
We used waveform data of F-net (NIED).

# Estimation of seismic wave velocity of seafloor surface and installation orientation at S-net station based on observed waveform of air gun: Toward sound source localization of large baleen whale

*Ryoichi Iwase[1]

1. National Research and Development Agency, Japan Agency for Marine-Earth Science and Technology

The vocalization of fin whale, one of the large baleen whales, has been detected with hydrophones and ocean bottom seismometers (OBSs) which are equipped with submarine cabled observatories off Kushiro-Tokachi in Hokkaido, off Sanriku, and off Boso Peninsula (Iwase, 2015). In recent years, a large cabled observatory "S-net"(Seafloor observation network for earthquakes and tsunamis along the Japan Trench), consisting of 150 stations in the vast range from Hokkaido to Chiba in the Pacific Ocean off the east coast of Japan, was deployed by National Research Institute for Earth Science and Disaster Resilience (NIED). The waveform data of the observatory are open to public. Not only for the observation and early detection of earthquakes and tsunamis, “S-net" would expand the capability of the vocalization detection area that had been limited to local to the one in a vast ocean area, It is expected that it will contribute to the elucidation of migratory behaviors of the baleen whales in the West Pacific, which has been a mostly unknown area, especially in the waters of Japan.
Meanwhile, in order to elucidate these behaviors, it is desirable that not only to detect whale vocalization but also to know individual movement based on sound source localization becomes possible. However, unlike earthquakes, the source sound pressure level of the whale vocalization is usually not so large as to be detected at multiple stations constituting the cabled observatory. It is necessary to localize the sound source with waveform data at a single station. As a sound source localization method using a single three component seismometer, there is a method of using the incident angle of the underwater sound at seafloor based on particle motion for the horizontal distance estimation, in addition to the estimation of the azimuth, of sound source. However, the OBS can only observe the apparent emergence angle of the transmitted wave, which is a composite of a pressure wave (P-wave) and a vertical shear wave (SV wave), which are both converted at the seafloor provided that the incidence angle is less than the critical angle. Therefore, the relationship between the incidence angle and the apparent emergence angle depends not only on the difference in P-wave velocity between the water and the sediment of the seafloor surface but also on the S-wave velocity in the sediment. Thus, both the P-wave velocity and the S-wave velocity in the sediment are necessary. In Iwase (2016), the seismic wave velocities in sediment were estimated *in situ* based on the observation of the transmitted wave of an air gun signal, whose sound source location is known, using an OBS at the cabled observatory offshore of Kamaishi in Sanriku which was deployed by Earthquake Research Institute (ERI), the University of Tokyo. Specifically, the seismic velocities were estimated by comparing the apparent emergence angle of the transmitted wave, which was obtained from the observed particle motion, with the theoretical emergence angle based on the Zoeppritz equation assuming plane-wave incidence at fluid-solid boundary.
With regard to S-net, JAMSTEC's research vessel "Kaimei", whose track line data are published on the web, passed through in the vicinity of some stations while oscillating the air gun. The same method in Iwase (2016) is applicable.
This time, the estimated results of seismic wave velocities of seafloor surface and installation orientation at S-net station will be reported based on the open data of NIED and JAMSTEC.

# Parametric time series –video sincronization tool

*Gerardo Manuel Mendo Pérez[1], Alejandra Arciniega Ceballos[1,2], Alejandro Rosado Fuentes[1]

1. Earth Science Graduate Program, National Autonomous University of Mexico, 2. Department of Volcanology, Institute of Geophysics, National Autonomus University of Mexico

In recent years, the development of experimental methodologies and techniques have facilitated the study of volcano-conduit dynamics through high-sensitive laboratory experiments; in which parametric time series and high-resolution videos have been analyzed separately. We present a computational tool that synchronizes parametric time series with high-resolution videos in cases where the experimental setup allows the physical phenomena to be filmed. The open-access program has been writen in Python using ObsPy (time series processing) and OpenCV3.0 (image processing) libraries and runs in different operating systems. It scales parametric time series and video frames in order to run both at same time and correlate characteristics of interest. In addition, the program can display multiple-parameter time series in one frame to study and interpret them together. We present some examples where elastic signals were sincronized with high-resolution videos in experiments that aim to understand elasto-dynamic behavior of conduits and the fluid-rock interaction. Our results display good correlation between the elastic characteristics shown in signals and the physical phenomena observed in the video. This program is an alternative tool for processing experimental data of parametric time series correlated with video frames. The program will be available under request to the main author's email.

# Estimation of seismic wave velocity of seafloor surface and installation orientation at S-net station based on observed waveform of air gun: Toward sound source localization of large baleen whale

*Ryoichi Iwase[1]

1. National Research and Development Agency, Japan Agency for Marine-Earth Science and Technology

The vocalization of fin whale, one of the large baleen whales, has been detected with hydrophones and ocean bottom seismometers (OBSs) which are equipped with submarine cabled observatories off Kushiro-Tokachi in Hokkaido, off Sanriku, and off Boso Peninsula (Iwase, 2015). In recent years, a large cabled observatory "S-net"(Seafloor observation network for earthquakes and tsunamis along the Japan Trench), consisting of 150 stations in the vast range from Hokkaido to Chiba in the Pacific Ocean off the east coast of Japan, was deployed by National Research Institute for Earth Science and Disaster Resilience (NIED). The waveform data of the observatory are open to public. Not only for the observation and early detection of earthquakes and tsunamis, “S-net" would expand the capability of the vocalization detection area that had been limited to local to the one in a vast ocean area, It is expected that it will contribute to the elucidation of migratory behaviors of the baleen whales in the West Pacific, which has been a mostly unknown area, especially in the waters of Japan.
Meanwhile, in order to elucidate these behaviors, it is desirable that not only to detect whale vocalization but also to know individual movement based on sound source localization becomes possible. However, unlike earthquakes, the source sound pressure level of the whale vocalization is usually not so large as to be detected at multiple stations constituting the cabled observatory. It is necessary to localize the sound source with waveform data at a single station. As a sound source localization method using a single three component seismometer, there is a method of using the incident angle of the underwater sound at seafloor based on particle motion for the horizontal distance estimation, in addition to the estimation of the azimuth, of sound source. However, the OBS can only observe the apparent emergence angle of the transmitted wave, which is a composite of a pressure wave (P-wave) and a vertical shear wave (SV wave), which are both converted at the seafloor provided that the incidence angle is less than the critical angle. Therefore, the relationship between the incidence angle and the apparent emergence angle depends not only on the difference in P-wave velocity between the water and the sediment of the seafloor surface but also on the S-wave velocity in the sediment. Thus, both the P-wave velocity and the S-wave velocity in the sediment are necessary. In Iwase (2016), the seismic wave velocities in sediment were estimated *in situ* based on the observation of the transmitted wave of an air gun signal, whose sound source location is known, using an OBS at the cabled observatory offshore of Kamaishi in Sanriku which was deployed by Earthquake Research Institute (ERI), the University of Tokyo. Specifically, the seismic velocities were estimated by comparing the apparent emergence angle of the transmitted wave, which was obtained from the observed particle motion, with the theoretical emergence angle based on the Zoeppritz equation assuming plane-wave incidence at fluid-solid boundary.
With regard to S-net, JAMSTEC's research vessel "Kaimei", whose track line data are published on the web, passed through in the vicinity of some stations while oscillating the air gun. The same method in Iwase (2016) is applicable.
This time, the estimated results of seismic wave velocities of seafloor surface and installation orientation at S-net station will be reported based on the open data of NIED and JAMSTEC.

# Parametric time series –video sincronization tool

*Gerardo Manuel Mendo Pérez[1], Alejandra Arciniega Ceballos[1,2], Alejandro Rosado Fuentes[1]

1. Earth Science Graduate Program, National Autonomous University of Mexico, 2. Department of Volcanology, Institute of Geophysics, National Autonomus University of Mexico

In recent years, the development of experimental methodologies and techniques have facilitated the study of volcano-conduit dynamics through high-sensitive laboratory experiments; in which parametric time series and high-resolution videos have been analyzed separately. We present a computational tool that synchronizes parametric time series with high-resolution videos in cases where the experimental setup allows the physical phenomena to be filmed. The open-access program has been writen in Python using ObsPy (time series processing) and OpenCV3.0 (image processing) libraries and runs in different operating systems. It scales parametric time series and video frames in order to run both at same time and correlate characteristics of interest. In addition, the program can display multiple-parameter time series in one frame to study and interpret them together. We present some examples where elastic signals were sincronized with high-resolution videos in experiments that aim to understand elasto-dynamic behavior of conduits and the fluid-rock interaction. Our results display good correlation between the elastic characteristics shown in signals and the physical phenomena observed in the video. This program is an alternative tool for processing experimental data of parametric time series correlated with video frames. The program will be available under request to the main author's email.

## [S-CG48] Science of slow earthquakes: Toward unified understandings of whole earthquake process

convener:Satoshi Ide(Department of Earth an Planetary Science, University of Tokyo), Hitoshi Hirose(Research Center for Urban Safety and Security, Kobe University), Kohtaro Ujiie(Graduate School of Life and Environmental Sciences, University of Tsukuba), Takahiro Hatano(Earthquake Research Institute, University of Tokyo), Chairperson:Kimihiro Mochizuki(Earthquake Research Institute, University of Tokyo), Ryuta Arai

Accumulating observational studies on various types of slow deformation events, such as tectonic tremors, very low frequency events, and slow slip events, portrays some universal characteristics in generally complex behavior, including interaction among events and influence by various outer loadings. Some of these phenomena seem to have causal relation with the occurrence of very large earthquakes. A unified understanding of these slow and fast earthquake processes requires an approach integrating geophysics, seismology, geodesy, geology, and non-equilibrium statistical physics. We welcome presentations based on, but not limited to, geophysical observation, data analysis, analytical theory, numerical simulation, field study, and laboratory experiments.

Slow earthquakes occur around the seismogenic zones of the plate boundary faults and they have so far been largely studied on the deep portions of the plate interface based on land-based geophysical observations. On the other hand, recent marine studies reveal that shallow slow earthquakes at the up-dip portions of seismogenic zones are also common in subduction zones. These shallow slow earthquakes have been found to occur from near the trench to ~10 km depth of the plate interface and their genesis is thought to be closely linked to fluid pressures and effective stresses at the fault. However, primary controls on seismogenesis at these depths, such as fault structures and stratigraphic/hydrogeologic properties around the subduction megathrust faults, are highly complex in three dimensions and poorly understood.

In order to refine our understanding of structural characteristics regulating slow earthquakes occurring at shallow plate boundaries, we collected 3-D seismic refraction/wide-angle reflection data from offshore Gisborne at the northern Hikurangi subduction margin, New Zealand, as part of an international collaborative project, NZ3D. The dataset covers an area of 60 km x 14 km ranging from the northern Tuaheni landslide complex and the easterly forearc slope to the subduction trench and was recorded on 97 ocean bottom seismographs deployed with an average spacing of 2 km on 4 parallel lines with over 140,000 airgun sources. In the study area, shallow slow slip events and tectonic tremor have been well documented (Wallace et al., 2016; Todd et al., 2018). Previous 2-D seismic reflection studies also show that the subduction of large-scale seamounts facilitates the transport of fluid-rich sediments deep into the subduction zone and produces conditions of high fluid pressures along the plate interface and pathways for fluid migration into the overriding plate (Bell et al., 2010; Barker et al., 2018).

Using the very dense airgun-OBS data, we constructed a preliminary three-dimensional P-wave velocity structure model of the accretionary forearc and the plate boundary from first arrival tomography. The velocity images from over 250,000 first arrivals revealed a thick low-velocity (Vp < 5.0 km/s) volume along the plate interface down to a depth of at least ~10 km. This velocity structure may represent a thick subduction channel filled with fluid-rich sediments associated with seamount subduction.

# Using earthquake focal mechanisms to investigate slow slip driving forces in the northern Hikurangi

*Emily Warren-Smith[1], Bill Fry[1], Laura Wallace[1]

1. GNS Science

Understanding the processes that drive slow slip events (SSEs) may assist in improving our understanding of the physics of both slow and fast earthquakes. Recent work has shown that the stress ratio, R, retrieved by focal mechanism inversion systematically decreases prior to SSEs in New Zealand's northern Hikurangi subduction zone, and subsequently increases during the evolution of each SSE. These R fluctuations are proposed to represent slow, precursory increases and fast concurrent decreases in fluid pressure within overpressured subducting oceanic crust during the SSE cycle.

These observations represent an exciting opportunity to improve forecasts of SSE occurrence via monitoring of R changes. Thus far, this cyclic behaviour has only been observed over a short time-period (9 months, 4 SSE cycles) when ocean-bottom seismographs were deployed.

Here we present the results of a waveform cross-correlation study that aims to extend the catalogue in time and reduce the magnitude of completeness for focal mechanisms of northern Hikurangi seismicity. This enables improved temporal coverage and statistical analysis of stress tensor changes across multiple SSE cycles. By using well constrained focal mechanisms of events recorded on >30 OBS and land stations as templates, we automatically assign correlation-derived relative polarities to waveforms and subsequently invert for focal mechanisms and R using many more earthquakes complete to a lower magnitude. This approach offers an important step towards accurate SSE forecasting and an improved understanding of the physical processes leading to slow rupture nucleation.

# Seismological structural changes around source regions of slow earthquakes in Nankai subduction zone inferred from broadband receiver functions

*Yasunori Sawaki[1], Yoshihiro Ito[2], Kazuaki Ohta[2], Takuo Shibutani[2], Tomotaka Iwata[2]

Coupled phenomena of tremors accompanying short-term slow slip events and very low frequency earthquakes (Ito et al., 2007) have been detected at deeper parts of seismogenic regions on the Nankai Subduction Zone in southwestern Japan. Elucidating detailed seismological structures on plate interfaces hosting slow earthquakes is very important to understand mechanisms and relationships of slow earthquakes and megathrust earthquakes. Few studies, however, have proposed detailed velocity structure models and their spatio-temporal variations with high resolution receiver functions (RFs) on plate interfaces. In this study, we calculate broadband RFs around source regions with slow earthquake events in the Nankai Subduction Zone. We also investigate frequency dependency of RFs to constrain detailed physical features near the plate interface.
RF method is one of the best approaches to estimate the velocity structure beneath seismic stations by extracting P-to-S phases converted on velocity discontinuity from teleseismic waveforms. In southwestern Japan, Shiomi et al. (2008) confirmed the oceanic Moho discontinuity in the Philippine Sea Slab. In usual cases, high cut filter (e.g. 0.6Hz: Shiomi et al., 2008) is used when deconvoluting vertical component waveforms from horizontal ones in order to avoid instability on calculation. Akuhara et al. (2017) recently calculated high frequency RFs up to 4 Hz using ocean bottom seismometers equipped off the Kii peninsula, and confirmed the existence of a thin low velocity zone composed of a fluid-rich sediment layer along the Nankai trough megathrust fault. In this study, we calculate RFs applying the Extended-Time Multitaper method modified by Shibutani et al. (2008) and the frequency dependency of RFs is examined by taking different frequency ranges up to 0.5, 1, 2, 3 and 4 Hz.
We have used Hi-net and F-net seismograms provided by National Research Institute for Earth Science and Disaster Resilience in Japan. We confirm that spectra of teleseismic waveforms have sufficient SN ratios up to 3 or 4 Hz. Fig.1 shows an example of the RFs at NKTH located on the Kii peninsula. The RFs at most of the stations contain positive and negative phases around 3-4 s after P-wave arrival, which correspond to oceanic Moho discontinuity and the plate interface, respectively. The amplitude and the arrival time of these phases depend on backazimuth, suggesting that dependency on the incident angle of a ray to the subducting plate interface. In case of a downdip for the subducting slab, incoming P-waves have lower incident angles and generate smaller convert S-waves. On the contrary, an updip case, incoming P-waves have higher incident angles and generate larger convert S-waves.
At higher frequency RFs (Fig.1, right), the phases from the plate interface are generally sharper than those at lower frequency, whereas the phases corresponding to oceanic Moho seems to tend to be broader or split into several phases, suggesting that the oceanic Moho is not a simple velocity discontinuity but would consists of several layers. The split positive phase just after the negative phase from the plate interface may relate to the thin low velocity zone inferred from Akuhara et al. (2017).

# Slip tendency maps for compressional and extensional stress states on a shallow decollement in Nankai Trough

*Yoshitaka Hashimoto[1], Shigeyuki Sato[1], Gregory F Moore[2], Masataka Kinoshita[3], Gaku Kimura[4], Ayumu Miyakawa[5], Kazuya Shiraishi[6], Yasuhiro Yamada[6]

Stress state along a subduction plate interface is one of important controls for wedge architectures, fault activations and seismogenic behaviors. In a shallow portion of a subduction plate interface, a large displacement along decollement could be expected for tsunamigenic events (Fujiwara et al., 2012) as well as slow earthquakes such as very low frequency earthquakes and slow slips have been observed (Araki et al., 2017, Nakano et al., 2018). Paleo-stress state has been estimated using micro-fault inversion method from exhumed accretionary complexes and oceanic accretionary wedges, which shows the stress state changes between compression and extension states with almost horizontal and vertical principal stress axes. The stress change could be related to seismic cycle.

In this study, we examined geographical features of a shallow decollement using 3D seismic profiles and mapped slip tendencies on the decollement with compressional and extensional stress state to discuss an effect of distribution of slip tendency on the fault slip behaviors. Slip tendency is a shear stress ratio to normal stress on a fault surface when a regional stress state is applied on a fault surface.

The target transect of the 3D seismic profiles is located at the Nankai Trough off Kii Peninsula, SW Japan where Philippine Sea Plate subducted into Eurasian Plate, and IODP NantroSEIZE project has been operated. The 3D seismic profiles had been reprocessed to make reflectors clear using an updated technology. We traced the shallow decollement to make geographic features (3D surface) by Petrel. We analyzed dip angle and dip azimuth for 50 m mesh of the surface. The characteristics of geographic features of the shallow decollement are 1) almost horizontal with dip angle ranging 5-15, 2) dip azimuth directing 300-350˚ (NW-NWN) in average. In addition, some narrow zones with dip azimuth directing 50-150˚ (SE-SES) are identified, which shows a relatively high frequency reliefs striking NE-SW direction. Some of these are related to the geography of oceanic basement.

Compressional and extensional stress states were applied on the surface to examine a change in slip tendency with change in stress state. We assumed that compressional one has (150, 0) sigma 1 and (90, 90) sigma 3 and others has (150, 0) sigma 3 and (90, 90) sigma 1. The 0.6 of friction coefficient was assumed as the maximum value. We calculated differential stresses for compressional and extensional stress states to make a plane with idealized attitude to applied stress state reactivated. This assumption implies that the estimated slip tendency is the maximum value.

Resulted slip tendency represents a strong relationship with geomorphic features. In compressional stress state, large slip tendency (0.4-0.5) distributes on the surface with dip azimuth directing 300-350˚ whereas small slip tendency (0.1-0.2) corresponds to the surface with dip azimuth directing 50-150˚. In extensional stress state, the similar distribution with that in compressional stress state is identified but the difference between the dip azimuths is very small; slip tendency ranges 0.1-0.2. The differences between slip tendencies in compressional and extensional stress states is almost similar to that for compressional stress state because slip tendency for extensional stress state is almost 0.1-0.2.

©2019. Japan Geoscience Union. All Right Reserved. 

If we take the difference in slip tendency as a kind of stress drop, relatively small stress drop are observed on the surface with dip azimuth directing 50-150˚, which is distributed in NE-SW zones. Nakano et al. (2018) found that VLFs in the region migrates toward NE, which is consistent with the directions of zones with stress drop is small. The area for VLFEs could be limited in these zones where the slip tendency is small both in compressional and extensional stress states, implying that the material with very low friction coefficient and/or high pore fluid pressure are expected to make a plane reactivated with small slip tendency.

# Permeability and its anisotropy on creeping Chihshang Fault, Taiwan

*Tyas Dwi Aprilniadi[1], Wen-Jie Wu[1], Li-Wei Kuo[1], Jian-Cheng Lee[2], Jia-Jyun Dong[3]

1. Department of Earth Sciences, National Central University, 2. Institute of Earth Sciences, Academia Sinica, 3. Graduate Institute of Applied Geology, National Central University

The Chihshang Fault in eastern Taiwan is a 20-km-long segment of the Longitudinal Valley Fault that a plate-suture boundary fault between the Eurasian continental margin and the Philippine Sea Plate has fastest shallow creep in the world and infrequently occurs earthquakes (Magnitude greater than 6). Here we performed permeability measurements on Lichi Mélange and conglomerate with an intra-vessel oil pressure apparatus (YOKO2) at room temperature at isotropic confining pressure, using helium as pore fluid. We made samples, with dip and normal direction of fault, from retrieved rock cores in WAN-2 borehole and attempted to build the permeability structure across creeping Chihshang Fault. Generally, intrinsic permeabilities of Lichi Mélange were lower than that of conglomerate and intrinsic permeabilities in dip direction were higher than that in normal direction. But the permeability differed in rock type and was associated with shear structures that fault zone architecture is not typical as simple mode suggested by Caine et al. (1996). The results show Lichi Mélange was a natural aquifuge blocking the fluid flow that may be responsible for fluid-rock interaction and seasonal fluctuation on creeping Chihshang Fault. The heterogeneous Lichi Mélange has complicated composition as other Mélange that the microstructural observation would be conducted for investigating the relationship between microstructures and permeability in creeping Chihshang Fault. Taking microstructures, permeability anisotropy and the fault zone architecture into consideration, we may depict the permeability structures of Chihshang Fault and further provide the information of matrix permeability for hydraulic properties in the field.

*Diana Mindaleva[1], Masaoki Uno[1], Fumiko Higashino[1], Atsushi Okamoto[1], Noriyoshi Tsuchiya[1]

1. Graduate school of environmental studies, Tohoku University

Aqueous fluids flow could be responsible for changing hydrologic and thermodynamic properties of rocks. It is generally accepted that fluids play a key role in the generation of earthquakes, tremors, and slow slip events. For example, it was suggested that tremors are related to fluids released during dehydration processes in the subduction slab (e.g., Abers et al., 2009; Katsumata and Kamaya, 2003; Obara et al., 2004). Hydrous minerals in subducting slabs release $H_2O$ due to dehydration reactions. Released water increases fluid pressure rapidly. However, fluid pressure gradients within the crust remain poorly constrained due to their heterogeneity. Therefore, it is important to constrain timescales of fluid infiltration to understand fluid pressure gradient, permeability, and tectonic evolution.

We have investigated fluid-rock reaction zones in mafic granulite and amphibolite samples from Mefjell, south-central part of the Sør Rondane Mountains (SRM), East Antarctica, and constrained pressure gradient and permeability. Mafic granulite and amphibolite samples are cut by numerous randomly-oriented veins. Samples are partially hydrated along veins associated with mm-scale hydration reactions zones. Reaction zones fingerprint relationship between fluid infiltration and rock response. We divide samples into several reaction zones increasing distance from the vein center by modal amount of minerals, reaction textures, and trace elements concentrations distributions profiles in apatite. The P-T conditions for the fluid infiltration in mafic granulite were estimated to be 0.65 GPa, 650˚C , and that for peak P-T conditions were 850˚C, 0.55-1.0 GPa. On the other hand, P-T conditions for the fluid infiltration in amphibolite were estimated to be around 500˚C.

Trace elements concentrations (Cl, Sr, and some REE) measured by EPMA and LA-ICP-MS in several apatite grains were gradually decreasing with distance from the vein. Cl distributions profiles were analyzed by a reactive-transport model to define transport mechanism by fitting to Peclet number (Pe#=vL/D, where v is pore velocity, L is length of reaction zone, D is self-diffusion coefficient) and time-scales of fluid infiltration. For mafic granulite Pe# is 0.025, for amphibolite is 90. Whereas diffusion transport is revealed to be dominant for mafic granulite, advection transport is likely for amphibolite. Duration of fluid infiltration was estimated to be 5.5 h for mafic granulite and 1-3 h for amphibolite, which is very short in geological timescales. This suggests rapid and intense fluid flux through the mantle wedge and onto overlying crust. Short timescales of fluid infiltration may reflect linkage to the seismic events.

To estimate permeability, the pressure gradient for the reaction zones was calculated from the water and other elements activities constrained by pseudosection analysis for different reaction zones. Bulk compositions at each reaction zone were used to create pseudosections. Permeability was calculated from the estimated pressure gradient and total flux $q=-\kappa(\partial P/\partial x)/\eta$, where q is total flux, k is permeability, $\eta$ is viscosity, and $(\partial P/\partial x)$ is pressure gradient. Results suggest low and contrasting permeability between mafic granulite dominated by diffusion and amphibolite dominated by advection mass transport mechanisms. This difference may be explained by different P-T conditions for fluid infiltration and heterogeneity of the pressure gradients. Therefore, it suggest that fluid infiltration in low

©2019. Japan Geoscience Union. All Right Reserved. 

permeable rocks caused fracturing and formed narrow reaction zones, which released fluid pressure in a short time. Above results of our study suggest importance of fluid transport phenomena in relation to the evolution of rocks hydrological properties.

# Generation of high fluid pressure at the base of the shallow mantle wedge—evidence from serpentinite of the Sanbagawa belt, SW Japan

*Simon Richard Wallis[1], Yui Kouketsu[2], Mari Yokota[1,2]

1. University of Tokyo, 2. Nagoya University

Serpentinite units derived from the mantle wedge in the Sanbagawa subduction-type metamorphic belt record interaction between the shallow mantle-wedge and the flow of SiO2-bearing fluids at two different depths in the paleo subduction zone. The mineralogy and geochemistry of two units indicate there was a major increase in the fluid flow perpendicular to the subduction boundary with decreasing pressure. The rate of flow can be related to the presence or absence of a thick shear zone. Estimates of fluid flux from subducted slabs combined with experimentally determined permeability of serpentinite suggests that the presence of a zone of gently dipping strongly foliated serpentinite is a key component of developing high fluid pressures at depths of 30–50 km in subduction zones—a key requirement for the development of slow earthquakes. Most of the SiO2 in these subduction fluids will be absorbed in the serpentinite and is unlikely to be available for precipitation and formation of an impermeable cap at higher levels in the system.

# Overpressured subduction plate boundary caused by infiltration of mantle-derived fluids: Evidence from helium isotope analysis on veins in subduction mélange

*Naoki Nishiyama[1], Kohtaro Ujiie[1], Hirochika Sumino[2]

1. University of Tsukuba, 2. The University of Tokyo

Fluid overpressures have been invoked as one of the key factors controlling slow earthquakes in subduction zones. The generation of fluid overpressures has been thought to occur by in-situ processes such as compaction disequilibrium and mineral dehydration in sediment and oceanic crust. To determine the origin of fluid responsible for overpressured subduction plate boundary, we examined noble gas and microthermometric analyses on quartz-calcite veins in the subduction mélange deformed at ~10–15 km depth.

The analyzed veins are sigmoidal extension vein arrays and shear veins. The former represents Riedel shear zones formed during subduction under vertical $\sigma_1$. The latter records the numerous low-angle brittle thrusting at very small shear strength with recurrence time comparable to that of slow earthquakes, which could account for the generation of tectonic tremors [1]. Homogenization and ice melting temperatures of fluid inclusions indicate that the both types of veins recorded the fluids with salinity of 3–7 wt% and near-lithostatic fluid pressures at 10–15 km depth. The measured $^{3}He/^{4}He$ range 1.6–2.5 Ra (Ra is the $^{3}He/^{4}He$ of air) regardless of types of veins, indicating the presence of mantle helium. The ratios of non-radiogenic heavy noble gas isotopes ($^{36}Ar$, $^{84}Kr$, and $^{130}Xe$) are similar to those of seawater and serpentinite in slab mantle [2]. Because porosity in sediments already decreased to <1 % at depths of 4–5 km [3], seawater captured in the pores would be completely expelled from the subducting sediments before reaching to 10–15 km depth, and thus the serpentinized slab mantle is the likely origin of the $^{36}Ar$, $^{84}Kr$, and $^{130}Xe$. The measured $^{3}He/^{4}He$, non-radiogenic heavy noble gas ratios, and salinity are consistent with those of slab-derived fluids observed in mantle wedge peridotites from subduction zones [4, 5], suggesting that fluids released from subducted serpentinite to the mantle wedge migrate toward shallow depths along subduction boundary. From a mixing calculation using $^{36}Ar$, $^{84}Kr$, and $^{130}Xe$ data, more than 64% of vein-forming fluids were originated from the subducted serpentinite. Therefore, the migration of mantle-derived fluids has a potential to induce brittle failures in plate boundaries via increasing fluid pressures.

# Geological and rheological conditions of subduction plate boundary between the seismogenic zone and the ETS zone in warm-slab environments

*Kohtaro Ujiie[1], Kazuya Noro[1], Norio Shigematsu[2], Ake Fagereng[3], Naoki Nishiyama[1], Christopher Tulley[3], Haruna MASUYAMA[1], Yasushi Mori[4]

1. Graduate School of Life and Environmental Sciences, University of Tsukuba, 2. Research Institute of Earthquake and Volcano Geology, National Institute of Advanced Industrial Science and Technology, Japan, 3. Cardiff University, 4. Kitakyushu Museum of Natural History and Human History

In subduction zones particularly under warm-slab environments, the transition zone between the locked seismogenic zone and the deeper, stably sliding zone is the site of slow earthquakes such as episodic tremor and slip (ETS) and long-term slow slip events (L-SSEs). Exhumed subduction mélanges on Kyushu Island, Japan, were deformed at depths of ~15–30 km and temperatures of ~370–500 ˚C under warm-slab environments and thus provide an invaluable opportunity to examine geological and rheological conditions that may responsible for slow earthquakes. The mélanges record low-angle thrust sense, viscous shear associated with metasomatic reactions. The metasomatism is caused by the infiltration of sodium-bearing fluid between pelitic schist and mafic to ultramafic rocks, resulting in albitization of pelitic schist. Microstructural observations and electron backscatter diffraction analysis show that viscous shear was accommodated by dislocation creep, mechanical rotation, and possible diffusion creep, resulting in dynamic recrystallization of quartz, strong shape and crystal preferred orientations of actinolite and chlorite, and random orientation of albite, respectively. Strain rate of viscous shear zones, estimated from the recrystallized grain size piezometer and flow law for quartz, increases with depth from ~$10^{-13}s^{-1}$to ~$10^{-10}s^{-1}$. The upper value of strain rate is consistent with the strain rate of L-SSEs in subduction zones, when the thickness of viscous shear zone is orders of 10–100 m, compatible with our field observation. Lattice-preferred orientation patterns of quartz c-axes also changes with depth from Type I crossed girdle to c-axis maximum subparallel to shear direction, showing a shear sense consistent with low-angle thrust faulting. Albitized pelitic schist formed by metasomatic reactions and associated viscous shear zones are absent in the mélange deformed at temperatures less than ~330 ˚C. In total, viscous shear associated with metasomatic reactions may account for strain rate, kinematics, and lower limit temperature of L-SSEs zone.

# Temperature variation in tectonic mélanges of the Shimanto Belt, SW Japan

*Tsai-Wei Chen[1], Donald M Fisher[1], Andrew J Smye[1], Yoshitaka Hashimoto[2]

1. Penn State Univ., 2. Kochi Univ.

Silica redistribution along plate interfaces is a fault zone aging process likely to affect the slip behavior of subduction interfaces. Numerical modeling for slip according to the rate law based on silica kinetics reproduces the characteristics of real-world subduction zones, such as an updip limit to the seismogenic zone, earthquake clustering, and a power-law size distribution of earthquake magnitudes. In the field, the structure of subduction fault zones is typically marked by veined sandstone blocks within mudstones with scaly fabric, with mudstones providing a local source of silica and other elements that precipitate as minerals veins, which act as a sink for mobile elements. The silica kinetics related to diffusion from shearing mudstones to cracking sandstone blocks in mélange provides a temperature dependent mechanism for fault zone aging whereby the contact area across the fault zone increases in the time between slip instabilities. In the Shimanto belt of Japan, scaly fabric and vein microstructures show textural variability as a function of temperature. There is a gradient in the age of paleosubducting oceanic crust from north to south within the inner Shimanto belt, from the Yokonami mélange, with a thick pelagic chert section and older basalt and younger mélanges in the south (Okitsu, Hyuga, and Mugi) with little or no chert section, suggesting younger subducting crust. Thus, the mélanges of the Shimanto belt were accreted at different temperatures and depths along the interface, and there also may have been differences in the subduction geotherm. We suggest that these variations in temperature are likely to lead to different silica kinetics and rates of mineral redistribution, recorded in microstructural variations that may reflect different frictional properties along the plate interface. The slip behavior of the plate interface depends on temperature as evidenced by down dip variations in slip mode and differences in earthquake size distributions for subduction zones with different age crust. We therefore have undertaken a study of oxygen isotope thermometry using coexisting mineral pairs of quartz-albite-calcite observed in the tectonic mélanges from the Shimanto belt at a variety of estimated temperatures. This data provides an independent method for evaluating the temperature during mineral redistribution that can be compared with current estimates based on vitrinite reflectance and fluid inclusion analyses.

# Frictional properties of opal gouge at low-temperature hydrothermal conditions and their implications for seismogenic faulting along subduction-zone megathrusts

*Kyuichi Kanagawa[1], Tomoya Nakanishi[2], Morito Kuwana[3], Michiyo Sawai[1], Takehiro Hirose[4]

1. School of Science, Chiba University, 2. Graduate School of Science and Engineering, Chiba University, 3. Faculty of Science, Chiba University, 4. Kochi Institute for Core Sample Research, Japan Agency for Marine-Earth Science and Technology

We conducted a series of triaxial friction experiments on opal gouge at low-temperature (≦200˚C) hydrothermal conditions, in order to address the change in frictional stability along subduction-zone megathrusts. The results revealed frictional properties of opal gouge dependent on temperature ($T$), displacement ($V$) or pore water presure ($P_p$), as described below.

When fitted by the rate- and state-friction constitutive law, friction parameter $a$ does not change much with $T$, $V$ or $P_p$, while friction parameter $b$ increases, and resultantly ($a-b$) value decreases with increasing $T$, decreasing $V$ or increasing $P_p$. Microstructural observations revealed that densification and coalescence of gouge particles occurred at higher $T$, suggesting the operation of pressure solution. Thus increasing activity of thermally activated pressure solution with increasing $T$, decreasing $V$ or increasing $P_p$ promotes gouge lithification to increase frictional strength, by which ($a-b$) value decreases to <0, and thereby the transition from aseismic faulting to seismic faulting along subduction-zone megathrusts. Our results also imply that increasing $P_p$ at that transition region where ($a-b$) ≈0 would decrease ($a-b$) value to <0, and hence promote slow seismic faulting with small negative ($a-b$) values, which is consistent with high $V_P/V_S$ ratios observed in the regions of slow earthquakes.

## [S-CG48] Science of slow earthquakes: Toward unified understandings of whole earthquake process

convener:Satoshi Ide(Department of Earth an Planetary Science, University of Tokyo), Hitoshi Hirose(Research Center for Urban Safety and Security, Kobe University), Kohtaro Ujiie(Graduate School of Life and Environmental Sciences, University of Tsukuba), Takahiro Hatano(Earthquake Research Institute, University of Tokyo), Chairperson:Takahiro Hatano, Takehito Suzuki

Accumulating observational studies on various types of slow deformation events, such as tectonic tremors, very low frequency events, and slow slip events, portrays some universal characteristics in generally complex behavior, including interaction among events and influence by various outer loadings. Some of these phenomena seem to have causal relation with the occurrence of very large earthquakes. A unified understanding of these slow and fast earthquake processes requires an approach integrating geophysics, seismology, geodesy, geology, and non-equilibrium statistical physics. We welcome presentations based on, but not limited to, geophysical observation, data analysis, analytical theory, numerical simulation, field study, and laboratory experiments.

# Rate and State Dependent Friction Law and Static Friction Force

*Hiroshi Matsukawa [1]

1. Aoyama Gakuin University

It is well known that the Rate and State Dependent Friction Law (RSF) plays an important role in the study of earthquake including slow-earthquake [1, 2]. RSF was introduced by Dietrich [3] and Ruina [4] based on the laboratory experiments and describes the sliding velocity and state-variable dependences of the friction coefficient. The dependences are analyzed by the thermal activation process of the deformation and detachment of actual contact points [5-7]. The thermal activation of the deformation of actual contact points, which is called the indirect process, cause the increase of the actual contact area and then the friction force with increasing contact time of actual contact point, which is inversely proportional to the sliding velocity. The thermal activation of the detachment of actual contact points, which is called the direct process, cause the increase of the friction force with increasing sliding velocity. Such analysis discuss the change of friction coefficient depending on the sliding velocity and state-variable. Here we extend the analysis and discuss the absolute value of the friction coefficient. In the case that the direct process overwhelm the indirect process, the friction coefficient can vanish in the limit of vanishing sliding velocity, that means the vanishing static friction force. The vanishing static friction force results from the thermal activation of the detachment of the actual contact points. The velocity dependence of the friction coefficient in the low velocity regime is investigated. It is also shown that even in the case that the indirect process overwhelm the direct process in the usual velocity regime, the direct process overwhelm the indirect process in the law velocity limit. In this case the steady state friction coefficient once increase from zero in the low velocity regime, shows a peak and then decreases with increasing sliding velocity. The relations with the laboratory experiment [8] and slow earthquake are discussed.

# Stable sliding, slow and silent slip events and laboratory earthquakes across the brittle ductile transition

*Alexandre Schubnel[1], Aubry Jérôme[1], François Passelègue[2]

1. Laboratoire de Géologie, ENS, PARIS, France, 2. EPFL, Switzerland

The transition from brittle to plastic deformation corresponds to the regime where brittle fracturing and plastic flow co-exist. This transition is of fundamental importance to understand how natural faults behave differently at the bottom of the seismogenic zone, at PT conditions where the deformation regime is not fully brittle anymore.

Here, we reproduced the complete spectrum of natural faulting at laboratory scale, from stable slip to slow earthquakes and up to fast instabilities, on samples of dolostones and carbonates. Transitions from creep to slow ruptures and from slow to fast ruptures, are obtained by increasing both pressure and temperature up to conditions encountered at 3 km depth (i.e. 100 MPa confining pressure and 100 ˚C), which corresponds to the onset of seismicity in nature. Increasing confining pressure and temperature augments the fault elastic stiffness, which decreases the nucleation length and enhances the slip velocities during the nucleation to values allowing flash weakening and decarbonation processes.

From our experimental results, we conclude that: (i) laboratory earthquakes may nucleate on inherited fault interfaces at brittle-ductile transition conditions; (ii) in this regime where plastic deformation of the bulk and dynamic fault slip may co-exist, laboratory earthquakes are promoted when the interface is smooth, or when the loading rate is slow; (iii) stable sliding tends to produce mirror-like surface, while stick-slips is associated with matte surfaces, on which the size of the asperities grows with increasing confining pressure, (iv) slower loading rates and higher confining pressures promote the occurrence of laboratory earthquakes associated with increasing plastic deformation, while increasing initial roughness promotes stable sliding and slow stick-slip.

# Dramatic velocity weakening of dry quartz friction at relatively slow slip velocities

*Akito Tsutsumi[1], Hirotaka Iida[2], Yuko Onoe[1]

1. Graduate School of Science, Kyoto University, 2. Geothermal Engineering. Co. Ltd.

Understanding the frictional properties of subduction-zone fault materials is crucial to understanding subduction-zone seismogenesis. Previous experimental studies have demonstrated that fault weakening in siliceous rocks occurred at relatively low slip velocities ($V > 0.01$ mm/s) [Goldsby and Tullis, 2002; Di Toro et al., 2004; Hayashi and Tsutsumi, 2010], under which conditions transformation reactions are unable to proceed because of low temperatures. Formation of a silica gel layer has been suggested as a possible cause of the weakening behavior [Goldsby and Tullis, 2002]. However, there exists only limited information on the frictionally generated material and little is known about the weakening mechanism. To study the effect of moisture on the fault zone process in siliceous material, we have performed friction experiments on a synthetic quartz sample under two different humidity conditions: in room humidity (relative humidity RH = 20 to 75%) and in dry (RH < 3%) conditions. to

Three types of friction experiments were performed using a rotary-type testing machine on a pair of hollow-cylindrical specimens of quartz with outer and inner diameter of 25 and 5 mm, respectively, at a constant normal stress of 1.5 MPa. Constant velocity tests and velocity stepping tests were conducted under a range of slip velocities from 0.005 to 105 mm/s. In slide-hold-slide (SHS) tests, samples were first slid at $v = 105$ mm/s, by which sliding friction coefficient $f$ decreases to attain a steady-state value of about $f = 0.2$. Then, rotation of the sample was stopped for periods of 1 to 10000s, after which rotation of the sample at the same rate was restarted.

In room humidity conditions, steady state friction shows velocity weakening at $v > 0.01$ mm/s, which is consistent to the previous studies. We find that steady-state friction values measured at the dry condition are almost constant at $f = 0.2$ for slip velocities $v$ from 0.1 to 100 mm/s. SHS tests show that time-dependent frictional healing is observed for hold time duration $t > 10$s in room humidity condition. On the contrary, the time-dependent frictional healing is negligible when tested in the dry condition.

Our results imply that the moisture-absorption strengthening, which has been proposed to be an effective mechanism for time-dependent healing of high-velocity friction of gabbro (Mizoguchi et al. 2006) is an important underlying mechanism of the frictional weakening of quartz rocks observed in ambient humidity conditions.

# Rupture nucleation processes accompanying tremor and slow slip in gel friction experiments

*Tetsuo Yamaguchi[1]

1. Graduate school of Engineering, Kyushu University

We have been elucidating similarities between our analogue experiments and earthquakes through some examples, such as coexistence of fast and slow slip, GR relation, size-duration scaling, and supershear rupture. In this study, we observed rupture nucleation processes for large events. As a result, we found the occurrence of tremor in coincident with slow slip. We also found that the duration of a slow event is proportional to the minus one-third power to the driving velocity. This power law behavior suggests that the slow slip process is determined independently of the characteristic velocity scale of the system. We will elucidate the relationship between frictional constitutive law and the macroscopic behavior. We will also discuss the realistic geological setup for our lab systems.

# Solution Orbit for k and epsilon Model for Turbulent Flow in Porous Media

*Takehito Suzuki[1]

1. Department of Physics and Mathematics, Aoyama Gakuin University

Turbulent flow within porous media such as fault rocks can affect dynamic earthquake rupture processes and has attracted interests of many researchers. Among models treating the turbulent flow, the k-epsilon model has widely been employed, where k is the turbulent kinetic energy and epsilon is the dissipation rate of k. However, analytical treatment associated with the effect of the initial values of k and epsilon on the final state has not been performed.

We assume a one-dimensional homogeneous porous medium and isotropic turbulence. We also assume that the density of the fluid, rho, and the porosity, phi, are constant, and the ensemble averages of phi k and phi epsilon will be written as k and epsilon below, respectively. With these assumptions, it should be emphasized that exactly the same straight line given by the equation epsilon=$c_k$ $u_D$ k /\sqrt{*K*} is a nullcline common to both variables on the k-epsilon phase space, where $c_k$ is a constant number, $u_D$ is averaged Darcy velocity, and *K* is permeability. We can regard this line as a line attractor or repeller as observed in other systems such as Suzuki (2017). Moreover, the straight line epsilon=0 (k axis) is also a nullcline for epsilon.

Actually, the analytical form of solution orbits is given by epsilon=epsilon$_0$ (k/$k_0$)^$C_2$, where $C_2$ is a constant, 1.9. Using this, we show below that the common nullcline epsilon=$c_k$ phi $u_D$ k/\sqrt{*K*} is a line attractor for this solution orbit. First, we define Region I as the region 0< epsilon < $c_k$ $u_D$ k /\sqrt{*K*} on the phase space, and Region II as the region epsilon > $c_k$ $u_D$ k/\sqrt{K}>0. We also define the point ($k_f$, epsilon$_f$ ) as the point where the solution orbit passing the point ($k_0$, epsilon$_0$) crosses the nullcline. With these definitions, we have relations $k_0$f and epsilon$_0$f if ($k_0$, epsilon$_0$) is in the Region I. This occurs because epsilon is proportional to k on the nullcline, while epsilon is proportional to k^$C_2$ on the solution orbit and $C_2$ >1. We can also conclude $k_0$>$k_f$ and epsilon$_0$>epsilon$_f$ if ($k_0$, epsilon$_0$) is in the Region II. Second, we should emphasize that k and epsilon increase (decrease) with increasing time in the Region I (II), since \partial k/\partial t and \partial epsilon/\partial t are positive (negative). Therefore, if ($k_0$, epsilon$_0$) is in the Region I (II), the solution moves to the upper right (lower left), and is absorbed into the nullcline with the limit t \to \infty. We can conclude that the nullcline is a line attractor, not a repeller. The steady stable solution is given by (k, epsilon)=($k_f$, epsilon$_f$).

Note that k and epsilon vanish with the limit t \to \infty for usual isotropic turbulent flow, even though the solution orbit for such flow is the same as one obtained here. Actually, the usual turbulent flow is described by the limit *K* \to \infty in the present model. The nullcline is k axis in such a case, and the Region I vanishes. Therefore, all the solutions are absorbed into the origin. The finite *K* enables the turbulence to be survive with t \to \infty for the homogeneous state.

Growing amounts of seismologic observations appear to be capturing a larger diversity in slip behavior along natural faults. One such behavior is the appearance of localized high-frequency events occurring within a larger preparatory region of accelerated preslip. A mechanism explaining this phenomenon is that fault zones have contrasting strength, which may affect the spatial variability of seismic coupling. Recent numerical studies of faults governed by rate-and-state (RS) friction, show that systematic variations in the strength heterogeneity could explain diverse slip behaviors, such as, stable sliding without spontaneous slip transients, or unstable with spontaneous rupture [Liu and Ampuero, 2017].

Here we detail results from a direct shear friction experiment where a well-instrumented fault was formed by pressing together mature (worn) surfaces of poly(methyl methacrylate), then subjecting it to shear, until gross ‘stick-slip’ failure occurred. Prior to failure, spontaneous ruptures were found to nucleate within a region of accelerated slip, but *arrested locally within a seismogenic section* of the interface. Seismic waves produced by these high-frequency events were measured by an array of calibrated piezoelectric transducers. The seismogenic section was found to form where a slow slip front propagated into a relatively locked region [Selvadurai and Glaser, 2015].

To model the behavior of this lab-scale seismogenic region, we use multi-cycle simulations and linear stability analysis in the open source software QDYN, which utilizes boundary element method and adaptive time-stepping [Luo et al., 2017]. We studied the postmortem surfaces and found that the worn fault displayed a clear bimodal Gaussian distribution of surface height. This unique distribution of surface roughness was determined to be a proxy for a heterogeneous description of the critical slip distance $D_c$ used in numerical calculation that modelled the seismogenic region as a VW section with constant normal stress that obeyed the slip law in terms of RS friction.

Our model showed that it was capable of producing the same diversity in slip behaviors from stable sliding to unstable with localized spontaneous ruptures and this was dependent on parameter selection. Preferentially smooth (polished) sections of fault exhibited low $D_c$ and were susceptible to rupture nucleation. However, the extent to which they propagated along the fault depended on the level strength heterogeneity. Wearing of the fault also led to a natural periodicity in the spatial distribution of strength, which produced numerical estimates of source characteristics that matched those made from an independent analysis of seismic waves. Matching numerical and experimental estimates of source characteristics (seismic moment, source length scale and stress drop) was used a calibration tool to accurately tune the model behavior and better understand conditions leading to the production of seismicity attributed to the interaction of a slow slip front into a relatively locked section of fault.

# Exponential dependence on perturbation stress of earthquake nucleation

*Saito Takuya[1], Takahiro Hatano[1]

1. The University of Tokyo

Recent observations have reported that some tremors in slow earthquake are sensitive to stress perturbations caused by ocean tides [1]. According to the preceding studies [1], occurrence frequencies of the susceptible tremors display exponential dependence on the stress magnitude. This study numerically investigates effects on earthquake nucleation growths of the periodic stress perturbations to see if the nucleation developed under the rate-and-state friction law reproduces the stress dependence. The numerical results suggest the exponential dependence on the perturbation stress magnitudes even in the presence of superimposed sinusoidal waves with the different periods. In addition, the exponential rates are found not to be sensitive to a change in the perturbation period or the superposition components of the sinusoidal perturbations, which implies the critical stresses magnitude are independent of a variety of the perturbations.

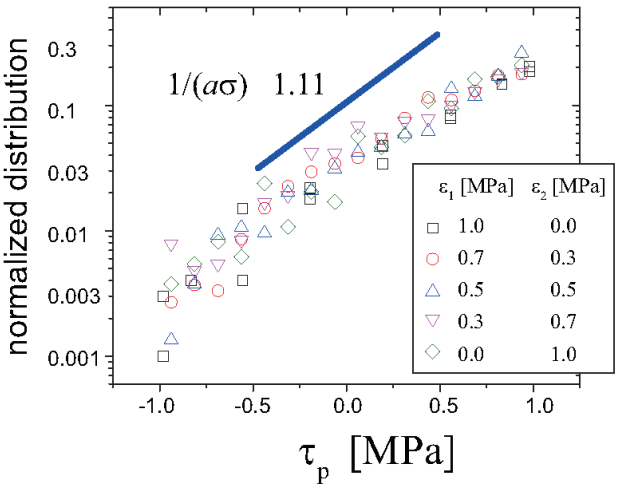

FIG. 1: Numerical results of stress dependence of the nucleation growth under the perturbation $\tau_p = \epsilon_1 \sin(\omega_1 t) + \epsilon_2 \sin(\omega_2 t + \phi_{2,ini})$. Horizontal or vertical axes represents stress magnitude or the normalized distribution, respectively. For each parameter condition, we measured the stresses of 1000 nucleation samples, which grow from randomly generated initial conditions, when the nucleation slip reaches the threshold velocity $V_{thr} = 1.0$ mm/s.

# Stochastic modeling of slow earthquakes comparable to observations

*Naofumi Aso[1], Ryosuke Ando[2], Satoshi Ide[2]

1. Tokyo Institute of Technology, 2. University of Tokyo

Slow earthquakes are often modeled using rate-and-state friction law with heterogeneously distributed parameters. However, we never know the exact friction law nor the perfect distribution of frictional parameters. Also, other physics are also proposed to contribute to the slow process, including pore fluid. Since any deterministic approaches cannot adequately capture the temporal stress change at a specific site because of the inherent unpredictability caused by various nonlinear processes, we instead focus on the stochastic approach to model slow earthquakes.
In stochastic modeling, we artificially add stochastic fluctuations in numerical simulations. When the result agrees with observations, the stochastic fluctuations are found to represent underlying physics. Then, we can make some predictions that could be evaluated by further observations. After capturing many characteristics of the stochasticity, we could finally approach physics. Although the deductive approach based on specific physics is often taken in earthquake source physics, the experimental approach has the potential to fill the gap between modeling and observations.
Here, we demonstrate that the consideration of stochastic stress fluctuations in ordinary crack simulations can reproduce a variety of observations of slow earthquakes, including burst-like tremor initiation, the existence of tremor front, decelerating tremor migration, and precursory slow earthquakes. The identical model can also reproduce both crack-like and pulse-like ordinary earthquakes by simply changing the strength drop and initial stress level.

# Migration of aqueous fluid near the subducting plate interface

*Manabu Morishige[1]

1. Japan Agency for Marine-Earth Science and Technology

At least in several subduction zones including Tohoku, Japan, and Cascadia, low surface heat flow has been observed in the forearc, which suggests the existence of a cold fore-arc mantle. This low heat flow has been explained by a thin, low-viscosity layer (LVL) on top of the subducting slab that decouples the movement between the slab and the overriding mantle wedge. Although the formation mechanism of the LVL remains unclear, hydrous minerals such as serpentine may play an essential role in it. The effects of the LVL on solid (or rock) velocity have been extensively investigated. However, little is known of aqueous fluid migration in and around the LVL, despite its importance to our understanding of seismic activity along the subducting plate interface which includes slow earthquakes. In this presentation, I propose a mechanism of fluid flow through the LVL based on a numerical modeling of two-phase flow.

It has been shown that the equations for the solid and fluid phases can be decoupled if porosity is small. I therefore take the following two-step approach based on this assumption. I first solve for solid velocity and the dynamic pressure gradient in and around the LVL. These results are then used to solve for the porosity and compaction pressure in this region.

Preliminary results show that a large amount of fluid is trapped within the LVL by the effects of compaction, that is, the fluid cannot easily flow into the overriding mantle wedge with high viscosity. Dynamic pressure gradient within the LVL becomes large when a thin LVL or high solid viscosity within the LVL is assumed, which leads to a faster fluid flow in the updip direction. These findings suggest that the effects of compaction and dynamic pressure gradient are critical to understand the fluid flow near the subducting plate interface. I also find that the fluid tends to stay near the basal region of the LVL when a non-linear solid viscosity is applied.

# EnKF estimation of frictional properties and slip evolution on a LSSE fault and the changing slip deficit rate on a megathrust fault

*Kazuro Hirahara[1,2]

1. Institute of Education, Research and Regional Cooperation for crisis Management Shikoku, Kagawa University , 2. Riken, AIP center

With EnKF(Ensemble Kalman Filter), we are developing a system of real-time estimation of frictional properties and slip evolution on LSSE(long-term slow slip event) faults together with the slip deficit rate of the megathrust existing at the up-dip portion of the LSSE faults from the observed GNSS data, through numerical experiments. In the present system, the state vector to be forecasted and updated includes slip rates, state variables and frictional parameters on a LSSE fault, and the slip deficit rate in the megathrust fault. The first 3 parameters are constrained by a RSF(rate and state friction) law and data, but the last one is only by data in a kinematic way. Nishikiori and Hirahara (2017) have shown that the system with EnKF has successfully estimated the slip deficit rate together with frictional properties and slip evolution on the assumed Bungo-Channel LSSE fault for the station distribution corresponding to the GEONET one. So far, we have mainly examined the case of the constant slip deficit rate of the locked megathrust fault, assuming a short and stationary period in the Nankai earthquake cycle.
Several simulation studies have suggested the activity of LSSE is changing during the megaquake cycle, and the real-time monitoring of LSSE activity is important for understanding the stress state of the megaquake fault. Hirahara and Nishikiori (2018) have preliminarily examined the effect of changing deficit rate of the locked region. This study is an extension of theirs. A time series of slip deficit rate derived from a simple simulation of the Nankai earthquake cycle with a RSF law produces shorter reoccurrence time and larger slip rate of the Bungo-Channel LSSE fault toward the occurrence of Nankai megaquake. Based on this simulation model, we produce the simulated deformation rate data at GEONET stations. Then we try to estimate the changing slip deficit rate of the Nankai earthquake fault together with frictional parameters and slip evolution on the LSSE fault. Here, we define v_lock=V_lock -Vpl, and assign Vpl=6.5cm/yr. We can correctly trace the v_lock around -6cm/y during almost locked period. However, when v_lock is larger than -4 cm/yr, our system can not trace v_lock and underestimate the value. Then other parameters become to be also estimated as values deviated from the true ones. Therefore, we try to apply covariance inflation to enlarge the error covariance of the forecast state vector. There are two types of covariance inflation to enlarge the error covariance of the forecast vector. One is multiplicative inflation, where the forecast vector is artificially enlarged. Another is additive inflation, where we add random perturbation to the analysis vector in the previous time step, and obtain the forecast one in the next time step. In the latter one, the perturbation is not added directly to the forecast vector but to the analyzed one in the previous time step, so that the dynamical balances are kept when the next forecast is obtained. We use the approach of additive inflation of covariance. Then, we can correctly estimate the value of v_lock as well as other parameters up to a high value of v_lock around 25 cm/yr. We discuss such problems of abrupt breaks when we encounter in applying our system in numerical experiments.

# On a reversely-dipping low-velocity layer in the Tohoku-slab beneath the forearc: unbending induced fluid pathway?

*Hitoshi Kawakatsu[1], HyeJeong Kim[1]

1. Earthquake Research Institute, University of Tokyo

Kawakatsu & Kim (2018, SSJ) have recently updated the receiver function reflectivity images beneath the Japanese islands reported earlier in a series of papers by Kawakatsu and others(e.g., Kawakatsu & Watada, 2007, Science). We collected data from recent 14 years (April 2004 to April 2018) of Hi-net recordings; the resulting new dataset is 2.4, 6.4 and 4.8 times larger in terms of the time period, the number of earthquakes, and the number of RF waveforms compared to the earlier works. New images obtained are generally consistent with the previous ones; as the data quantity increases, the covered area widens and images tend to be clearer and smoother. One exception is that there is a glimpse of reversely-dipping low-velocity layer (LVL) within the slab beneath the forearc region dipping toward the Japan trench. When compared with the recent tomographic model that incorporates data from a seafloor cable seismic network S-net, the LVL appears to correspond to a strong P-wave LVL dipping also toward the trench that is imaged from the slab surface at around a depth of 40km to at least 60km. As this LVL is observed along the entire Tohoku Japan arc, it might be a representation of some mechanical process associated with subduction, unless some systematic bias is introduced in tomography (e.g., mis-location of off-shore earthquake depths). We speculate that this structure may continue to the bottom of the slab as imaged by the tomography though not resolved, and be related with the slab unbending that straightens the slab in the mantle (e.g., Kawakatsu, 1986, JGR). Tensile stress caused by unbending near the slab bottom may open a pathway for the sub-slab fluid to migrate upwards all the way to the slab top to further supply fluids around the slab surface, as well as to hydrate the lower-layer of the double seismic zone as suggested by Seno & Yamanaka (1996, AGU Monograph). Geophysical and geochemical consequences of this hypothesis that might be testable via various ways may be discussed.

Subduction zones worldwide show the common pattern of a lower seismicity plane, where earthquakes occur at intermediate depth within the mantle of the subducting slab. In order to explain the occurrence of these earthquakes different earthquake nucleation mechanisms have been proposed. Some of them attribute seismicity to different transient phenomena that accompany the metamorphic breakdown of water bearing mineral phases. Event though such mechanisms can well explain the distinct shape of the lower seismicity plane and can well be reproduced in laboratory experiments, they are based on the assumption that the subducting plate is hydrated tens of kilometers below the oceanic Moho. Direct evidence for this assumption is scarce.

To detect the possible presence of fluids in the slab mantle, as predicted by the dehydration hypotheses, we estimated the Poisson's ratio of a small rock volume that hosts intra-slab earthquakes by employing a non-tomographic seismic method that has its greatest sensitivity in the direct vicinity of the earthquakes and delivers unique results. We interpret our results by means of a state-of-the-art coupled thermodynamic-poroelastic model. We additionally determine focal mechanisms in the lower seismicity plane to gain information about the prevailing stresses.

The joint interpretation yields a picture in which seismicity occurs at a low rate at 50km depth in a dehydrating but not over-pressured environment at low, overall tensile differential stresses. The modeling results indicate that the fluid occupies a minor volume fraction in the order of only 0.1% and constitutes an interconnected, vein-shaped and therefore transient pore network. These findings are in agreement with results from laboratory experiments, numerical simulations and outcrop studies. They imply that the oceanic mantle of the subducting Nazca slab must be at least weakly hydrated to a depth of 20-30km below the seafloor. Our interpretation can also be applied to tomographic images of other lower seismicity planes, e.g. in Japan.

Ocean Resource Research Center for Next Generation, Chiba Institute of Technology

It has been argued that water is abundant enough across subducting slabs to trigger lower seismic planes (i.e., >40-km-thick hydrous mantle; Peacock, 2001). Geodynamic modeling, however, suggests that the Pacific slab has a low water content beneath Northreast Japan (NEJ) (Nakao et al., 2018), despite presence of the clear lower seismic plane. The model shows that the thickly serpentinized slab mantle (>10 km for 100-Ma slab) causes slow plate convergence, stationary trenches, and slab penetration into the 660-km boundary, in contrast to the case of NEJ (Lallemand et al., 2008; Fukao & Obayashi, 2013). Moreover, seismic velocity and anisotropy structures also indicate a small amount of water around the lower plane in the Pacific slab (Zhang et al., 2004; Reynard et al., 2010). To address this discrepancy, we performed numerical simulations of water transport within and along the subducting slab of a variable age and initial water content. It is demonstrated that the loci of fluid liberation from the subducted slab of an old age (130 Ma) broadly correspond to the upper seismic plane beneath NEJ. On the other hand, loci of any dehydration reaction within the old slab may not explain the lower seismic plane. Instead, the loci of chlorite breakdown for a 36-Ma slab correspond to the lower plane beneath NEJ. In this case, the breakdown and formation of chlorite repeatedly occur, and liberated fluid forms a long curved-linear locus similar to the shape and extent of lower seismic plane in the Pacific slab beneath NEJ. We suggest that the repeated chlorite breakdown which effectively reutilizes a small amount of water contained initially in the slab may trigger the long lower seismic plane beneath NEJ.

# Subduction of serpentinized fracture zone and intraslab earthquakes in southern Mexico

*Marina Manea[1,2]

1. Computational Geodynamics Laboratory, Geosciences Center, National Autonomous University of Mexico, 2. Institute of Astronomy, Romanian Academy

Oceanic fracture zones are born where spreading centers are offset, creating strong gradients in oceanic floor age and vertical offsets in the oceanic lithosphere. Several lines of evidence, such as tectonic uplift and localized volcanic activity distributed along fracture zones, suggest that oceanic fracture zones represent zones of weakness where seawater can infiltrate several kilometers down into the lithosphere and transform mantle peridotites into serpentinites. Such major serpentinized fracture zones are often consumed into subduction zones where they release large quantities of fluids. The southern Mexican subduction zone is similarly characterized by the presence of a large fracture zone, the Tehuantepec fracture zone (TFZ), which presumably is serpentinized. Moreover, the region where TFZ enters into subduction is marked by a relatively low intraplate seismic activity and a large seismic gap where no large megathrust occurred in the last 100 years or more.

In general the physical processes associated with such seismic gaps are not well understood. However, the presence of TFZ in this area can provide a unique opportunity to advance our knowledge into earthquake mechanics linked to mantle thermal structure. The peculiar 2017 M8.2 Tehuantepec intraslab earthquake nucleated in the vicinity of TFZ, and, from analyses of regional geophysical observations, it is demonstrated that this large normal faulting event ruptured the entire ~26 Ma Cocos slab right beneath the megathrust region. The faulting most likely reactivated a bend fault fabric and ruptured to a depth well below the predicted brittle-ductile transition for the Cocos slab, including regions where temperature is expected to exceed 1000˚C, at far greater P-T conditions than previously considered. Additionally, since the rupture area also propagated laterally along the trench and stopped abruptly when encountered the subducted TFZ, we propose that large and serpentinized fracture zones can act as barriers for intraslab earthquakes. I have to acknowledge that all numerical computations were performed at the National Laboratory for Advanced Scientific Visualization at UNAM (LAVIS).

# Reaction-induced embrittlement of the lower continental crust

*Alexandre Schubnel[1], Sarah Incel[2], Julien Gasc[1], Nadège Hilairet[5], Yanbin Wang[3], Feng Shi[3], Loic Labrousse[4]

1. Laboratoire de Géologie, ENS, 2. University of Oslo, 3. GCECARS, University of Chicago, 4. ISTEP, Sorbonne Université, 5. UMET, Université de Lille

Field observations and geophysical data reveal a causal link between brittle seismic failure and eclogitization of the lower continental crust. We present results from experimental deformation of plagioclase-rich samples at eclogite-facies conditions and quantify the link between rock rheology and the kinetics of the eclogitization reactions. The deformation was ductile both in the absence of reaction and when the progress of eclogitization was fast compared to the imposed strain rate. However, when the reaction rate was relatively slow, the breakdown of plagioclase into nanocrystalline reaction products induced a weakening that triggered seismic failure. Fluid-induced plagioclase breakdown under eclogite-facies conditions is an exothermic reaction accompanied by a negative change in solid volume. This is similar to other mineral transformations that are known to trigger transformational faulting. We demonstrate that mineral reactions lead to brittle deformation in situations where reaction rates are slow compared to the deformation rate. This reaction-induced instability may provide a generic mechanism for embrittlement at depths beyond the normal seismogenic zone.

# Transformation-induced, melt-enhanced faulting in orthoenstatite: implications for global intermediate-depth earthquakes

Feng Shi[1], Jianguo Wen[2], Tony Yu[1], Lupei Zhu[3], *Yanbin Wang[1]

1. Center for Advanced Radiation Sources, University of Chicago, Chicago, IL, USA, 2. Center for Nanoscale Materials, Argonne National Laboratory, Argonne, IL, USA, 3. Department of Earth & Atmospheric Sciences, Saint Louis University, St. Louis, MO, USA

Intermediate-depth earthquakes, which occur at ~50-300 km depths and account for ~90% of all deep earthquakes between 50 and 700 km, are ubiquitously observed along convergent plate margins and post great hazards in many regions of the world. Earthquake-depth distribution in oceanic subduction zones exhibits a prevalent secondary seismicity peak between 180 and 240 km, where major dehydration reactions are expected to have completed [1, 2]. This secondary seismcity peak is a direct manifestation of earthquake activities in the lower plane of the double seimic zone [3]. One of the main constituents of oceanic slabs is harzburgite, which consists mainly of olivine and orthoenstatite (OEn) [4]. The latter transforms to high-pressure clinoenstatite (HP-CEn) at ~120 –210 km depths, depending on aluminum content and slab temperature [5, 6]. We conducted deformation experiments on OEn at conditions corresponding to ~ 40 –250 km depths. Within its stability field, OEn deforms plastically; no brittle failure is detected with acoustic emission (AE) monitoring. In the HP-CEn stability field, metastable OEn generates numerous AEs generated, and fails by macroscopic faulting between ~773 and 1373 K. Outside this temperature range, metastable OEn flows plastically again with no AEs detected. Recovered failed samples contain large conjugated faults, with ultrafine-grained gouge layers containing melts that are more Al-rich. OEn grain boundaries are decorated with fine grained (grainsize < 1 micron) garnet and clinoenstatite (CEn). The latter is interpreted as back-transformed HP-CEn upon pressure release. Within large OEn grains, finer-grained garnet forms thin lamellae preferentially parallel to the OEn (100) twin planes. These results suggest that micro-ruptures start in metastable OEn by syn-deformational transformation, which, aided by exothermic latent heat production, results in exsolution lamellae of garnet and CEn, both along the OEn (100) planes, associated with intragranular ruptures. These micro-ruptures conglomerate along weakened grain boundaries to form intergragular faults consisting of ultrafine grained reaction and shear zones, which, through adiabatic heating and local melting, self-organize into macroscopic faults. We propose that in harzburgite, the observed OEn instability triggers shear localization in olivine, resulting in adiabatic instability, a mechanism hypothesized on theoretical grounds [7, 8] and recently observed in laboratory experiments [9].

# The Isolated M7.9 Deep Earthquake of 30 May 2015 Under the Present Bonin Wadati-Benioff Zone: Evidence from the New ISC-EHB Earthquake Catalogue (1930-2015) and CMT Focal Mechanisms

*Stephen Kirby[1], E. Robert Engdahl[2], Emile Andre Okal[3]

1. United States Geological Survey, Menlo Park, 2. University of Colorado, 3. Northwestern University

The M7.9 deep earthquake of 30 May 2015 at a depth of about 680 km was surprising in that it occurred more that 150 km distant from any event in the main Bonin sector Wadati-Benioff Zone (WBZ) above it and more than 120 km deeper than any well-recorded event in the Bonin subduction system. We applied the recently developed ISC-EHB methodology (GJI, 2018, v. 214, 474-484) to produce a comprehensive catalogue of hypocenters for the Izu-Bonin-Marianas region from 1904 to 2015. This methodology, which utilizes only events well-recorded telesesismically along with reported depth phases, ensures that the hypocenters in any given region are relatively well constrained in both location and depth. Individual trench-normal cross sections though the Southern-Bonin/Northern-Marianas subduction systems (including the transition through the Ogasawara Plateau collision zone) display a very sharply defined Bonin inclined seismic zone with no ISC-EHB events at depths and positions between the 2015 deep event and the Izu-Bonin Wadati Benioff Zone (WBZ) above it. Moreover the 2015 deep event occurred at least 200 km north of a possible tear in the main slab at about latitude about 25-26 ˚N where the deep WBZ bends back under the intermediate-depth segment. Most of the CMT focal mechanisms deeper than 300 km within the Bonin WBZ have normal-faulting mechanisms. Some published papers have claimed that the 2015 deep Bonin earthquake occurred in a steeply-dipping sector of the Bonin slab based largely on seismic tomography, but none of these studies have demonstrated sufficient resolution for convincing evidence of high-wave-speed slab material clearly linking the 2015 hypocenter with the main Bonin WBZ. Other published papers show independent evidence that the 2105 event occurred below the Bonin WBZ. We are left with the interpretation that the 2015 event occurred in a slab fragment separated from the main Bonin WBZ. We offer a possible fragmentation scenario involving a oceanic plateau collision, a consequent slab detachment, and an eastward trench stepback. Isolated deep earthquakes in slab fragments can rupture by transformational faulting in metastable olivine (MO) where stresses can originate by the residual stresses caused by heterogeneous volume changes associated with the MO->Spinel transformation (Okal and Kirby, PEPI, 1998).

# What Can $M_w$ −4 Lab-Quakes Teach Us About Deep-Focus Earthquakes?

*Julien Gasc[1], Julien Fauconnier[1], Clémence Daigre[1], Arefeh Moarefvand[1], Damien Deldicque[1], Blandine Gardonio[1], Alexandre Schubnel[1], Pamela Burnley[2]

1. Laboratoire de Géologie, ENS-CNRS, Paris, FRANCE, 2. University of Nevada Las Vegas, Las Vegas, USA

In recent years, several experimental studies have shed new light on possible faulting mechanisms responsible for intermediate and deep-seated earthquakes. These studies rely not only on the traditional analysis of mechanical data and recovered microstructures, but also on the in situ collection of acoustic data –in the form of Acoustic Emissions (AEs)– used to identify possible co-seismic faulting, i.e., brittle failure.

I will give an overview of this recent work and detail how, recently, deep-focus earthquakes mechanisms could be investigated at 1.5 GPa and 750-900˚C, in a new-generation Griggs-type apparatus using sintered $Mg_2GeO_4$ samples. This compound is an analogue of natural olivine for which the transition towards the high pressure phase (spinel structure) occurs at atmospheric pressure, instead of ~14 GPa for the silicate. This transition induces a mechanical instability –the so-called *transformational faulting*– that leads to macroscopic failure of the samples in a narrow temperature window. The boundaries of this brittle window, as for other reactions (quartz-coesite, antigorite dehydration, plagioclase breakdown and so on), are defined by the reaction kinetics. Here, faulting only occurs in cases where spinel nucleates but hardly grows, i.e., when reaction rates are slow.

At 900˚C mechanical data show a softening, indicative of ductile plastic flow, whereas large amounts of hardening followed by rapid stress drops (and audible stick slips) are recorded at 750˚C. AEs were detected in both cases and differences between P and S waves arrival times suggest that the majority of AEs originate inside the sample. Coherence analysis of the AEs seems to suggest that some bursts of events have similar sources. Surprisingly, AEs are more numerous (~600) at higher temperature, where deformation takes place in a ductile way, accommodated by the development of a wide mylonitic shear band. However, at 750˚C, far more energy is released acoustically upon brittle faulting despite a lower number of AEs (~100). Therefore, higher temperatures favor larger reaction rates, which, in turn, allow the growth of ductile fine-grained spinel. Our results confirm that the brittle temperature window (1) is a function of both equilibrium overstep (reaction kinetic) and strain rate and (2) seems to shift towards lower temperatures with decreasing strain rates, which may explain how earthquakes can occur in a slowly reacting metastable olivine wedge at strain rates orders of magnitude lower than in the lab.

# Deep intraslab earthquake rupture due to grain size assisted thermal runaway

*Marcel Thielmann[1], Thibault Duretz[2]

1. Bavarian Geoinstitute, University of Bayreuth, Germany, 2. Université de Rennes, Rennes, France

The rupture of the 2017 Mw 8.2 Tehuantepec earthquake has been shown to extend to temperatures above 1,000 ˚C. Ruptures penetrating to regions of such temperatures are highly unusal and raise the question whether the governing rupture mechanisms at these temperatures are comparable to shallow earthquakes. It has been suggested that dehydration embrittlement could result in deep intraslab earthquakes. However, dehydration embrittlement requires the presence of fluids. In the case of the Tehuantepec earthquake, this means that fluids would have to infiltrate the slab to depths that have not been observed.
An alternative mechanism that may lead to failure at these temperatures and depths is thermal runaway, in particular in conjunction with grain size reduction. Due to the conversion from mechanical work to heat during irreversible deformation, this mechanism weakens the rock. In certain conditions, it then results in zones of highly localized viscous creep along which a significant amount of displacement can be accumulated.
Here, we investigate the onset and formation of a ductile shear zone nucleating a cold temperatures and then propagating to regions of higher temperature using 2D numerical models with a nonlinear viscoelastic rheology. We show that it is indeed possible to form a ductile shear zone through the combined action of grain size reduction and shear heating and determine the parameter ranges where this feedback loop may result in ductile shear zone formation and thus also deep earthquake rupture.

# Fault model of the 2012 off-Miyagi intraslab earthquake doublet and its implication for rheological signature of incoming Pacific plate

*Tatsuya Kubota[1], Ryota Hino[2], Syuichi Suzuki[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Graduate School of Science, Tohoku University

An Mjma 7.3 earthquake composed of a deep reverse-faulting subevent (~60km, Mw 7.2; subevent 1) and a shallow normal-faulting subevent (~20km, Mw 7.1; subevent 2) occurred on 7 December 2012, within the Pacific Plate near the Japan Trench. Since the fault mechanisms of two subevents are consistent with the stress field within the incoming plate near the trench, characterized by the deep compressional and shallow tensile stresses due to the bending of the subducting plate (bending stress, e.g., Chapple and Forsyth, 1979 JGR), we have estimated the finite fault model of this earthquake to discuss the intraplate stress field in this region (Kubota, 2017 PhD thesis, Tohoku Univ). In this study, we conducted more comprehensive discussions for the intraplate stress state, the physical properties, and the relationship between the 2012 earthquake and the Tohoku-Oki earthquake.

We first estimated the initial sea-surface height distribution by inverting the tsunami records and compared it with the vertical deformation expected from the Global CMT solution, to find that the subsided area was generated only by subevent 2 and the uplift area was by both subevents. Then we estimated the optimum fault model for subevent 2, which explains the subsided area of the initial height distribution and the aftershock distribution determined by Obana et al. (2015 AGU FM). Finally, based on the the teleseismic records and the residual displacement between the initial height and the vertical displacement expected from the subevent 2 fault model, we estimated the subevent 1 fault model. We also evaluated the estimation error of our fault model based on the models which had relatively good reproductivity of the sea-surface deformation. As a result, the depth range of the faults of subevents 1 and 2 fell into ~ 45 –70 km and ~ 5 (seafloor) –35 km, respectively.

The down-dip edge of the shallow normal-faulting seismicity in 2012 (~35 km) significantly deepened compared to that in 2007 (~25 km, Hino et al., 2009 G3). However, consideringthe vertical stress gradient of the bending stress (~15 MPa/km), the coseismic stress change by the 2011 Tohoku-Oki earthquake around the normal-faulting seismicity (~20 MPa) is too small to cause normal-faulting earthquakes in that depth range, suggesting that the plate down to ~ 35 km is required to have been already yielded before the Tohoku-Oki earthquake and the frictional strength in the normal-faulting depth range is required to be significantly weaker than the empirical relationship (e.g., Byerlee, 1978). Accounting for the result of the active seismic survey of Fujie et al. (2018 Nature Comm), who suggested the existence of the pore fluid at the shallow part of the subducting plate (< ~ 5 km), the strength reduction is caused by the pore fluid infiltration down to ~ 35 km, along the bending faults (e.g., Faccenda et al., 2009 Nature Geo).

We also obtained the down-dip depth of the deep reverse-faulting subevent at ~70 km, which obviously below the brittle-ductile transition depth expected for the age of the plate. The deep penetration of the fault is explained by the viscoelastic relaxation following the Tohoku-Oki earthquake (e.g., Tomita et al., 2017 Science Adv), which increases the strain rate in the deeper part of the plate. Since the increase of the strain rate makes the brittle-ductile transition depth (e.g., Scholtz, 1988), the depth range of the brittle rupture are extended deeper than that before the Tohoku-Oki earthquake. This result suggests that deep reverse-faulting earthquake in the incoming plate can grow larger after the massive interplate

# Source-rupture process of the intraplate earthquake; its diversity related to the fault geometry and damaged fault zone

*Ryo Okuwaki[1], Yuji Yagi[1]

1. Graduate School of Life and Environmental Sciences, University of Tsukuba

Supershear rupture is one of the features that characterizes the earthquake-rupture complexity. Both the theoretical analyses and the laboratory experiments suggests that the rupture-front propagation can exceed the shear wave velocity of the medium due to the excess of the energy flux into the rupture tip. However in real earthquakes, extrinsic factor that controls the manner of supershear rupture has yet been well captured and a relationship between the geometric complexity of the fault and the supershear rupture propagation has been elusive. Geometrical complexity of the fault system is a challenging feature against a reliable estimate of kinematic slip evolution on the basis of finite-fault inversion, since the presumed, fixed rectangle-fault plane or even configuration of the multiple rectangles may not necessarily, fully represent a real fault geometry. Especially for the strike-slip (mode-II rupture) earthquake, the radiation pattern of the wave is sensitive around nodal-shear planes, and if the earthquake involves the geometric complexity in the fault system, the radiation pattern at a certain location on a fault cannot be reproduced when the presumed model fault geometry deviates from the real one. Although supershear-rupture propagation has often been observed in the large strike-slip earthquake (e.g. Mw 7.8 2001 Kunlun, Tibet and Mw 7.9 2002 Denali, Alaska earthquakes), such limitations of finite-fault modeling has prevented us to discuss a relationship between supershear rupture and the fault geometry.

Here we present a kinematic rupture model for the intraplate, Mw 7.5 2018 Palu, Indonesia, earthquake. The 2018 Palu earthquake occurred along the strike-slip Palu-Koro fault zone, which is located around the triple junction of the Australia, Eurasia, and Philippines sea plates. The trace of the surface rupture of the 2018 Palu earthquake, mapped by the Interferometric Synthetic Aperture Rader (InSAR), shows the geometric complexity around the epicenter and south of the Palu bay. We inverted the teleseismic waveforms to resolve both the spatiotemporal evolution of shear slip and the variation of fault geometry by representing slip with five-basis potency-density tensors, without forcing a shear plane to be consistent with a pre-fixed model plane. A possibility of supershear rupture was taken into account by resolving slip in a wide parametric-model space with longer duration of slip-rate function and faster maximum rupture velocity.

The resultant model showed that a rupture front persistently propagated at a high speed (~5 km/s) that exceeds the local shear wave velocity throughout 200-km long within 40 s, but also showed the transient deceleration and acceleration of slip migration, which can be seen as an inchworm walking. The transient deceleration and acceleration of the slip migration was resolved in the area where the strike angle was rotated from the reference-model strike (358˚), which also coincides with the geometric discontinuity of the surface rupture resolved by the InSAR analyses. We will then discuss possible roles of geometric discontinuity that develops inchworm-like slip evolution and damaged fault zone that enables long-lived supershear rupture propagation, which may be characteristic factors that control diverse rupture process of the intraplate earthquake.

# Aftershocks of the NEXT Cascadia Intraslab Earthquake

*Paul Bodin[1,2]

1. University of Washington Seattle, 2. Pacific Northwest Seismic Network

In 1949, 1965, and 2001 damaging (M6.5-M6.8) deep (~60 km) earthquakes ruptured faults within the Juan de Fuca slab beneath the Puget Sound region of the Cascadia subduction zone in the Pacific Northwest of the U.S.. Each had only a few and very small (approximately M<4) aftershocks. Immediately after the *next* such damaging intraslab earthquake shall we tell the public and first responders that there will likely be no damaging aftershocks? While this low likelihood of aftershocks seems probable based on the historical record, there is no compelling well-agreed-upon physical reason to expect this behavior. For example, recent deep intraslab earthquakes in Japan, Alaska, and Mexico have been followed by strong aftershock sequences. Is the lack of aftershocks following Cascadian intraslab earthquakes unique or extreme? And is it expected and explainable? Possible explanations for regulating the production rate of aftershocks include physical environmental characteristics such as pressure and temperature, geological differences like rock types and faulting geometry, dynamic frictional factors like slip rates, afterslip, and stress drop, and possible roles of fluids. We survey aftershock occurrence following recent smaller Cascadian intraslab earthquakes and following recent large intraslab earthquakes in a number of subduction zones and attempt to classify and distinguish between hypotheses for the lack of Cascadian deep earthquake aftershocks. Is this another possibly unique feature of Cascadia, like the nearly complete lack of instrumentally observed interface earthquakes of any size?

[E] Poster | S (Solid Earth Sciences)：S-CG Complex & General

Thu. May 30, 2019 3:30 PM - 5:00 PM JST | Thu. May 30, 2019 6:30 AM - 8:00 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_14

## [S-CG50] Intraslab and intraplate earthquakes

convener:Saeko Kita(International Institute of Seismology and Earthquake Engineering, BRI), Tomohiro Ohuchi(Geodynamics Research Center, Ehime University), Marcel Thielmann(Bavarian Geoinstitute, University of Bayreuth), Ryo Okuwaki(Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology)

The purpose of this session is to share recent advances of geo-scientifical studies for intraslab and shallow-depth intraplate earthquakes. We seek to formulate future directions of the interdisciplinary study of the occurrence of intermediate-depth and deep earthquakes from the viewpoint of seismology, geodynamics and mineral physics. We welcome presentations from a wide variety of scientific disciplines, including seismology, seismotectonics, geodynamics, mineral and rock physics, other geophysics, geology, and numerical modeling.

# Changes in seismicity rate, stress orientations, and b-values before and after ETS events in the Philippine sea plate under Kii Peninsula

*Saeko Kita[1], Heidi Houston[2], Sachiko Tanaka[3], Youichi Asano[3], Takuo Shibutani[4], Naoki Suda[5]

1. Building Research Institute, 2. USC, 3. NIED, 4. DPRI, Kyoto University, 5. Hiroshima University

The slip on the plate interface has the potential to affect the stress field and seismicity within the subducting slab. Several studies have examined the interaction of slow slip phenomena with intraslab earthquakes [Nankai and Tokai regions, Han et al. 2014; Mexico, Radiguet et al. 2018, 2018 JpGU meeting; New Zealand, 2018, Warren-Smith, 2018 AGU meeting]. Kita et al. [2018, SSJ meeting] reported the stress change in the whole slab associated with ETS times based on stress tensor inversion results. However, we find a clear double seismic zone under Kii Peninsula, as also noted in a previous study [e.g. Miyoshi and Ishibashi, 2004]. Therefore, we here examine seismicity rate variations, stress changes, and b-value variations of seismicity separately for the upper plane events and oceanic mantle ones relative to ETS timings beneath the Kii Peninsula. We use the JMA earthquake catalog, the NIED tremor catalog, the upper surface of the Philippine sea plate estimated by Shibutani and Hirahara [2016], P-wave polarity data by NIED, and a stress tensor inversion code [Vavrycuk, 2014].

We determined the timings of ~30 large ETS beneath the Kii Peninsula from 2001 to 2017, and categorized slab seismicity relative to the occurrence times of nearby the ETS (i.e., 60 days before or after). We then combined or stacked the slab seismicity based on these relative occurrence times. The rate of seismicity both in the upper plane events and in the oceanic mantle ones after the ETS timings clearly decreased, compared to the rate before the ETS timings. The peaks of b-values of seismicity both in the upper plane events and oceanic mantle ones were found to occur 1.5 months before ETS. A change in stress orientations before and after the ETS was seen in the oceanic mantle, and a relatively small change was seen for the upper plane events. The stress change in the upper plane events appears to be larger in the region updip of the ETS zone. The results of our study suggest that the aseismic slip on the plate boundary may affect the stress field and the occurrence of seismicity within the subducting slab beneath the Kii Peninsula. Fluid migration from the oceanic slab into the ETS zone on the plate boundary could be related to the interaction of slow slip phenomena with intraslab earthquakes.

# Inhomogeneous conduit across slab controlled by intraslab stress heterogeneity in the Nankai subduction zone

*Makoto Otsubo[1], Ayumu Miyakawa[2], Ikuo Katayama[3], Keishi Okazaki[4]

1. Geological Survey of Japan, Research Institute of Earthquake and Volcano Geology, 2. Geological Survey of Japan, Research Institute of Geology and Geoinformation, 3. Hiroshima University, 4. JAMSTEC

Non volcanic deep low-frequency tremors and slow slip events occur simultaneously in the transition zone from locked to continuously creeping fault at the down dip portion of the Nankai Trough subduction zone, southwestern Japan. The occurrence of these slow earthquakes is attributed to the effect of high pore pressures on the plate boundaries. The Nankai Trough subduction zone has a discontinuous band of occurrence of these slow earthquakes along the trench. Here we show that spatial variation of intraslab stress can control fluid migration through the subducted Philippine Sea slab to the plate boundary. The tri-axial normal faulting stress detected by the stress tensor inversion by using focal mechanisms in the slab controls anisotropies of permeability trending NNW–SSE sub-horizontal orientation from the subducted Philippine Sea slab to the plate boundary. The inhomogeneous condition controlled by the spatial stress heterogeneities in the subducted Philippine Sea slab represents the intraslab fluid pathway. The hypothesis is consistent with spatial heterogeneity of slow earthquake activities and $^{3}He/^{4}He$ ratio distributions.

# New insights into the mechanism of deep-focus earthquakes

*Ayako Tsuchiyama[1], Junichi Nakajima[1]

1. Tokyo Institute of Technology

Generally, deep-focus earthquakes were generated in subducting slabs and occurred along some specific regions such as Izu-Bonin zone and Tonga-Fiji zone. We have not identified their occurrence mechanisms, even though some plausible hypotheses, dehydration embrittlement, thermal and shear plastic instability, and transformational faulting, were proposed. In this study, we try to obtain new constraints that deepen the understanding of deep-focus earthquakes through waveform analysis of earthquakes in the Izu-Bonin subduction zone.

First, we picked up 460 quakes at a depth range of 300-400 km in 2003-2015 beneath Tokai area from the catalog data provided by Japan Meteorological Agency, and relocated them with double-difference earthquake relocation algorithm (hypoDD; Waldhauser and Ellsworth, 2000). Second, we computed their coherence values between all available pairs of earthquakes with cross-spectrum analysis. Then, we were successful to identify a few earthquake clusters that had a very high coherence value over 0.9 in a long time window of 40 s including P and S waves. Moreover, we relocated these earthquakes with hypoDD again by using precisely-determined differential travel-time data derived from waveform data. As a result, we could find that earthquakes in each cluster occurred on single fault plane with complementary rapture areas.

Additionally, we implemented moment tensor inversion (Gephart and Forsyth, 1984) and estimated the stress field around the region where we discovered a few clusters showing waveform similarities. Moreover, we computed the amount of stress drop of the similar earthquakes with spectrum analysis of seismic wave. Through these waveform analyses, we interpreted that the mechanism of these similar deep-focus earthquakes could be explained by combining two possible mechanisms; dehydration embrittlement that regulates the rupture initiation and thermal and shear plastic instability that controls the rupture propagation along a pre-existing fault.

# Faulting in deforming harzburgite under wet conditions

*Tomohiro Ohuchi[1], Xinglin Lei[2], Yuji Higo[3], Yoshinori Tange[3], Takeshi Sakai[1]

1. Geodynamics Research Center, Ehime University, 2. National Institute of Advanced Industrial Science and Technology, 3. Japan Synchrotron Radiation Research Institute

The subduction zone produces a major fraction of the Earth's seismic activity. The mechanisms of intermediate-depth (> 40 km depth) and deep-focus (> 300 km) earthquakes are fundamentally different from those of shallow (< 40 km) earthquakes. This is because the frictional strength of silicate rocks exceeds the upper limit of the stress level in the upper mantle (< 300 MPa: Obata and Karato, 1995) at pressures higher than 1 GPa (~30 km depth). Therefore, the cause of intraslab seismicity at intermediate depths has been attributed to dehydration of serpentinite (e.g., Peakock, 2001) because the water released during dehydration reaction of serpentinite reduces the effective confining pressure. The dehydration embrittlement model is now widely accepted, because the location of the double seismic zone in the subducting Pacific slab corresponds to the main dehydration field in the pressure-temperature diagram of the hydrous peridotite (Omori et al., 2002).

To evaluate the effect of water on semi-brittle behavior of harzburgite, we conducted in-situ uniaxial deformation experiments on as-is/water-saturated harzburgite at pressures 1.2-3.0 GPa and temperatures 770-1250 K with a constant displacement rate using a deformation-DIA apparatus. Pressure, stress, and strain were measured in situ by using x-ray diffraction patterns and radiographs. Acoustic emissions (AEs) were also recorded continuously on six sensors, and three-dimensional AE source location were determined.

Formation of throughgoing faults was observed even when differential stress is much lower than the confining pressure (i.e., > 0.3 times of confining pressure) in water-saturated harzburgite. This is contrast to the case of water-saturated dunite (Ohuchi et al., 2018), in which fracture strength exceeds the confining pressure (i.e., Goetze's criterion). Creep strength of water-saturated harzburgite was lower than that of as-is harzburgite (~0.5-1 GPa at each temperature). Weakening of the harzburgite by the aqueous fluid resulted in the reduction in the number of AE events and decrease in fault slip rate (< 3.6E-4 $s^{-1}$ at a stress of < 1.05 GPa). Stress/pressure drop around the timing of a faulting was limited at strains of 1E-4 $s^{-1}$. The aseismic faulting observed in the water-saturated harzburgite implies that silent slip events around the subduction interface is due to semi-brittle flow of water-saturated harzburgite (i.e., a dehydration product of antigorite).

Keywords: harzburgite, water, semi-brittle flow

# Semi-brittle behavior of olivine single crystals under the conditions of Earth’s mantle transition zone

Yoshihisa Naruse[1], *Tomohiro Ohuchi[1]

1. Geodynamics Research Center, Ehime University

The origin of deep-focus earthquakes, which occur at depths of 300-700km in the subducting slabs, fundamentally differs from that of other earthquakes and has been attributed to the pressure-induced phase transition in olivine. Previous studies on $Mg_2GeO_4$ olivine have shown that grain size reduction induced by the phase transition in olivine causes shear localization (e.g., Burnley et al., 1991; Schubnel et al., 2013). Schubnel et al. (2013) reported intense acoustic emissions around the timing of a faulting which would be induced by shear localization in polycrystalline $Mg_2GeO_4$ olivine. In order to understand the relationship between fracturing and the phase transition in olivine, we conducted deformation experiments on single crystals of San Carlos olivine ($Fo_{91}$) at pressure of 10-15 GPa and temperatures of 1000-1100 degC using a deformation-DIA apparatus. Single crystal of olivine was chosen to exclude the effect of grain boundaries on nucleation of high-pressure phases of olivine (i.e., wadsleyite and ringwoodite).

Array of microcrack parallel to either (100), (010) or (110) plane was developed at an ~50 degree to the direction of uniaxial compression. Rotation of olivine axes associating the formation of subgrain boundaries was observed around the microcrack arrays, showing that plastic deformation of the olivine single crystal inevitably associated formation of the microcracks. In most samples, microcracks coalesced and then a few throughgoing fractures were developed. Particles of wadsleyite /ringwoodite having a diameter of a few micrometer or less were preferentially nucleated on the microcrack surfaces. Ultrafine-grained domains, which consist of the wadsleyite /ringwoodite particles, were formed along the throughgoing fractures. Development of a banded ultrafine-grained domain was also observed along a throughgoing fracture, implying that shear localization could occur as a result of semi-brittle flow of olivine and a transition from dislocation creep to grain-size-sensitive creep in subducting slabs at depths > 410 km.

# High-pressure deformation experiments on peridotite gouges under hydrothermal conditions, using a deformation-DIA apparatus

*Maki Semba[1], Ken-ichi Hirauchi[1], Tomohiro Ohuchi[2], Katsuyoshi Michibayashi[3]

1. Department of Geosciences, Faculty of Science, Shizuoka University, 2. Geodynamics Research Center, Ehime University, 3. Department of Earth and Planetary Sciences, Nagoya university

In subducting oceanic plates, the focal depth of intraslab earthquakes is deeper (>40 km) than that of interplate earthquakes. Since the normal stress on faults (e.g., outer-rise faults) hosting the intraslab earthquakes is too high to generate brittle shear failure, there may be some mechanisms to weaken effective fault strength. In addition, the hypocenter distribution of intraslab earthquakes forms double-planed structure of the deep seismic zone, and the location of the lower plane is in accord with the stability limit of serpentine (antigorite), suggesting shear deformation of antigorite-bearing peridotite gouges in the presence of hydrothermal water. Here, in order to understand the influence of hydrous minerals on the fault strength, we performed deformation experiments on simulated peridotite gouges with compositions of dunite (100% olivine) and harzburgite (70% olivine/30% orthopyroxene) under hydrothermal conditions, using a deformation-DIA apparatus. The experiments were conducted at a temperature of 580˚C, a confining pressure of 2.5 GPa, and shear strain rates of 2.70 $\times 10^{-5}$ to 1.03 $\times 10^{-4}$ $s^{-1}$. In the deformed peridotite gouges, localized shear zones such as $R_1$ and B shears were observed, and these shears were accompanied with newly formed hydrous phases (serpentine or talc). Olivine grains have a crystal preferred orientation characterized by a slip system of [001] (010). These results indicate that semi-brittle flow is a major deformation mechanism of the peridotite gouges. Considering low coefficients of friction of serpentine and talc, we can suggest that the infiltration of seawater along outer-rise fault planes and subsequent hydrothermal alteration result in effective shear strengths low enough to produce intraslab earthquakes.

# Stable fault slip in antigorite-olivine aggregates at high pressures

Mai Ikehara[1], *Tomoaki Kubo[1], Takuya Iwasato[2], Yuji Higo[3], Masahiro Imamura[1], Yoshinori Tange[3]

1. Kyushu University, 2. Shin-Nippon Nondestructive Inspection Co., Ltd., 3. JASRI

Intermediate-depth earthquakes are observed to occur within subducting oceanic plates at depths of about 60-300 km where most materials exhibit plastic deformation rather than brittle failure, owing to high pressures and temperatures. Dehydration embrittlement of hydrous minerals, particularly antigorite serpentine, is one of the most popular hypotheses for explaining shear instability under such conditions (e.g., Raleigh and Paterson, 1965). Recent high-pressure deformation experiments, monitoring Acoustic Emission (AE) activities upon syndeformational antigorite dehydration, showed that dehydration embrittlement was not observed on single-phase antigorite (Gasc et al., 2017), whereas dehydration related faulting was formed on antigorite-olivine aggregates with strong AEs (Ferrand et al., 2017). However, most of the previous high-pressure studies have been conducted in axial compression at relatively low pressures (< 3.5 GPa), insufficient to consider intermediate-depth earthquakes. Therefore, in this study, we conducted high-pressure shear deformation experiments on two-phase aggregates of antigorite and olivine, considering partially serpentinized peridotites, in order to investigate possible shear localization and shear instability up to 7 GPa.

Deformation experiments were conducted at 5-7 GPa, 350-700 ℃ using Deformation-DIA apparatuses at SPring-8 (BL04B1). Monochromatic X-rays (50-60 keV) were used to measure dehydration kinetics, shear strain and stress with recording AEs. We used three kinds of starting materials; natural cored antigorite from Kawarakoba in Nagasaki prefecture, forsterite polycrystal, and two-phase sintered mixtures of antigorite and San Carlos olivine (antigorite 10, 30, 50 vol %). The samples were cut into disks having thickness of 300 $\mu$m and used for a shear deformation study by being assembled between two 45˚-cut alumina pistons. In shear deformation experiments, the starting disk was compressed to 5 or 7 GPa at room temperature, annealed at 350 or 400 ℃ for 1 h, and then deformed with an anvil displacement rate of 200 $\mu$m/h. In some experiments, we increased temperature during shear deformation with a ramping rate of 0.1 ℃/sec to induce dehydration reaction. Microstructures of the recovered samples were examined by an optical microscope and a scanning electron microscope (SEM).

From X-ray radiography images, we observed shear localization in all two-phase samples deformed within the antigorite stability field at 5 GPa. The locallization occurred when homogeneous shear strain $\gamma$ reached 0.4-0.9 (strain rate 1.3-2.2 $\times 10^{-4}$/s), and then most strains were partitioned to the fault zone with the slip velocity of 4.6-9.1 $\times 10^{-2}$ $\mu$m/s. Because no AEs were detected from the sample region, the localized deformation is thought to occur by stable sliding. SEM observations revealed that a thin shear deformation zone was formed along the fault, where the plastic deformation of both antigorite and olivine was significant. Striation and nanograins were observed on the fault plane, suggesting the formation of nanogouge. In contrast, homogeneous deformation was developed during antigorite dehydration with temperature ramping, even in the sample showing shear localization in the antigorite stability field. Under higher pressure condition 7 GPa, shear localization did not occur in all samples regardless of temperature. These results suggest that, although AE activities were detected with the dehydration in the antigorite-olivine aggregates up to 3.5 GPa in the previous study, further increase of pressure inhibits shear instability and shear localization. Thus, other dehydration reactions and/or instability mechanisms are required to explain intermediate-depth earthquakes deeper than ~100 km.

# Rheology and frictional instability of lawsonite in high pressure deformation experiments

*Rei Shiraishi[1], Jun Muto[1], Akihiro Tsunoda[2], Sando Sawa[1], Akio Suzuki[1]

1. Department of Earth Science, Graduate School of Science, Tohoku University, 2. Earthquake Research Institute, University of Tokyo

The cause of intermediate-depth earthquakes (50-300 km) in subducting slabs have been proposed to be the dehydration embrittlement (e.g., Raleigh and Paterson, 1965), because there are many kinds of hydrous minerals in a subducting slab and hypocenter distribution coincides with the dehydration boundary determined by high pressure experiments (e.g., Hacker et al., 2003). Many experimental studies on antigorite have been conducted, but a few previous works about dehydration embrittlement of lawsonite-bearing rocks experimentally. Lawsonite, $CaAl_2Si_2O_7(OH)_2H_2O$, is a hydrous mineral which contains 11 wt% water in its structure as both water molecules and a hydroxy group (Cmodi and Zanazzi, 1996). Lawsonite is one of the candidate for dehydration embrittlement in cold subducting slabs, however previous works have apparently contradictory results. Okazaki and Hirth (2016) showed that lawsonite dehydration induced unstable fault slip based on deformation experiments of pure lawsonite using Griggs-type deformation apparatus at 1 GPa. On the other hand, Incel et al. (2017) also investigated deformation properties of lawsonite and glaucophane mixture at 1.5 to 3.0 GPa using deformation-DIA apparatus. They insisted that there is no evidence for a straightforward relation to the dehydration of lawsonite and the brittle failure of samples. So, we have conducted the deformation experiments of lawsonite under the cold slab conditions in order to clarify the deformation property of lawsonite and understand the relationship between dehydration and brittle failure.

Experiments were carried out using Deformation-Cubic Anvil Press (D-CAP) installed at KEK PF AR-NE7A beamline. Pure lawsonite powder (98%) was used as starting materials. Deformation experiments were carried out at a pressure of 6 GPa and temperatures of 300 - 800 ˚C. The temperature was increased at the same time as deformation started. The temperature ramping rate over the strain rate was set the ranges for the real subducting slab, which ranges from $10^2$ to $10^4$ ˚C (Chernak and Hirth, 2011; Okazaki and Hirth, 2016). During deformation stages, strain, stress and transformation rate were measured for in-situ using a monochromatic X-ray beam with an energy of 60 keV.

Four experiments showed rapid stress drop during temperature ramping before lawsonite dehydration starts. We observed microstructure of recovered samples, there are many through going faults and microcracks but no dehydration products. Our results indicate that brittle process and frictional sliding occur without dehydration of lawsonite. This suggests that the intermediate-depth earthquakes can be caused by the deformation itself of lawsonite without the dehydration of lawsonite.

# Grain Size Dependency of Olivine-Spinel Phase Transformational Mechanism Responsible for Deep-focus Earthquakes

*Sando Sawa[1], Jun Muto[1], Nobuyoshi Miyajima[2], Hiroyuki Nagahama[1]

1. Department of Earth Science, Tohoku University, 2. Bayerisches Geoinstitut, University of Bayreuth

Deep-focus earthquakes occur at the depth from 440 km to 660 km in the subducting slab. The mechanism responsible for the earthquakes is thought to be different from that of shallow earthquakes, so that previous studies have reported the various mechanisms. By the geophysical observations and deformation experiments, the phase transformational faulting mechanism is presumed as the precursor of deep-focus earthquakes (e.g., Zhan et al., 2014). The phase transformational faulting mechanism is that metastable olivine in the slab undergoes the phase transformation to fine-grained spinel and faulting occurs with strain localization into the fine-grained spinel. This shear instability depends on grain size. Furthermore, the grain size may restrict the pressure- and temperature-conditions where the shear instability occurs, that is, the region of slab where deep-focus earthquakes occur. However, previous studies have conducted deformation experiments with finer grain size than expected in the slab (e.g., Burnley et al., 1991). Hence, the results from the laboratory experiments cannot directly apply to the geophysical observation. In this study, to reveal the grain size dependency on the phase transformational faulting, we conducted the deformation experiments of germanate olivine (about 3 $\mu$m), which is an analogue material of silicate olivine, finer-grained than that in previous studies (30 $\mu$m). We used a Griggs-type solid-confining media deformation apparatus. The confining pressure, temperature and strain rate are 1.2 GPa, 400~900 ℃ and $2.0\times10^{-4}$ $s^{-1}$, respectively. Even though deformation experiments were conducted under wider temperature conditions than previous studies, we did not observe any shear instability event with apparent stress drops. Also, Raman spectroscopy clarified that the germanate olivine underwent the transformation to spinel at temperatures higher than 500 ℃. Shear instability does not occur because the difference in grain sizes between olivine and nucleated spinel in this study was smaller than those in previous studies. Also, the transformation temperature in this study was much lower than those in previous study (T > 1000 ℃ in Burnley et al., 1991). Considering the rate equation of the transformation (Chan, 1956), small grain size promotes the transformation, but these fast rates of the transformation cannot be explained only by the effect of the grain size. Therefore, the presence of water such as absorbed water in a starting material can also contribute to promote the transformation. Hence, both small initial grain size and a little amount of water promote the transformation even at lower temperature. These results indicate that the phase transformational faulting mechanism has strong grain size dependency. In summary, the pressure- and temperature-conditions where the faulting occurs depends on the grain size of olivine and amount of water. Because the grain size in the slab is larger than that in the experiments, by extrapolating from these results, we may restrict the region of slab where deep-focus earthquakes occur.

# Seismicity and mineral destabilizations in the subducting mantle up to 6 GPa, 200 km depth

*Thomas P. Ferrand[1]

1. Earthquake Research Institute

In the subducting oceanic lithosphere, a significant part of the seismicity is triggered in the mantle, especially along the upper and lower Wadati-Benioff planes. Several studies have investigated the potential involvement of dehydration reactions in the triggering mechanism of mantle earthquakes. Recent experimental results reveal that, under subduction conditions, mechanical instabilities nucleate in strong stable mineral aggregates during the destabilization of minor amounts of antigorite, i.e. the high-temperature serpentine, through a stress transfer, without any fluid overpressure. Here I confront these laboratory results to seismological observations. On one hand, most of the natural hydrous magnesium silicates seem to be known, with experimentally-deduced stability limits up to 7 GPa, at least, available as relatively accurate estimates. On the other hand, recent achievements in thermal structure of subduction zones combined with precise hypocentre relocation give access to pressure and temperature conditions at earthquakes hypocentres. A series of P-T diagrams summarizes the stability limit of minerals that may be part of natural peridotite with variable compositions at pressures from 0.5 to 6 GPa and temperatures from 200 to 950˚C, and compares it with seismicity. Both hydrous and anhydrous phases are considered. A myriad of minor metamorphic reactions could participate in a transformation-driven stress transfer, even if the stability limits of serpentine minerals seem to correlate with most of the observed seismicity.

# Receiver function imaging of subducting Pacific plate and mantle wedge under Japanese islands using denser network of stations

*HyeJeong Kim[1], Hitoshi Kawakatsu[1], Takeshi Akuhara[1], Masanao Shinohara[1]

1. Earthquake Research Institute, The University of Tokyo

Receiver function imaging has been frequently used by different groups focusing on different depths of the Japanese subduction zone. The overlying crust (Shiomi and Park, 2008, Bianchi et al, 2015), the Pacific plate before (Kawakatsu et al., 2009) and after subduction (Kawakatsu and Watada, 2007; Wirth and Long, 2012), and the mantle transition zones (Kawakatsu and Yoshioka, 2011; Tauzin et al., 2018) were discussed using the NIED array stations (Hi-net and F-net). Recently, deployment of ocean bottom seismometers (OBSs) enabled studies of subduction zones closer to the trench (e.g., Akuhara and Mochizuki, 2015). Kawakatsu and Kim (2018, SSJ) have obtained a new version of receiver function imaging using 14-year long of Hi-net data. However, there are other land stations (e.g., J-array) that can improve the station coverage. Here, we collect data from available on-land stations deployed in north-eastern Japan to obtain a denser 2-D array of stations. Additionally, data from temporary OBS stations (Shinohara et al. 2012) are gathered to image the subducted Pacific plate in shallower depths than previously available. Continuous imaging from ocean to land will help to constrain transition of the hydrated oceanic crust along subduction that is expressed as a low velocity layer for better understanding of the hydration/dehydration processes during subduction, which might be related to the occurrence of subduction zone earthquakes.

# Strong S-wave attenuation in the mantle wedge beneath the NE Japan and interpretations of high-frequency wave propagation path of intraslab earthquakes

*Takahiro Shiina[1,2], Kei Katsumata[2], Kiyoshi Yomogida[3], Aitaro Kato[1]

1. Earthquake Research Institute, The University of Tokyo, 2. Institute of Seismology and Volcanology, Graduate School of Science, Hokkaido University, 3. Graduate School of Science, Hokkaido University

For intraslab earthquakes at intermediate-depths in NE Japan, especially at greater than about 100-km depths, it has been often recorded that high-frequency waveform higher than 8 Hz show a remarkable delay of arrival compared with S wave which predominates in a low-frequency band. The magnitude of the delay is little in the forearc region, whereas it increases up to about 40 s in the backarc region. In this study, we investigate the details in the propagation processes of the high-frequency later phase observed for the intraslab earthquakes at the intermediate-depths. To constrain the source location of the high-frequency later phase, we employ the source-scanning algorithm (SSA) [Kao and Shan, 2004] with realistic velocity and attenuation structures, assuming that the high-frequency later phase is generated by the single scattering process. Namely, we estimate a scattering point by using mean-square amplitudes which is synthesized from two horizontal components of the observed waveforms.
Results in frequency bands of 4-32 Hz show that scattering points are distributed beneath the forearc region. The scattering points can reproduce the observed delays of amplitude amplifications associating with the high-frequency later phases. Moreover, similar locations of the scattering points are imaged along the forearc region in the entire NE Japan. These results indicate that high-frequency later phase is a wave scattered at the forearc region and that short wave-length heterogeneity generally developed in the forearc region of NE Japan.
This interpretation well matches implications from previous studies [e.g., Yomogida et al., 2004; Hasemi and Horiuchi, 2010]. Additionally, the obtained distributions of scattering points which appear to surround the highly attenuating mantle wedge suggest that attenuation structure strongly controls propagation paths of seismic wave, in particular, a high-frequency wave. In other words, the identifications of high-frequency later phase may become easy because the amplitude of direct wave crossing the high-attenuation zone decreases. To confirm this consideration, we estimate *Qs* along the direct wave by using the coda-normalization method [e.g., Aki, 1980]. This estimation provides 2-3 times smaller path-averaged *Qs* in seismic records of which rays lay on the backarc and the volcanic front than that of which rays lay on the forearc region. These results support that spatial variation in *QS* produces heterogenous propagations of seismic waves emitted from intraslab earthquakes. It is thus required to take scattering and attenuation structures simultaneously into account to understand complex behaviors of high-frequency waves in a future study.

[E] Poster | S (Solid Earth Sciences)：S-CG Complex & General

Thu. May 30, 2019 5:15 PM - 6:30 PM JST | Thu. May 30, 2019 8:15 AM - 9:30 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_26

## [S-CG50] Intraslab and intraplate earthquakes

convener:Saeko Kita(International Institute of Seismology and Earthquake Engineering, BRI), Tomohiro Ohuchi(Geodynamics Research Center, Ehime University), Marcel Thielmann(Bavarian Geoinstitute, University of Bayreuth), Ryo Okuwaki(Research Institute of Earthquake and Volcano Geology, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology)

The purpose of this session is to share recent advances of geo-scientifical studies for intraslab and shallow-depth intraplate earthquakes. We seek to formulate future directions of the interdisciplinary study of the occurrence of intermediate-depth and deep earthquakes from the viewpoint of seismology, geodynamics and mineral physics. We welcome presentations from a wide variety of scientific disciplines, including seismology, seismotectonics, geodynamics, mineral and rock physics, other geophysics, geology, and numerical modeling.

# Changes in seismicity rate, stress orientations, and b-values before and after ETS events in the Philippine sea plate under Kii Peninsula

*Saeko Kita[1], Heidi Houston[2], Sachiko Tanaka[3], Youichi Asano[3], Takuo Shibutani[4], Naoki Suda[5]

1. Building Research Institute, 2. USC, 3. NIED, 4. DPRI, Kyoto University, 5. Hiroshima University

The slip on the plate interface has the potential to affect the stress field and seismicity within the subducting slab. Several studies have examined the interaction of slow slip phenomena with intraslab earthquakes [Nankai and Tokai regions, Han et al. 2014; Mexico, Radiguet et al. 2018, 2018 JpGU meeting; New Zealand, 2018, Warren-Smith, 2018 AGU meeting]. Kita et al. [2018, SSJ meeting] reported the stress change in the whole slab associated with ETS times based on stress tensor inversion results. However, we find a clear double seismic zone under Kii Peninsula, as also noted in a previous study [e.g. Miyoshi and Ishibashi, 2004]. Therefore, we here examine seismicity rate variations, stress changes, and b-value variations of seismicity separately for the upper plane events and oceanic mantle ones relative to ETS timings beneath the Kii Peninsula. We use the JMA earthquake catalog, the NIED tremor catalog, the upper surface of the Philippine sea plate estimated by Shibutani and Hirahara [2016], P-wave polarity data by NIED, and a stress tensor inversion code [Vavrycuk, 2014].

We determined the timings of ~30 large ETS beneath the Kii Peninsula from 2001 to 2017, and categorized slab seismicity relative to the occurrence times of nearby the ETS (i.e., 60 days before or after). We then combined or stacked the slab seismicity based on these relative occurrence times. The rate of seismicity both in the upper plane events and in the oceanic mantle ones after the ETS timings clearly decreased, compared to the rate before the ETS timings. The peaks of b-values of seismicity both in the upper plane events and oceanic mantle ones were found to occur 1.5 months before ETS. A change in stress orientations before and after the ETS was seen in the oceanic mantle, and a relatively small change was seen for the upper plane events. The stress change in the upper plane events appears to be larger in the region updip of the ETS zone. The results of our study suggest that the aseismic slip on the plate boundary may affect the stress field and the occurrence of seismicity within the subducting slab beneath the Kii Peninsula. Fluid migration from the oceanic slab into the ETS zone on the plate boundary could be related to the interaction of slow slip phenomena with intraslab earthquakes.

# Inhomogeneous conduit across slab controlled by intraslab stress heterogeneity in the Nankai subduction zone

*Makoto Otsubo[1], Ayumu Miyakawa[2], Ikuo Katayama[3], Keishi Okazaki[4]

1. Geological Survey of Japan, Research Institute of Earthquake and Volcano Geology, 2. Geological Survey of Japan, Research Institute of Geology and Geoinformation, 3. Hiroshima University, 4. JAMSTEC

Non volcanic deep low-frequency tremors and slow slip events occur simultaneously in the transition zone from locked to continuously creeping fault at the down dip portion of the Nankai Trough subduction zone, southwestern Japan. The occurrence of these slow earthquakes is attributed to the effect of high pore pressures on the plate boundaries. The Nankai Trough subduction zone has a discontinuous band of occurrence of these slow earthquakes along the trench. Here we show that spatial variation of intraslab stress can control fluid migration through the subducted Philippine Sea slab to the plate boundary. The tri-axial normal faulting stress detected by the stress tensor inversion by using focal mechanisms in the slab controls anisotropies of permeability trending NNW–SSE sub-horizontal orientation from the subducted Philippine Sea slab to the plate boundary. The inhomogeneous condition controlled by the spatial stress heterogeneities in the subducted Philippine Sea slab represents the intraslab fluid pathway. The hypothesis is consistent with spatial heterogeneity of slow earthquake activities and $^{3}He/^{4}He$ ratio distributions.

# New insights into the mechanism of deep-focus earthquakes

*Ayako Tsuchiyama[1], Junichi Nakajima[1]

1. Tokyo Institute of Technology

Generally, deep-focus earthquakes were generated in subducting slabs and occurred along some specific regions such as Izu-Bonin zone and Tonga-Fiji zone. We have not identified their occurrence mechanisms, even though some plausible hypotheses, dehydration embrittlement, thermal and shear plastic instability, and transformational faulting, were proposed. In this study, we try to obtain new constraints that deepen the understanding of deep-focus earthquakes through waveform analysis of earthquakes in the Izu-Bonin subduction zone.

First, we picked up 460 quakes at a depth range of 300-400 km in 2003-2015 beneath Tokai area from the catalog data provided by Japan Meteorological Agency, and relocated them with double-difference earthquake relocation algorithm (hypoDD; Waldhauser and Ellsworth, 2000). Second, we computed their coherence values between all available pairs of earthquakes with cross-spectrum analysis. Then, we were successful to identify a few earthquake clusters that had a very high coherence value over 0.9 in a long time window of 40 s including P and S waves. Moreover, we relocated these earthquakes with hypoDD again by using precisely-determined differential travel-time data derived from waveform data. As a result, we could find that earthquakes in each cluster occurred on single fault plane with complementary rapture areas.

Additionally, we implemented moment tensor inversion (Gephart and Forsyth, 1984) and estimated the stress field around the region where we discovered a few clusters showing waveform similarities. Moreover, we computed the amount of stress drop of the similar earthquakes with spectrum analysis of seismic wave. Through these waveform analyses, we interpreted that the mechanism of these similar deep-focus earthquakes could be explained by combining two possible mechanisms; dehydration embrittlement that regulates the rupture initiation and thermal and shear plastic instability that controls the rupture propagation along a pre-existing fault.

# Faulting in deforming harzburgite under wet conditions

*Tomohiro Ohuchi[1], Xinglin Lei[2], Yuji Higo[3], Yoshinori Tange[3], Takeshi Sakai[1]

1. Geodynamics Research Center, Ehime University, 2. National Institute of Advanced Industrial Science and Technology, 3. Japan Synchrotron Radiation Research Institute

The subduction zone produces a major fraction of the Earth's seismic activity. The mechanisms of intermediate-depth (> 40 km depth) and deep-focus (> 300 km) earthquakes are fundamentally different from those of shallow (< 40 km) earthquakes. This is because the frictional strength of silicate rocks exceeds the upper limit of the stress level in the upper mantle (< 300 MPa: Obata and Karato, 1995) at pressures higher than 1 GPa (~30 km depth). Therefore, the cause of intraslab seismicity at intermediate depths has been attributed to dehydration of serpentinite (e.g., Peakock, 2001) because the water released during dehydration reaction of serpentinite reduces the effective confining pressure. The dehydration embrittlement model is now widely accepted, because the location of the double seismic zone in the subducting Pacific slab corresponds to the main dehydration field in the pressure-temperature diagram of the hydrous peridotite (Omori et al., 2002).

To evaluate the effect of water on semi-brittle behavior of harzburgite, we conducted in-situ uniaxial deformation experiments on as-is/water-saturated harzburgite at pressures 1.2-3.0 GPa and temperatures 770-1250 K with a constant displacement rate using a deformation-DIA apparatus. Pressure, stress, and strain were measured in situ by using x-ray diffraction patterns and radiographs. Acoustic emissions (AEs) were also recorded continuously on six sensors, and three-dimensional AE source location were determined.

Formation of throughgoing faults was observed even when differential stress is much lower than the confining pressure (i.e., > 0.3 times of confining pressure) in water-saturated harzburgite. This is contrast to the case of water-saturated dunite (Ohuchi et al., 2018), in which fracture strength exceeds the confining pressure (i.e., Goetze's criterion). Creep strength of water-saturated harzburgite was lower than that of as-is harzburgite (~0.5-1 GPa at each temperature). Weakening of the harzburgite by the aqueous fluid resulted in the reduction in the number of AE events and decrease in fault slip rate (< 3.6E-4 $s^{-1}$ at a stress of < 1.05 GPa). Stress/pressure drop around the timing of a faulting was limited at strains of 1E-4 $s^{-1}$. The aseismic faulting observed in the water-saturated harzburgite implies that silent slip events around the subduction interface is due to semi-brittle flow of water-saturated harzburgite (i.e., a dehydration product of antigorite).

# Semi-brittle behavior of olivine single crystals under the conditions of Earth’s mantle transition zone

Yoshihisa Naruse[1], *Tomohiro Ohuchi[1]

1. Geodynamics Research Center, Ehime University

The origin of deep-focus earthquakes, which occur at depths of 300-700km in the subducting slabs, fundamentally differs from that of other earthquakes and has been attributed to the pressure-induced phase transition in olivine. Previous studies on $Mg_2GeO_4$ olivine have shown that grain size reduction induced by the phase transition in olivine causes shear localization (e.g., Burnley et al., 1991; Schubnel et al., 2013). Schubnel et al. (2013) reported intense acoustic emissions around the timing of a faulting which would be induced by shear localization in polycrystalline $Mg_2GeO_4$ olivine. In order to understand the relationship between fracturing and the phase transition in olivine, we conducted deformation experiments on single crystals of San Carlos olivine ($Fo_{91}$) at pressure of 10-15 GPa and temperatures of 1000-1100 degC using a deformation-DIA apparatus. Single crystal of olivine was chosen to exclude the effect of grain boundaries on nucleation of high-pressure phases of olivine (i.e., wadsleyite and ringwoodite).

Array of microcrack parallel to either (100), (010) or (110) plane was developed at an ~50 degree to the direction of uniaxial compression. Rotation of olivine axes associating the formation of subgrain boundaries was observed around the microcrack arrays, showing that plastic deformation of the olivine single crystal inevitably associated formation of the microcracks. In most samples, microcracks coalesced and then a few throughgoing fractures were developed. Particles of wadsleyite /ringwoodite having a diameter of a few micrometer or less were preferentially nucleated on the microcrack surfaces. Ultrafine-grained domains, which consist of the wadsleyite /ringwoodite particles, were formed along the throughgoing fractures. Development of a banded ultrafine-grained domain was also observed along a throughgoing fracture, implying that shear localization could occur as a result of semi-brittle flow of olivine and a transition from dislocation creep to grain-size-sensitive creep in subducting slabs at depths > 410 km.

# High-pressure deformation experiments on peridotite gouges under hydrothermal conditions, using a deformation-DIA apparatus

*Maki Semba[1], Ken-ichi Hirauchi[1], Tomohiro Ohuchi[2], Katsuyoshi Michibayashi[3]

1. Department of Geosciences, Faculty of Science, Shizuoka University, 2. Geodynamics Research Center, Ehime University, 3. Department of Earth and Planetary Sciences, Nagoya university

In subducting oceanic plates, the focal depth of intraslab earthquakes is deeper (>40 km) than that of interplate earthquakes. Since the normal stress on faults (e.g., outer-rise faults) hosting the intraslab earthquakes is too high to generate brittle shear failure, there may be some mechanisms to weaken effective fault strength. In addition, the hypocenter distribution of intraslab earthquakes forms double-planed structure of the deep seismic zone, and the location of the lower plane is in accord with the stability limit of serpentine (antigorite), suggesting shear deformation of antigorite-bearing peridotite gouges in the presence of hydrothermal water. Here, in order to understand the influence of hydrous minerals on the fault strength, we performed deformation experiments on simulated peridotite gouges with compositions of dunite (100% olivine) and harzburgite (70% olivine/30% orthopyroxene) under hydrothermal conditions, using a deformation-DIA apparatus. The experiments were conducted at a temperature of 580˚C, a confining pressure of 2.5 GPa, and shear strain rates of 2.70 $\times 10^{-5}$ to 1.03 $\times 10^{-4}$ $s^{-1}$. In the deformed peridotite gouges, localized shear zones such as $R_1$ and B shears were observed, and these shears were accompanied with newly formed hydrous phases (serpentine or talc). Olivine grains have a crystal preferred orientation characterized by a slip system of [001] (010). These results indicate that semi-brittle flow is a major deformation mechanism of the peridotite gouges. Considering low coefficients of friction of serpentine and talc, we can suggest that the infiltration of seawater along outer-rise fault planes and subsequent hydrothermal alteration result in effective shear strengths low enough to produce intraslab earthquakes.

Keywords: deformation-DIA apparatus, peridotite, serpentinization, frictional strength

# Stable fault slip in antigorite-olivine aggregates at high pressures

Mai Ikehara[1], *Tomoaki Kubo[1], Takuya Iwasato[2], Yuji Higo[3], Masahiro Imamura[1], Yoshinori Tange[3]

1. Kyushu University, 2. Shin-Nippon Nondestructive Inspection Co., Ltd., 3. JASRI

Intermediate-depth earthquakes are observed to occur within subducting oceanic plates at depths of about 60-300 km where most materials exhibit plastic deformation rather than brittle failure, owing to high pressures and temperatures. Dehydration embrittlement of hydrous minerals, particularly antigorite serpentine, is one of the most popular hypotheses for explaining shear instability under such conditions (e.g., Raleigh and Paterson, 1965). Recent high-pressure deformation experiments, monitoring Acoustic Emission (AE) activities upon syndeformational antigorite dehydration, showed that dehydration embrittlement was not observed on single-phase antigorite (Gasc et al., 2017), whereas dehydration related faulting was formed on antigorite-olivine aggregates with strong AEs (Ferrand et al., 2017). However, most of the previous high-pressure studies have been conducted in axial compression at relatively low pressures (< 3.5 GPa), insufficient to consider intermediate-depth earthquakes. Therefore, in this study, we conducted high-pressure shear deformation experiments on two-phase aggregates of antigorite and olivine, considering partially serpentinized peridotites, in order to investigate possible shear localization and shear instability up to 7 GPa.

Deformation experiments were conducted at 5-7 GPa, 350-700 ℃ using Deformation-DIA apparatuses at SPring-8 (BL04B1). Monochromatic X-rays (50-60 keV) were used to measure dehydration kinetics, shear strain and stress with recording AEs. We used three kinds of starting materials; natural cored antigorite from Kawarakoba in Nagasaki prefecture, forsterite polycrystal, and two-phase sintered mixtures of antigorite and San Carlos olivine (antigorite 10, 30, 50 vol %). The samples were cut into disks having thickness of 300 $\mu$m and used for a shear deformation study by being assembled between two 45˚-cut alumina pistons. In shear deformation experiments, the starting disk was compressed to 5 or 7 GPa at room temperature, annealed at 350 or 400 ℃ for 1 h, and then deformed with an anvil displacement rate of 200 $\mu$m/h. In some experiments, we increased temperature during shear deformation with a ramping rate of 0.1 ℃/sec to induce dehydration reaction. Microstructures of the recovered samples were examined by an optical microscope and a scanning electron microscope (SEM).

From X-ray radiography images, we observed shear localization in all two-phase samples deformed within the antigorite stability field at 5 GPa. The locallization occurred when homogeneous shear strain $\gamma$ reached 0.4-0.9 (strain rate 1.3-2.2 $\times 10^{-4}$/s), and then most strains were partitioned to the fault zone with the slip velocity of 4.6-9.1 $\times 10^{-2}$ $\mu$m/s. Because no AEs were detected from the sample region, the localized deformation is thought to occur by stable sliding. SEM observations revealed that a thin shear deformation zone was formed along the fault, where the plastic deformation of both antigorite and olivine was significant. Striation and nanograins were observed on the fault plane, suggesting the formation of nanogouge. In contrast, homogeneous deformation was developed during antigorite dehydration with temperature ramping, even in the sample showing shear localization in the antigorite stability field. Under higher pressure condition 7 GPa, shear localization did not occur in all samples regardless of temperature. These results suggest that, although AE activities were detected with the dehydration in the antigorite-olivine aggregates up to 3.5 GPa in the previous study, further increase of pressure inhibits shear instability and shear localization. Thus, other dehydration reactions and/or instability mechanisms are required to explain intermediate-depth earthquakes deeper than ~100 km.

# Rheology and frictional instability of lawsonite in high pressure deformation experiments

*Rei Shiraishi[1], Jun Muto[1], Akihiro Tsunoda[2], Sando Sawa[1], Akio Suzuki[1]

1. Department of Earth Science, Graduate School of Science, Tohoku University, 2. Earthquake Research Institute, University of Tokyo

The cause of intermediate-depth earthquakes (50-300 km) in subducting slabs have been proposed to be the dehydration embrittlement (e.g., Raleigh and Paterson, 1965), because there are many kinds of hydrous minerals in a subducting slab and hypocenter distribution coincides with the dehydration boundary determined by high pressure experiments (e.g., Hacker et al., 2003). Many experimental studies on antigorite have been conducted, but a few previous works about dehydration embrittlement of lawsonite-bearing rocks experimentally. Lawsonite, $CaAl_2Si_2O_7(OH)_2H_2O$, is a hydrous mineral which contains 11 wt% water in its structure as both water molecules and a hydroxy group (Cmodi and Zanazzi, 1996). Lawsonite is one of the candidate for dehydration embrittlement in cold subducting slabs, however previous works have apparently contradictory results. Okazaki and Hirth (2016) showed that lawsonite dehydration induced unstable fault slip based on deformation experiments of pure lawsonite using Griggs-type deformation apparatus at 1 GPa. On the other hand, Incel et al. (2017) also investigated deformation properties of lawsonite and glaucophane mixture at 1.5 to 3.0 GPa using deformation-DIA apparatus. They insisted that there is no evidence for a straightforward relation to the dehydration of lawsonite and the brittle failure of samples. So, we have conducted the deformation experiments of lawsonite under the cold slab conditions in order to clarify the deformation property of lawsonite and understand the relationship between dehydration and brittle failure.

Experiments were carried out using Deformation-Cubic Anvil Press (D-CAP) installed at KEK PF AR-NE7A beamline. Pure lawsonite powder (98%) was used as starting materials. Deformation experiments were carried out at a pressure of 6 GPa and temperatures of 300 - 800 ˚C. The temperature was increased at the same time as deformation started. The temperature ramping rate over the strain rate was set the ranges for the real subducting slab, which ranges from $10^2$ to $10^4$ ˚C (Chernak and Hirth, 2011; Okazaki and Hirth, 2016). During deformation stages, strain, stress and transformation rate were measured for in-situ using a monochromatic X-ray beam with an energy of 60 keV.

Four experiments showed rapid stress drop during temperature ramping before lawsonite dehydration starts. We observed microstructure of recovered samples, there are many through going faults and microcracks but no dehydration products. Our results indicate that brittle process and frictional sliding occur without dehydration of lawsonite. This suggests that the intermediate-depth earthquakes can be caused by the deformation itself of lawsonite without the dehydration of lawsonite.

# Grain Size Dependency of Olivine-Spinel Phase Transformational Mechanism Responsible for Deep-focus Earthquakes

*Sando Sawa[1], Jun Muto[1], Nobuyoshi Miyajima[2], Hiroyuki Nagahama[1]

1. Department of Earth Science, Tohoku University, 2. Bayerisches Geoinstitut, University of Bayreuth

Deep-focus earthquakes occur at the depth from 440 km to 660 km in the subducting slab. The mechanism responsible for the earthquakes is thought to be different from that of shallow earthquakes, so that previous studies have reported the various mechanisms. By the geophysical observations and deformation experiments, the phase transformational faulting mechanism is presumed as the precursor of deep-focus earthquakes (e.g., Zhan et al., 2014). The phase transformational faulting mechanism is that metastable olivine in the slab undergoes the phase transformation to fine-grained spinel and faulting occurs with strain localization into the fine-grained spinel. This shear instability depends on grain size. Furthermore, the grain size may restrict the pressure- and temperature-conditions where the shear instability occurs, that is, the region of slab where deep-focus earthquakes occur. However, previous studies have conducted deformation experiments with finer grain size than expected in the slab (e.g., Burnley et al., 1991). Hence, the results from the laboratory experiments cannot directly apply to the geophysical observation. In this study, to reveal the grain size dependency on the phase transformational faulting, we conducted the deformation experiments of germanate olivine (about 3 $\mu$m), which is an analogue material of silicate olivine, finer-grained than that in previous studies (30 $\mu$m). We used a Griggs-type solid-confining media deformation apparatus. The confining pressure, temperature and strain rate are 1.2 GPa, 400~900 ℃ and $2.0\times10^{-4}$ $s^{-1}$, respectively. Even though deformation experiments were conducted under wider temperature conditions than previous studies, we did not observe any shear instability event with apparent stress drops. Also, Raman spectroscopy clarified that the germanate olivine underwent the transformation to spinel at temperatures higher than 500 ℃. Shear instability does not occur because the difference in grain sizes between olivine and nucleated spinel in this study was smaller than those in previous studies. Also, the transformation temperature in this study was much lower than those in previous study (T > 1000 ℃ in Burnley et al., 1991). Considering the rate equation of the transformation (Chan, 1956), small grain size promotes the transformation, but these fast rates of the transformation cannot be explained only by the effect of the grain size. Therefore, the presence of water such as absorbed water in a starting material can also contribute to promote the transformation. Hence, both small initial grain size and a little amount of water promote the transformation even at lower temperature. These results indicate that the phase transformational faulting mechanism has strong grain size dependency. In summary, the pressure- and temperature-conditions where the faulting occurs depends on the grain size of olivine and amount of water. Because the grain size in the slab is larger than that in the experiments, by extrapolating from these results, we may restrict the region of slab where deep-focus earthquakes occur.

# Seismicity and mineral destabilizations in the subducting mantle up to 6 GPa, 200 km depth

*Thomas P. Ferrand[1]

1. Earthquake Research Institute

In the subducting oceanic lithosphere, a significant part of the seismicity is triggered in the mantle, especially along the upper and lower Wadati-Benioff planes. Several studies have investigated the potential involvement of dehydration reactions in the triggering mechanism of mantle earthquakes. Recent experimental results reveal that, under subduction conditions, mechanical instabilities nucleate in strong stable mineral aggregates during the destabilization of minor amounts of antigorite, i.e. the high-temperature serpentine, through a stress transfer, without any fluid overpressure. Here I confront these laboratory results to seismological observations. On one hand, most of the natural hydrous magnesium silicates seem to be known, with experimentally-deduced stability limits up to 7 GPa, at least, available as relatively accurate estimates. On the other hand, recent achievements in thermal structure of subduction zones combined with precise hypocentre relocation give access to pressure and temperature conditions at earthquakes hypocentres. A series of P-T diagrams summarizes the stability limit of minerals that may be part of natural peridotite with variable compositions at pressures from 0.5 to 6 GPa and temperatures from 200 to 950˚C, and compares it with seismicity. Both hydrous and anhydrous phases are considered. A myriad of minor metamorphic reactions could participate in a transformation-driven stress transfer, even if the stability limits of serpentine minerals seem to correlate with most of the observed seismicity.

# Receiver function imaging of subducting Pacific plate and mantle wedge under Japanese islands using denser network of stations

*HyeJeong Kim[1], Hitoshi Kawakatsu[1], Takeshi Akuhara[1], Masanao Shinohara[1]

1. Earthquake Research Institute, The University of Tokyo

Receiver function imaging has been frequently used by different groups focusing on different depths of the Japanese subduction zone. The overlying crust (Shiomi and Park, 2008, Bianchi et al, 2015), the Pacific plate before (Kawakatsu et al., 2009) and after subduction (Kawakatsu and Watada, 2007; Wirth and Long, 2012), and the mantle transition zones (Kawakatsu and Yoshioka, 2011; Tauzin et al., 2018) were discussed using the NIED array stations (Hi-net and F-net). Recently, deployment of ocean bottom seismometers (OBSs) enabled studies of subduction zones closer to the trench (e.g., Akuhara and Mochizuki, 2015). Kawakatsu and Kim (2018, SSJ) have obtained a new version of receiver function imaging using 14-year long of Hi-net data. However, there are other land stations (e.g., J-array) that can improve the station coverage. Here, we collect data from available on-land stations deployed in north-eastern Japan to obtain a denser 2-D array of stations. Additionally, data from temporary OBS stations (Shinohara et al. 2012) are gathered to image the subducted Pacific plate in shallower depths than previously available. Continuous imaging from ocean to land will help to constrain transition of the hydrated oceanic crust along subduction that is expressed as a low velocity layer for better understanding of the hydration/dehydration processes during subduction, which might be related to the occurrence of subduction zone earthquakes.

# Strong S-wave attenuation in the mantle wedge beneath the NE Japan and interpretations of high-frequency wave propagation path of intraslab earthquakes

*Takahiro Shiina[1,2], Kei Katsumata[2], Kiyoshi Yomogida[3], Aitaro Kato[1]

1. Earthquake Research Institute, The University of Tokyo, 2. Institute of Seismology and Volcanology, Graduate School of Science, Hokkaido University, 3. Graduate School of Science, Hokkaido University

For intraslab earthquakes at intermediate-depths in NE Japan, especially at greater than about 100-km depths, it has been often recorded that high-frequency waveform higher than 8 Hz show a remarkable delay of arrival compared with S wave which predominates in a low-frequency band. The magnitude of the delay is little in the forearc region, whereas it increases up to about 40 s in the backarc region. In this study, we investigate the details in the propagation processes of the high-frequency later phase observed for the intraslab earthquakes at the intermediate-depths. To constrain the source location of the high-frequency later phase, we employ the source-scanning algorithm (SSA) [Kao and Shan, 2004] with realistic velocity and attenuation structures, assuming that the high-frequency later phase is generated by the single scattering process. Namely, we estimate a scattering point by using mean-square amplitudes which is synthesized from two horizontal components of the observed waveforms.
Results in frequency bands of 4-32 Hz show that scattering points are distributed beneath the forearc region. The scattering points can reproduce the observed delays of amplitude amplifications associating with the high-frequency later phases. Moreover, similar locations of the scattering points are imaged along the forearc region in the entire NE Japan. These results indicate that high-frequency later phase is a wave scattered at the forearc region and that short wave-length heterogeneity generally developed in the forearc region of NE Japan.
This interpretation well matches implications from previous studies [e.g., Yomogida et al., 2004; Hasemi and Horiuchi, 2010]. Additionally, the obtained distributions of scattering points which appear to surround the highly attenuating mantle wedge suggest that attenuation structure strongly controls propagation paths of seismic wave, in particular, a high-frequency wave. In other words, the identifications of high-frequency later phase may become easy because the amplitude of direct wave crossing the high-attenuation zone decreases. To confirm this consideration, we estimate *Qs* along the direct wave by using the coda-normalization method [e.g., Aki, 1980]. This estimation provides 2-3 times smaller path-averaged *Qs* in seismic records of which rays lay on the backarc and the volcanic front than that of which rays lay on the forearc region. These results support that spatial variation in *QS* produces heterogenous propagations of seismic waves emitted from intraslab earthquakes. It is thus required to take scattering and attenuation structures simultaneously into account to understand complex behaviors of high-frequency waves in a future study.

Thu. May 30, 2019 10:45 AM - 12:15 PM JST | Thu. May 30, 2019 1:45 AM - 3:15 AM UTC | Poster Hall International Exhibition Hall8, Makuhari Messe_6

## [S-CG51] Role of volatiles on Earth and planetary dynamics

convener:Takayuki Ishii(Bavarian Research Institute, University of Bayreuth), Eiji Ohtani(Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University), Michihiko Nakamura(Division of Earth and Planetary Materials Science, Department of Earth Science, Graduate School of Science, Tohoku University), Bjorn Mysen(Geophysical Laboratory, Carnegie Inst. Washington)

This session addresses how volatile species affect dynamics of the<br/>Earth and planets from natural observations, laboratory experiments, and<br/>numerical modeling in the temperature, pressure, and oxygen activity<br/>range from the early stage of the planet formation to the present. The<br/>volatiles can be critical in zones of magma storage and ascent, mantle<br/>upwelling and melting in the fluid-enriched subduction zones, in the<br/>mantle transition zone, in the lower mantle, in the core-mantle boundary,<br/>and in Earth and planetary cores. However, volatiles affect properties<br/>and processes differently depending on their pressure, temperature, and<br/>redox conditions, which vary in time and space. <br/> This session aims to address how volatiles control the dynamic<br/>processes of the Earth and planets, governed by their geophysical and<br/>geochemical properties. We welcome papers dealing with geological and<br/>laboratory observations coupled with numerical modeling on the role of<br/>volatiles. The topics include (1) Stability relations, chemical and<br/>physical properties of crystalline, molten and fluid phases,<br/>partitioning of volatiles among these phases, (2) Rheological and other<br/>physical properties of minerals, and the effects of intergranular fluid<br/>on the properties, (3) Volatiles and dehydration induced seismicity and<br/>volcanism in various tectonic regions including subduction zones, and (4)<br/>Effects of volatiles in numerical simulation of geo-tectonics, and (5)<br/>Magma outgassing and its control of volcanic eruption dynamics.

The flow of fluids through porous media such as groundwater flow or magma migration is one of the most important processes in geological sciences. The property controlling the efficiency of the flow is the permeability of the rock, thus an accurate determination and prediction of its value is of crucial importance. For this reason, permeability of rocks has been measured across different scales. As laboratory measurements exhibit a range of limitations, the numerical prediction of permeability at conditions where laboratory experiments struggle has become an important method to complement laboratory approaches. At high resolutions, this prediction becomes computationally very expensive, which makes it crucial to develop methods that maximize accuracy. In this work we introduce the open-source finite difference solver LaMEM that can be used to numerically predict the permeability of porous media under laminar conditions. We employ a stencil rescaling method to increase accuracy due to a better description of the solid-fluid interface, thus reducing the computational cost. To validate the method, we perform a series of tests employing both analytical solutions for simplified geometries as well as results from other numerical approaches for more complicated geometries. Furthermore we compare our numerical results to laboratory measurements on glass bead samples with porosities ranging from 20% to 2.5%, showing good agreement.

# Grain growth-induced fluid localization and permeability reduction

*Wakana Fujita[1], Michihiko Nakamura[1], Kentaro Uesugi[2]

1. Graduate School of Science, Tohoku University, 2. JASRI/SPring-8

Efficiency of segregation of geological fluids such as aqueous fluids and melts is an essential elementary process for volatile cycles in subduction zones. Permeability is an intrinsic rock property that controls flow rate of fluid. Various permeability models have been presented by numerical models of textually equilibrated rocks (e.g. 1, 2), laboratory measurements on synthetic rocks (e.g. 3) and estimation from cross-sectional area of synthetic rocks (4). However, there exist discrepancies among those models. Because permeability is very sensitive to microscopic geometry of pore fluid, those disagreements may arise from lack of understanding toward three-dimensional (3D) microstructure of fluid network.

Dihedral angle has been considered to be a critical parameter that controls fluid geometry and thus permeability. Beside, some previous studies shed light on the effect of grain growth on fluid distribution because it could induce pore fluid distortion and coalescence (5, 6). These studies suggest that in the actual systems where the microstructure of rocks evolve in dynamic processes, grain growth would be important along with the dihedral angle.

To investigate the effect of grain growth on the fluid distribution and permeability, we present 3D images of quartz–CHO fluid aggregates, containing nominal fluid fractions between 0.03 and 0.10. Samples were synthesized from a powdered mixture of Arkansus quartz and amorphous silica prepared by sol-gel method and hot-pressed in a piston–cylinder apparatus at 900˚C and 1.0 GPa for 192h. The fluid fractions and the dihedral angles were controlled using brucite added in the capsule bottom and oxalic acid dihydrate mixed with $SiO_2$ powder. 3D images were obtained using synchrotron X-ray microtomography at BL20XU experimental hutch2 of SPring-8. Regardless of dihedral angles ($CO_2$ content in fluids), both cross-sectional area and 3D images of samples showed grain-scale fluid localization which would be formed by pore fluid coalescence induced by grain growth. Computed permeabilities using numerical model, LaMEM (7) were almost consistent with laboratory measurements by (3) but more than one order of magnitude lower than a numerical model by (2). This would indicate that localized fluids extensively reduce permeability by reducing the diameter of fluid tubes along grain edges, which would suggest transport of water into Earth’ s deep interior by the subducting slab.

# Pargasite stability in the upper mantle at $H_2O$-undersaturated conditions

*Marija Putak Juricek[1], Hans Keppler[1]

1. BGI

Amphibole is the most commonly occurring hydrous mineral in mantle xenoliths and the majority of upper mantle amphiboles have compositions close to pargasite end member. Previous experimental work has demonstrated that pargasite stability is sensitive to variations in bulk alkali and water content of the starting material. While it has been successfully shown that addition of more alkali leads to stabilization of pargasite to higher P and T, the effect of water on amphibole stability is not so straightforward.

At $H_2O$-saturated conditions, alkali elements partition strongly into aqueous fluid and become less available for crystallization of amphibole. As a result, amphibole seemingly becomes stable at higher P and T when less $H_2O$ is added to the starting material. This observation led to the hypothesis that pargasite may be a ubiquitous phase in the upper mantle, which is believed to contain only several hundred ppm of $H_2O$. However, most of the previous studies determined pargasite stability at $H_2$ O-saturated conditions where solid phases coexist with an aqueous fluid during experiments. Since such environments are not representative of the nearly dry upper mantle, the purpose of this study is to investigate pargasite stability at $H_2O$-undersaturated conditions.

Because of the high specific surface area of powders, adsorption of atmospheric $H_2O$ on fine grained starting materials prevents attaining $H_2O$-undersaturation by adding small amounts of water to the sample. Instead, $H_2O$-undersaturated conditions may be precisely controlled by diluting the water in the sample with another component. Under such conditions, solid phases are expected to coexist with a low water activity fluid throughout the experiment. As molecular nitrogen is mostly insoluble in upper mantle minerals, it can be used to adjust the water activity of the fluid to a desired low value.

All experiments were performed in a piston cylinder apparatus. The samples for $H_2O$-undersaturated experiments were prepared by adding silver azide ($AgN_3$) and brucite to a synthetic peridotite mixture. In several experiments water was added directly as $H_2O_{(l)}$. The amount of water was kept constant in all experiments (1 wt. percent) and the molar fraction of water in the $N_2$-$H_2O$ fluid was adjusted to the desired value by weighing an appropriate amount of $AgN_3$, which decomposed to metallic silver and molecular nitrogen during heating. In $H_2O$-saturated experiments, no silver azide was added to the peridotite mixture. Experimental products were analyzed using JEOL JXA-8200 electron microprobe.

Preliminary results show that pargasite is not stable in equilibrium with fluids diluted to $X_{H2O}$=0.1 at pressures above 1 GPa. At $H_2O$-saturated conditions pargasite stability field can extend to pressures of 4 GPa and above 1100 ℃, depending on bulk alkali and water contents. Results from experiments at $X_{H2O}$ =0.1 and $X_{H2O}$=1 suggest that pargasite can exist only in regions of the upper mantle which have been affected by high water activity fluids, such as areas in the vicinity of subduction zones. The ambient nominally anhydrous upper mantle, better represented by experiments at $H_2O$-undersaturated conditions, is not expected to contain pargasite.

[c]School of Earth Sciences, University of Bristol, Bristol BS8 1RJ, UK

[d]Department of Earth Science, University of Cambridge, Cambridge CB2 3EQ, UK

The water content in the mantle transition zone (MTZ) exerts a controlling influence on the dynamical and chemical evolution of Earth, but is poorly known. In principle the water content at the top of the transition zone can be inferred by comparing the velocity and density contrasts across the 410-km seismic discontinuity with predictions based on the phase transition of olivine to wadsleyite. The high-quality elastic data of at pressure and temperature (PT) conditions of the transition zone are crucial but are very challenge for experiments to obtain. Calculating these elastic data at high PT conditions in conventional method are also very expensive. Instead, these elastic data were calculated using the method of Wu and Wentzcovitch (2011), which reduces the computational workload to tenth of the conventional method. All calculations for two phases were conducted using the same computational details as far as possible, which guarantees that the velocity and density differences between two phases have very high precise. All these calculated elastic data agree well with the available experimental data. The iron and water effect on the elasticity are also well described.

With these high-quality elastic data covered the PT condition of the transition zone, we analyze the water and wadsleyite content at the top of the transition zone. We found that the water content of wadsleyite at the top of the transition zone can be well constrained when density and velocities jumps are considered together. For a pyrolitic mantle composition with ~60% olivine, our best fit is ~ 0.5 wt% water at the top of the transition zone. If the transition zone is dry, as suggested by some electrical conductivity models, the upper mantle may only contain ~ 50% olivine.

Earth’s deep water cycle plays a key role for the dynamic evolution of our planet and the development of habitable conditions. Surface water can be transported to Earth’s mantle by subduction of oceanic lithosphere. Experimental investigations have shown that water can be efficiently stored in Dense Hydrous Magnesium Silicates (DHMS) in cold subducting slabs. However, quantification of the incoming water budget based on the interpretation of seismological observations is hampered by a lack of elasticity measurements of DHMSs. Here, we report single-crystal elasticity measurements of Fe-bearing phase E, a DHMS that is stable at pressures and temperature of Earth’s mantle transition zone. A very low bulk modulus has been reported for phase E, suggesting that it might produce seismic velocity heterogeneities detectable by seismological investigations. However, the shear modulus of phase E has not been quantified.

We synthesized Fe-bearing phase E single crystals in a multi-anvil apparatus. Chemical composition as well as crystal structure have been determined using electron microprobe analysis, Mössbauer spectroscopy, and single-crystal X-ray diffraction. We derived the full elastic stiffness tensor by Brillouin spectroscopy on two single crystals of selected orientations. We found phase E to have both the lowest bulk modulus and shear modulus among the DHMSs at ambient conditions. Phase E shows very low compressional and shear velocities especially when compared to the other principal minerals likely present in subducting slabs after serpentine breakdown. Modelling of seismic velocities in dry and hydrated upper mantle and transition zone rocks suggests that the presence of even small amounts of phase E can appreciably lower seismic wave velocities. Phase E could be used as seismological indicator for water stored at depth in subducting scenarios. The elasticity of phase E under mantle conditions will be explored in future research.

# Discovery of two hexagonal phases in (Fe,Al)OOH under the P-T conditions of the deep lower mantle

*Lu Liu[1,2], Li Zhang[1], Hongsheng Yuan[1]

1. Center for High Pressure Science and Technology Advanced Research, 2. University of Science and Technology of China

Deep water can cause a series of complex seismological phenomena by changing the density and thermal stability of lower mantle components. δ-H solid solution phase (AlOOH-$MgSiO_2(OH)$) is stable at lower mantle conditions[1],because the crystallographic frameworks of the phase H is similar to that of the δ-AlOOH phase, with very strong hydrogen bonds[2,3]. δ-AlOOH and ε-FeOOH can also form solid solution[4] (δ - ε solution). It is reasonable to infer that δ - ε solid solution may have similar thermal stability as that of H- δ solution, considering their similar crystal structure[5]. In our experiments, we synthesized the δ - ε solution at 79GPa and 1600K in a laser-heated diamond anvil cell. As the temperature increases to 2100k, the orthorhombic δ - ε solution transformed into a hexagonal-structured phase. By combining powder X-ray diffraction techniques with multigrain indexation[6], we determined its hexagonal lattice with a=b=10.019Å and c=2.614Å. At 79GPa and 2400K, the hexagonal phase transforms into another hexagonal phase, with the lattice parameters of a=b=2.733Å and c=9.343Å. The discovery of these two new phases may provide new insights into the deep-water storage.

# Effect of grid resolution on tectonic regimes in global-scale convection models

*Enrico Marzotto[1], Marcel Thielmann[1], Gregor Golabek[1]

1. Bayerisches Geoinstitut

Global-scale convection models using a visco-plastic rheology coupled with a temperature-dependent viscosity usually show different tectonic regimes: mobile, episodic or stagnant lid.

In the mobilelidregime, the lid is continuously subducting into the mantle (plate-like behavior). The episodic lid regime is characterized by the stability of the lid until sufficiently large lithospheric stresses break it, causing rapid resurfacing. Finally the stagnant lid regime is defined by an undeformable lid that does not participate in convection

In numerical simulations these three types of regimes can be obtained by varying some target parameters such as: temperature-dependency of viscosity and yield stress.

The yield stress in particular is a key parameter because it sets the stress necessary to cause plastic yielding, hence, in a visco-plastic rheology, the stress necessary to break the cold surface regions. A high yield stress will result in a stagnant lid. On the other hand, a low yield stress causes a weak lid that is constantly broken and sinks into the mantle.Despite the key importance of physical parameters, also numerical parameters have an effect on the tectonic regime, determining different outcomes justby changing the grid resolution.

Here we use the code StagYY (*Tackley, 2008*) in a 2D spherical annulus geometry (*Hernlund & Tackley, 2008*) to determine the resolution-dependent tectonic regime for different yield stresses in global-scale convection models. To assess the effect of grid resolution on lid behavior we use 16 different resolutions keeping all physical parameters unchanged. To make sure that steady state has been reached each simulation is run for 15 Gyrs. Tested resolutions vary from 128x32 to 1024x256 grid points. To understand this influence on the tectonic regime we study the resolution within the lid requiring an appropriate lid definition, based on the thermal and velocity field. Our results show that there is a correspondence between low radial resolution and mobile lid regime and that low aspect ratio cells (azimuthal to radial grid spacing) favor a plate-like behavior of the lid, while for large aspect ratios the mobile lid regime is persistent.

This work is the first part of a larger project, aiming to studyslab stagnation and hydration of the mantle transition zone (MTZ) using self-consistent global-scale mantle convection models, where subducting slabs carry water from the surface into the Earth’ s interior and potentially hydrate the MTZ. We expect that our previous work packages will help us to obtain realistic slab ponding in the MTZ, so we can study the hydration state of this region over time.

# A 3-D crust and uppermost mantle electrical conductivity model of subduction zone beneath NE Japan

*Masahiro Ichiki[1,2], Toshiki Kaida[1], Yasuo Ogawa[3]

1. Graduate School of Science, Tohoku University, 2. International Research Institute of Disaster Science, 3. School of Science, Tokyo Institute of Technology

The crustal fluids beneath NE Japan is originated from dehydration of subducting Pacific slab or from convection in the backarc mantle, as is shown by seismic tomography [e.g. Zhao, 2017]. We investigated the fluid transportation paths from upper mantle to crust of subduction zone using electrical conductivity exploration.

We expanded electromagnetic field observation sites (96 sites) to northern part of NE Japan and obtained magnetotelluric responses and geomagnetic transfer functions in the period range of 20 –30720 seconds (22 periods) by BIRRP code [Chave and Thomson, 2004]. We used WSINV3D [Siripunvaraporn and Egbert, 2009] to invert those responses into three dimensional electrical resistivity model.

The preliminary model gives normalized root mean square misfit 5.87. A prominent conductor appears in the crust to uppermost mantle and the conductor spreads towards backarc direction. In our previous model [Ichiki et al., 2015], we found the overturned shape conductor towards backarc direction in the mantle wedge beneath central part of NE Japan. This study has found it beneath northern part NE Japan as well.

Those imply the crustal fluid and/or melt is transported along the pathway that is the plate boundary beneath the volcanic front to the backarc crust. The fluid transportation can explain the presence of enigmatic backarc volcano in the NE Japan. In this presenation, we speculate and discuss evolution of this pathway in geological time on the basis of the chlonological data of igneous rocks [Yoshida et al., 2013].

# *The conditions of sublithospheric diamond formation constrained from ferric iron-rich exsolution from ferropericlase inclusions.*

*Caterina Melai[1], Daniel Frost[1], Tiziana Boffa Ballaran[1], Catherine McCammon[1]

1. Bayerisches Geoinstitute

Ferropericlase is apparently one of the more common inclusions to be found in sub-lithospheric diamonds, which are considered to form in the convecting mantle. Although relatively rare, these inclusions have been examined in a number of studies in the hope of providing information on the formation conditions of such deep diamonds, which could potentially be in the transition zone or lower mantle. The wide range of oxide Fe/(Fe+Mg) ratios found has raised the idea that they may form through the oxidation of iron metal. During TEM investigations, however, evidence for the exsolution of $Fe_2O_3$-rich phases such as magnesioferrite have been found, which implies that a more complex scenario may be involved. Ferropericlase-magnesiowüstite diamond inclusions are most likely some of the deepest available samples from the mantle and they potentially provide the most direct evidence for deep mantle carbon transport processes. The ferric iron contents of such inclusions alone may not provide a direct estimate for the oxygen fugacity at which the inclusions were trapped, particularly if pressure has a strong effect on the $fo_2$ - $Fe^{3+}/Fe_{tot}$ relationship. However, using experimental data it is possible to determine the oxygen fugacity at which the exsolution observed in the diamond inclusions occurred and coupled with the oxide $Fe^{3+}/Fe_{tot}$ ratio this could be used to estimate the pressure of formation.

The ferropericlase- magnesioferrite system has been investigated by several studies at room pressure but the stability field of the two components has been shown to become more complicated at high pressure due to the formation of mixed valence oxides. We have combined experimental measurements with thermodynamic modelling in order to address two main questions: at which P, T, $fO_2$ conditions do $Fe_2O_3$ -rich phases exsolve from ferropericlase? And what is the maximum $Fe^{3+}/Fe_{tot}$ ratio of ferropericlase. To answer these questions, multianvil experiments have been performed between 6 –25 GPa and 1200-1800˚C using a starting composition of $(Mg_{86}Fe_{14})O$ plus 20 % $Fe_2O_3$. Pt powder was added to the experiments to act as a redox sensor and minor amounts of Ni, Cr, Mn and Na were also added. Samples were then analyzed with the scanning electron microscope, electron microprobe, Mössbauer spectroscopy and X-ray diffraction. In the recovered experiments ferropericlase coexists with magnetite-magnesioferrite solid solution up to 10 GPa and $Mg_2Fe_2O_5$-$Fe_4O_5$ solid solution at higher pressures. In the calculation of the oxygen fugacity a ferropericlase model in the FeO-$Fe_{2/3}O$-MgO system was employed and exchange of Mg and $Fe^{2+}$ in magnetite was accounted for. Oxygen fugacities at which the phases coexist can be calculated in the magnetite-magnesioferrite field using three different equilibria and a quite simple ferropericlase mixing model results in calculated oxygen fugacities that are within 0.1 log units of each other for all three equilibria. The results show that magnetite-magnesioferrite solid solution should not be in equilibrium with ferropericlase in the diamond stability field. Our results imply that the exsolution of $Fe^{3+}$ rich phases observed in natural samples likely occurred at pressures corresponding to the transition zone or deeper.

# Probing the variation of the oxygen fugacity in diamond anvil cells using the Fe-Ir alloy as redox sensor

*Serena Dominijanni[1], Catherine McCammon[1], Leonid Dubrovinsky[1], Dan Frost[1], Nobuyoshi Miyajima[1]

1. Bayerisches Geoinstitut

Understanding the oxygen fugacity ($fO_2$) in diamond anvil cells (DACs) is an important issue for many reasons, among them reconciling contradictory results that have been obtained for carbonate studies (Cerantola et al., 2017; Dorfman et al., 2018) that might be due to different redox conditions during the experiments. We therefore investigated the $fO_2$ conditions during DAC experiments using powder X-ray diffraction (beamlines ID15b and ID27) and energy-domain Synchrotron Mössbauer Source (SMS) spectroscopy (beamline ID18) at the European Synchrotron Radiation Facility (Grenoble, France). Double sided laser heating experiments (Aprilis et al., 2017) were carried out at high pressure and temperature using a mixture of synthetic ferropericlase ($Mg_{0.75}Fe_{0.25}$)O and pure iridium powder as a sliding redox sensor (Borisov and Palme, 2000; Swartzendruber, 1984; Taylor et al., 1992). The Fe content in the Fe-Ir alloy, together with the amount of FeO in ferropericlase, allows a calculation of $fO_2$ during the experiments (Stagno et al., 2011; Woodland and O'Neill, 1997). Preliminary results from powder X-ray diffraction data show that, after heating, an Fe-Ir metal alloy that can be indexed in the Fm-3m space group is formed by the reaction of pure Ir and Fe from ferropericlase according to the reaction:

(Mg,Fe)O + Ir --> (Mg,Fe)O + (Fe,Ir)

The compressibility of the Fe-Ir alloy and ferropericlase was measured up to ~ 60 GPa and SMS data were collected before and after heating. X-ray diffraction results coupled with energy-dispersive X-ray spectroscopy (EDS) measurements and a simple thermodynamic model indicate that the redox conditions during the DAC experiments were close to the iron-wüstite (IW) buffer, although some inhomogeneity was observed. Further chemical analyses and additional experiments are ongoing to understand the variation of oxygen fugacity in a DAC during laser heating.

# Goethite behavior at Earth's lower mantle conditions

*Egor Gennadievich Koemets[1], Maxim Bykov[1], George Aprilis[2], Timofey Fedotenko[2], Stella Chariton[1], Saiana Khandarkhaeva[1], Iuliia Koemets[1], Marcel Thielmann[1], Natalia Dubrovinsaia[2], Leonid Dubrovinsky[1]

1. BGI (Bayerisches Geoinstitut), Universität Bayreuth, Germany, 2. Material Physics and Technology at Extreme Conditions, Laboratory of Crystallography, Universität Bayreuth, Germany

Water and water-bearing species have a strong impact on numerous processes in Earth’ s interiors. Presence of water affects chemical and physical properties of mantle minerals, changes melting temperatures, sound velocities and viscosity of materials, and causing different global phenomena such as, for example, arc volcanism and plate tectonics. Thereby, the deep Earth’ s regions enriched with water are crucial for understanding our planet’ s geodynamics and geochemistry. Still, mechanisms of water circulation between geospheres remain poorly understood. Recent studies suggest that goethite present in Banded Iron Formations (BIFs) may transfer some quantities of water to the deep Earth interiors with subducting slabs. It was reported that goethite remains stable in the sinking slab until it reaches the base of a lower mantle. By the meaning of in situ powder XRD it was revealed that at pressures corresponding to the depths ~1500-1800 km and moderately high temperatures goethite undergoes a phase transition to form a novel stable pyrite-type phase $FeO_2H_x$ with $0 \leqq x \leqq 1$ (named as Py-phase). Thus, goethite and its HP pyrite-type form became a candidate for water and/or hydrogen transfer and storage to the lower mantle and the core-mantle boundary. Using laser-heating in diamond anvil cells we performed a series of experiments on an investigation of goethite (as a starting material) stability at P-T conditions covering possible range in subducting slabs. By the meaning of sensitive in situ single-crystal XRD in DACs we registered decomposition of goethite and formation of known (such as $\iota$-$Fe_2O_3$, $\eta$-$Fe_2O_3$, a high-pressure orthorhombic form of $Fe_3O_4$, $Fe_5O_7$) and novel iron-oxygen compounds. Results of structure solution and refinement established these compounds to be orthorhombic $Fe_7O_{10}$ and hexagonal non-stoichiometric phase $Fe_{6.31}O_9$. Our results suggest that FeOOH cannot transport water into the deep of Earth’ s mantle.

# The oxygen content of sulphides in the mantle and a geothermometer for diamond formation

*Sumith Abeykoon[1], Dan Frost[1], Vera Laurenz[1]

1. Bayerisches Geoinstitut, University of Bayreuth

Sulphides are ubiquitous accessory minerals in mantle rocks and form the most prevalent type of inclusion in diamonds. Diamond sulphide inclusions are trapped as sulphide melts that crystallise on cooling to form Fe-Ni monosulphide solid solution (MSS) and ultimately recrystallizes to assemblages containing pyrrhotite, $Fe_{(1-x)}S$ (x = 0 to 0.2), pentlandite, $(Fe,Ni)_9S_8$, and sometimes pyrite ($FeS_2$). Sulphide inclusions are also found in many xenoliths but those which are hosted by diamonds provide potentially the most pristine samples from the lithospheric mantle and deeper. Previous experiments indicate that oxygen partitions into sulphide melts and although sparse, some measurements of natural sulphide inclusions from mantle xenoliths indeed show measurable and in some cases relatively high oxygen concentrations. If the parameters that control sulphide oxygen concentration can be determined then they could be potentially used to understand conditions in the mantle and in particular in sublithospheric diamonds. The oxygen content of sulphides separating to the core during core formation could have also influenced the oxygen fugacity of the early mantle.
We have measured the oxygen contents of sulphide melts within experimentally produced mantle assemblages at high pressures and temperatures. A series of multi-anvil experiments were conducted to equilibrate a peridotite assemblage with molten sulphide (FeS) at pressures between 3 –11 GPa and temperatures of 1300 ˚C –1700 ˚C. The effects of pressure, temperature, oxygen fugacity and composition have been investigated. Oxygen fugacity was determined in some experiments by saturating the sulphide in Ir to produce a separate Ir-Fe metal alloy, for which the Fe content is a function of oxygen fugacity. The results show that sulphide melt oxygen contents can range up to 16 weight % FeO, at mantle conditions. Moreover, the content of oxygen in the sulphide is found to be not controlled by $fO_2$ or $fS_2$, which is in disagreement with previous experimental studies conducted at ambient pressure conditions. The experiments indicate that the oxygen concentration is mainly controlled by the FeO activity in coexisting silicates phases and the temperature, although further work is still required to calibrate effects of Ni and Cu. In order to fit the data and to account for the FeO dependence, we developed a thermodynamic model using an end-member equilibrium between olivine, pyroxene and FeO in the sulphide melt. The resulting relationship can be used as a geothermometer based on sulphide inclusion oxygen contents and could be particularly useful for determining diamond formation temperatures for sub lithospheric diamonds.

Washington)

This session addresses how volatile species affect dynamics of the<br/>Earth and planets from natural observations, laboratory experiments, and<br/>numerical modeling in the temperature, pressure, and oxygen activity<br/>range from the early stage of the planet formation to the present. The<br/>volatiles can be critical in zones of magma storage and ascent, mantle<br/>upwelling and melting in the fluid-enriched subduction zones, in the<br/>mantle transition zone, in the lower mantle, in the core-mantle boundary,<br/>and in Earth and planetary cores. However, volatiles affect properties<br/>and processes differently depending on their pressure, temperature, and<br/>redox conditions, which vary in time and space. <br/> This session aims to address how volatiles control the dynamic<br/>processes of the Earth and planets, governed by their geophysical and<br/>geochemical properties. We welcome papers dealing with geological and<br/>laboratory observations coupled with numerical modeling on the role of<br/>volatiles. The topics include (1) Stability relations, chemical and<br/>physical properties of crystalline, molten and fluid phases,<br/>partitioning of volatiles among these phases, (2) Rheological and other<br/>physical properties of minerals, and the effects of intergranular fluid<br/>on the properties, (3) Volatiles and dehydration induced seismicity and<br/>volcanism in various tectonic regions including subduction zones, and (4)<br/>Effects of volatiles in numerical simulation of geo-tectonics, and (5)<br/>Magma outgassing and its control of volcanic eruption dynamics.

The flow of fluids through porous media such as groundwater flow or magma migration is one of the most important processes in geological sciences. The property controlling the efficiency of the flow is the permeability of the rock, thus an accurate determination and prediction of its value is of crucial importance. For this reason, permeability of rocks has been measured across different scales. As laboratory measurements exhibit a range of limitations, the numerical prediction of permeability at conditions where laboratory experiments struggle has become an important method to complement laboratory approaches. At high resolutions, this prediction becomes computationally very expensive, which makes it crucial to develop methods that maximize accuracy. In this work we introduce the open-source finite difference solver LaMEM that can be used to numerically predict the permeability of porous media under laminar conditions. We employ a stencil rescaling method to increase accuracy due to a better description of the solid-fluid interface, thus reducing the computational cost. To validate the method, we perform a series of tests employing both analytical solutions for simplified geometries as well as results from other numerical approaches for more complicated geometries. Furthermore we compare our numerical results to laboratory measurements on glass bead samples with porosities ranging from 20% to 2.5%, showing good agreement.

# Grain growth-induced fluid localization and permeability reduction

*Wakana Fujita[1], Michihiko Nakamura[1], Kentaro Uesugi[2]

1. Graduate School of Science, Tohoku University, 2. JASRI/SPring-8

Efficiency of segregation of geological fluids such as aqueous fluids and melts is an essential elementary process for volatile cycles in subduction zones. Permeability is an intrinsic rock property that controls flow rate of fluid. Various permeability models have been presented by numerical models of textually equilibrated rocks (e.g. 1, 2), laboratory measurements on synthetic rocks (e.g. 3) and estimation from cross-sectional area of synthetic rocks (4). However, there exist discrepancies among those models. Because permeability is very sensitive to microscopic geometry of pore fluid, those disagreements may arise from lack of understanding toward three-dimensional (3D) microstructure of fluid network.

Dihedral angle has been considered to be a critical parameter that controls fluid geometry and thus permeability. Beside, some previous studies shed light on the effect of grain growth on fluid distribution because it could induce pore fluid distortion and coalescence (5, 6). These studies suggest that in the actual systems where the microstructure of rocks evolve in dynamic processes, grain growth would be important along with the dihedral angle.

To investigate the effect of grain growth on the fluid distribution and permeability, we present 3D images of quartz–CHO fluid aggregates, containing nominal fluid fractions between 0.03 and 0.10. Samples were synthesized from a powdered mixture of Arkansus quartz and amorphous silica prepared by sol-gel method and hot-pressed in a piston–cylinder apparatus at 900˚C and 1.0 GPa for 192h. The fluid fractions and the dihedral angles were controlled using brucite added in the capsule bottom and oxalic acid dihydrate mixed with $SiO_2$ powder. 3D images were obtained using synchrotron X-ray microtomography at BL20XU experimental hutch2 of SPring-8. Regardless of dihedral angles ($CO_2$ content in fluids), both cross-sectional area and 3D images of samples showed grain-scale fluid localization which would be formed by pore fluid coalescence induced by grain growth. Computed permeabilities using numerical model, LaMEM (7) were almost consistent with laboratory measurements by (3) but more than one order of magnitude lower than a numerical model by (2). This would indicate that localized fluids extensively reduce permeability by reducing the diameter of fluid tubes along grain edges, which would suggest transport of water into Earth’ s deep interior by the subducting slab.

# Pargasite stability in the upper mantle at $H_2O$-undersaturated conditions

*Marija Putak Juricek[1], Hans Keppler[1]

1. BGI

Amphibole is the most commonly occurring hydrous mineral in mantle xenoliths and the majority of upper mantle amphiboles have compositions close to pargasite end member. Previous experimental work has demonstrated that pargasite stability is sensitive to variations in bulk alkali and water content of the starting material. While it has been successfully shown that addition of more alkali leads to stabilization of pargasite to higher P and T, the effect of water on amphibole stability is not so straightforward.

At $H_2O$-saturated conditions, alkali elements partition strongly into aqueous fluid and become less available for crystallization of amphibole. As a result, amphibole seemingly becomes stable at higher P and T when less $H_2O$ is added to the starting material. This observation led to the hypothesis that pargasite may be a ubiquitous phase in the upper mantle, which is believed to contain only several hundred ppm of $H_2O$. However, most of the previous studies determined pargasite stability at $H_2$ O-saturated conditions where solid phases coexist with an aqueous fluid during experiments. Since such environments are not representative of the nearly dry upper mantle, the purpose of this study is to investigate pargasite stability at $H_2O$-undersaturated conditions.

Because of the high specific surface area of powders, adsorption of atmospheric $H_2O$ on fine grained starting materials prevents attaining $H_2O$-undersaturation by adding small amounts of water to the sample. Instead, $H_2O$-undersaturated conditions may be precisely controlled by diluting the water in the sample with another component. Under such conditions, solid phases are expected to coexist with a low water activity fluid throughout the experiment. As molecular nitrogen is mostly insoluble in upper mantle minerals, it can be used to adjust the water activity of the fluid to a desired low value.

All experiments were performed in a piston cylinder apparatus. The samples for $H_2O$-undersaturated experiments were prepared by adding silver azide ($AgN_3$) and brucite to a synthetic peridotite mixture. In several experiments water was added directly as $H_2O_{(l)}$. The amount of water was kept constant in all experiments (1 wt. percent) and the molar fraction of water in the $N_2$-$H_2O$ fluid was adjusted to the desired value by weighing an appropriate amount of $AgN_3$, which decomposed to metallic silver and molecular nitrogen during heating. In $H_2O$-saturated experiments, no silver azide was added to the peridotite mixture. Experimental products were analyzed using JEOL JXA-8200 electron microprobe.

Preliminary results show that pargasite is not stable in equilibrium with fluids diluted to $X_{H2O}$=0.1 at pressures above 1 GPa. At $H_2O$-saturated conditions pargasite stability field can extend to pressures of 4 GPa and above 1100 ℃, depending on bulk alkali and water contents. Results from experiments at $X_{H2O}$ =0.1 and $X_{H2O}$=1 suggest that pargasite can exist only in regions of the upper mantle which have been affected by high water activity fluids, such as areas in the vicinity of subduction zones. The ambient nominally anhydrous upper mantle, better represented by experiments at $H_2O$-undersaturated conditions, is not expected to contain pargasite.

The water content in the mantle transition zone (MTZ) exerts a controlling influence on the dynamical and chemical evolution of Earth, but is poorly known. In principle the water content at the top of the transition zone can be inferred by comparing the velocity and density contrasts across the 410-km seismic discontinuity with predictions based on the phase transition of olivine to wadsleyite. The high-quality elastic data of at pressure and temperature (PT) conditions of the transition zone are crucial but are very challenge for experiments to obtain. Calculating these elastic data at high PT conditions in conventional method are also very expensive. Instead, these elastic data were calculated using the method of Wu and Wentzcovitch (2011), which reduces the computational workload to tenth of the conventional method. All calculations for two phases were conducted using the same computational details as far as possible, which guarantees that the velocity and density differences between two phases have very high precise. All these calculated elastic data agree well with the available experimental data. The iron and water effect on the elasticity are also well described.

With these high-quality elastic data covered the PT condition of the transition zone, we analyze the water and wadsleyite content at the top of the transition zone. We found that the water content of wadsleyite at the top of the transition zone can be well constrained when density and velocities jumps are considered together. For a pyrolitic mantle composition with ~60% olivine, our best fit is ~ 0.5 wt% water at the top of the transition zone. If the transition zone is dry, as suggested by some electrical conductivity models, the upper mantle may only contain ~ 50% olivine.

Earth’s deep water cycle plays a key role for the dynamic evolution of our planet and the development of habitable conditions. Surface water can be transported to Earth’s mantle by subduction of oceanic lithosphere. Experimental investigations have shown that water can be efficiently stored in Dense Hydrous Magnesium Silicates (DHMS) in cold subducting slabs. However, quantification of the incoming water budget based on the interpretation of seismological observations is hampered by a lack of elasticity measurements of DHMSs. Here, we report single-crystal elasticity measurements of Fe-bearing phase E, a DHMS that is stable at pressures and temperature of Earth’s mantle transition zone. A very low bulk modulus has been reported for phase E, suggesting that it might produce seismic velocity heterogeneities detectable by seismological investigations. However, the shear modulus of phase E has not been quantified.

We synthesized Fe-bearing phase E single crystals in a multi-anvil apparatus. Chemical composition as well as crystal structure have been determined using electron microprobe analysis, Mössbauer spectroscopy, and single-crystal X-ray diffraction. We derived the full elastic stiffness tensor by Brillouin spectroscopy on two single crystals of selected orientations. We found phase E to have both the lowest bulk modulus and shear modulus among the DHMSs at ambient conditions. Phase E shows very low compressional and shear velocities especially when compared to the other principal minerals likely present in subducting slabs after serpentine breakdown. Modelling of seismic velocities in dry and hydrated upper mantle and transition zone rocks suggests that the presence of even small amounts of phase E can appreciably lower seismic wave velocities. Phase E could be used as seismological indicator for water stored at depth in subducting scenarios. The elasticity of phase E under mantle conditions will be explored in future research.

# Discovery of two hexagonal phases in (Fe,Al)OOH under the P-T conditions of the deep lower mantle

*Lu Liu[1,2], Li Zhang[1], Hongsheng Yuan[1]

1. Center for High Pressure Science and Technology Advanced Research, 2. University of Science and Technology of China

Deep water can cause a series of complex seismological phenomena by changing the density and thermal stability of lower mantle components. δ-H solid solution phase (AlOOH-$MgSiO_2(OH)$) is stable at lower mantle conditions[1],because the crystallographic frameworks of the phase H is similar to that of the δ-AlOOH phase, with very strong hydrogen bonds[2,3]. δ-AlOOH and ε-FeOOH can also form solid solution[4] (δ - ε solution). It is reasonable to infer that δ - ε solid solution may have similar thermal stability as that of H- δ solution, considering their similar crystal structure[5]. In our experiments, we synthesized the δ - ε solution at 79GPa and 1600K in a laser-heated diamond anvil cell. As the temperature increases to 2100k, the orthorhombic δ - ε solution transformed into a hexagonal-structured phase. By combining powder X-ray diffraction techniques with multigrain indexation[6], we determined its hexagonal lattice with a=b=10.019Å and c=2.614Å. At 79GPa and 2400K, the hexagonal phase transforms into another hexagonal phase, with the lattice parameters of a=b=2.733Å and c=9.343Å. The discovery of these two new phases may provide new insights into the deep-water storage.

# Effect of grid resolution on tectonic regimes in global-scale convection models

*Enrico Marzotto[1], Marcel Thielmann[1], Gregor Golabek[1]

1. Bayerisches Geoinstitut

Global-scale convection models using a visco-plastic rheology coupled with a temperature-dependent viscosity usually show different tectonic regimes: mobile, episodic or stagnant lid.

In the mobilelidregime, the lid is continuously subducting into the mantle (plate-like behavior). The episodic lid regime is characterized by the stability of the lid until sufficiently large lithospheric stresses break it, causing rapid resurfacing. Finally the stagnant lid regime is defined by an undeformable lid that does not participate in convection

In numerical simulations these three types of regimes can be obtained by varying some target parameters such as: temperature-dependency of viscosity and yield stress.

The yield stress in particular is a key parameter because it sets the stress necessary to cause plastic yielding, hence, in a visco-plastic rheology, the stress necessary to break the cold surface regions. A high yield stress will result in a stagnant lid. On the other hand, a low yield stress causes a weak lid that is constantly broken and sinks into the mantle.Despite the key importance of physical parameters, also numerical parameters have an effect on the tectonic regime, determining different outcomes justby changing the grid resolution.

Here we use the code StagYY (*Tackley, 2008*) in a 2D spherical annulus geometry (*Hernlund & Tackley, 2008*) to determine the resolution-dependent tectonic regime for different yield stresses in global-scale convection models. To assess the effect of grid resolution on lid behavior we use 16 different resolutions keeping all physical parameters unchanged. To make sure that steady state has been reached each simulation is run for 15 Gyrs. Tested resolutions vary from 128x32 to 1024x256 grid points. To understand this influence on the tectonic regime we study the resolution within the lid requiring an appropriate lid definition, based on the thermal and velocity field. Our results show that there is a correspondence between low radial resolution and mobile lid regime and that low aspect ratio cells (azimuthal to radial grid spacing) favor a plate-like behavior of the lid, while for large aspect ratios the mobile lid regime is persistent.

This work is the first part of a larger project, aiming to studyslab stagnation and hydration of the mantle transition zone (MTZ) using self-consistent global-scale mantle convection models, where subducting slabs carry water from the surface into the Earth’ s interior and potentially hydrate the MTZ. We expect that our previous work packages will help us to obtain realistic slab ponding in the MTZ, so we can study the hydration state of this region over time.

# A 3-D crust and uppermost mantle electrical conductivity model of subduction zone beneath NE Japan

*Masahiro Ichiki[1,2], Toshiki Kaida[1], Yasuo Ogawa[3]

1. Graduate School of Science, Tohoku University, 2. International Research Institute of Disaster Science, 3. School of Science, Tokyo Institute of Technology

The crustal fluids beneath NE Japan is originated from dehydration of subducting Pacific slab or from convection in the backarc mantle, as is shown by seismic tomography [e.g. Zhao, 2017]. We investigated the fluid transportation paths from upper mantle to crust of subduction zone using electrical conductivity exploration.

We expanded electromagnetic field observation sites (96 sites) to northern part of NE Japan and obtained magnetotelluric responses and geomagnetic transfer functions in the period range of 20 –30720 seconds (22 periods) by BIRRP code [Chave and Thomson, 2004]. We used WSINV3D [Siripunvaraporn and Egbert, 2009] to invert those responses into three dimensional electrical resistivity model.

The preliminary model gives normalized root mean square misfit 5.87. A prominent conductor appears in the crust to uppermost mantle and the conductor spreads towards backarc direction. In our previous model [Ichiki et al., 2015], we found the overturned shape conductor towards backarc direction in the mantle wedge beneath central part of NE Japan. This study has found it beneath northern part NE Japan as well.

Those imply the crustal fluid and/or melt is transported along the pathway that is the plate boundary beneath the volcanic front to the backarc crust. The fluid transportation can explain the presence of enigmatic backarc volcano in the NE Japan. In this presenation, we speculate and discuss evolution of this pathway in geological time on the basis of the chlonological data of igneous rocks [Yoshida et al., 2013].

# *The conditions of sublithospheric diamond formation constrained from ferric iron-rich exsolution from ferropericlase inclusions.*

*Caterina Melai[1], Daniel Frost[1], Tiziana Boffa Ballaran[1], Catherine McCammon[1]

1. Bayerisches Geoinstitute

Ferropericlase is apparently one of the more common inclusions to be found in sub-lithospheric diamonds, which are considered to form in the convecting mantle. Although relatively rare, these inclusions have been examined in a number of studies in the hope of providing information on the formation conditions of such deep diamonds, which could potentially be in the transition zone or lower mantle. The wide range of oxide Fe/(Fe+Mg) ratios found has raised the idea that they may form through the oxidation of iron metal. During TEM investigations, however, evidence for the exsolution of $Fe_2O_3$-rich phases such as magnesioferrite have been found, which implies that a more complex scenario may be involved. Ferropericlase-magnesiowüstite diamond inclusions are most likely some of the deepest available samples from the mantle and they potentially provide the most direct evidence for deep mantle carbon transport processes. The ferric iron contents of such inclusions alone may not provide a direct estimate for the oxygen fugacity at which the inclusions were trapped, particularly if pressure has a strong effect on the $fo_2$ - $Fe^{3+}/Fe_{tot}$ relationship. However, using experimental data it is possible to determine the oxygen fugacity at which the exsolution observed in the diamond inclusions occurred and coupled with the oxide $Fe^{3+}/Fe_{tot}$ ratio this could be used to estimate the pressure of formation.

The ferropericlase- magnesioferrite system has been investigated by several studies at room pressure but the stability field of the two components has been shown to become more complicated at high pressure due to the formation of mixed valence oxides. We have combined experimental measurements with thermodynamic modelling in order to address two main questions: at which P, T, $fO_2$ conditions do $Fe_2O_3$ -rich phases exsolve from ferropericlase? And what is the maximum $Fe^{3+}/Fe_{tot}$ ratio of ferropericlase. To answer these questions, multianvil experiments have been performed between 6 –25 GPa and 1200-1800˚C using a starting composition of $(Mg_{86}Fe_{14})O$ plus 20 % $Fe_2O_3$. Pt powder was added to the experiments to act as a redox sensor and minor amounts of Ni, Cr, Mn and Na were also added. Samples were then analyzed with the scanning electron microscope, electron microprobe, Mössbauer spectroscopy and X-ray diffraction. In the recovered experiments ferropericlase coexists with magnetite-magnesioferrite solid solution up to 10 GPa and $Mg_2Fe_2O_5$-$Fe_4O_5$ solid solution at higher pressures. In the calculation of the oxygen fugacity a ferropericlase model in the FeO-$Fe_{2/3}O$-MgO system was employed and exchange of Mg and $Fe^{2+}$ in magnetite was accounted for. Oxygen fugacities at which the phases coexist can be calculated in the magnetite-magnesioferrite field using three different equilibria and a quite simple ferropericlase mixing model results in calculated oxygen fugacities that are within 0.1 log units of each other for all three equilibria. The results show that magnetite-magnesioferrite solid solution should not be in equilibrium with ferropericlase in the diamond stability field. Our results imply that the exsolution of $Fe^{3+}$ rich phases observed in natural samples likely occurred at pressures corresponding to the transition zone or deeper.

# Probing the variation of the oxygen fugacity in diamond anvil cells using the Fe-Ir alloy as redox sensor

*Serena Dominijanni[1], Catherine McCammon[1], Leonid Dubrovinsky[1], Dan Frost[1], Nobuyoshi Miyajima[1]

1. Bayerisches Geoinstitut

Understanding the oxygen fugacity ($fO_2$) in diamond anvil cells (DACs) is an important issue for many reasons, among them reconciling contradictory results that have been obtained for carbonate studies (Cerantola et al., 2017; Dorfman et al., 2018) that might be due to different redox conditions during the experiments. We therefore investigated the $fO_2$ conditions during DAC experiments using powder X-ray diffraction (beamlines ID15b and ID27) and energy-domain Synchrotron Mössbauer Source (SMS) spectroscopy (beamline ID18) at the European Synchrotron Radiation Facility (Grenoble, France). Double sided laser heating experiments (Aprilis et al., 2017) were carried out at high pressure and temperature using a mixture of synthetic ferropericlase ($Mg_{0.75}Fe_{0.25}$)O and pure iridium powder as a sliding redox sensor (Borisov and Palme, 2000; Swartzendruber, 1984; Taylor et al., 1992). The Fe content in the Fe-Ir alloy, together with the amount of FeO in ferropericlase, allows a calculation of $fO_2$ during the experiments (Stagno et al., 2011; Woodland and O'Neill, 1997). Preliminary results from powder X-ray diffraction data show that, after heating, an Fe-Ir metal alloy that can be indexed in the Fm-3m space group is formed by the reaction of pure Ir and Fe from ferropericlase according to the reaction:

(Mg,Fe)O + Ir --> (Mg,Fe)O + (Fe,Ir)

The compressibility of the Fe-Ir alloy and ferropericlase was measured up to ~ 60 GPa and SMS data were collected before and after heating. X-ray diffraction results coupled with energy-dispersive X-ray spectroscopy (EDS) measurements and a simple thermodynamic model indicate that the redox conditions during the DAC experiments were close to the iron-wüstite (IW) buffer, although some inhomogeneity was observed. Further chemical analyses and additional experiments are ongoing to understand the variation of oxygen fugacity in a DAC during laser heating.

Water and water-bearing species have a strong impact on numerous processes in Earth’ s interiors. Presence of water affects chemical and physical properties of mantle minerals, changes melting temperatures, sound velocities and viscosity of materials, and causing different global phenomena such as, for example, arc volcanism and plate tectonics. Thereby, the deep Earth’ s regions enriched with water are crucial for understanding our planet’ s geodynamics and geochemistry. Still, mechanisms of water circulation between geospheres remain poorly understood. Recent studies suggest that goethite present in Banded Iron Formations (BIFs) may transfer some quantities of water to the deep Earth interiors with subducting slabs. It was reported that goethite remains stable in the sinking slab until it reaches the base of a lower mantle. By the meaning of in situ powder XRD it was revealed that at pressures corresponding to the depths ~1500-1800 km and moderately high temperatures goethite undergoes a phase transition to form a novel stable pyrite-type phase $FeO_2H_x$ with $0 \leqq x \leqq 1$ (named as Py-phase). Thus, goethite and its HP pyrite-type form became a candidate for water and/or hydrogen transfer and storage to the lower mantle and the core-mantle boundary. Using laser-heating in diamond anvil cells we performed a series of experiments on an investigation of goethite (as a starting material) stability at P-T conditions covering possible range in subducting slabs. By the meaning of sensitive in situ single-crystal XRD in DACs we registered decomposition of goethite and formation of known (such as $\iota$-$Fe_2O_3$, $\eta$-$Fe_2O_3$, a high-pressure orthorhombic form of $Fe_3O_4$, $Fe_5O_7$) and novel iron-oxygen compounds. Results of structure solution and refinement established these compounds to be orthorhombic $Fe_7O_{10}$ and hexagonal non-stoichiometric phase $Fe_{6.31}O_9$. Our results suggest that FeOOH cannot transport water into the deep of Earth’ s mantle.

# The oxygen content of sulphides in the mantle and a geothermometer for diamond formation

*Sumith Abeykoon[1], Dan Frost[1], Vera Laurenz[1]

1. Bayerisches Geoinstitut, University of Bayreuth

Sulphides are ubiquitous accessory minerals in mantle rocks and form the most prevalent type of inclusion in diamonds. Diamond sulphide inclusions are trapped as sulphide melts that crystallise on cooling to form Fe-Ni monosulphide solid solution (MSS) and ultimately recrystallizes to assemblages containing pyrrhotite, $Fe_{(1-x)}S$ (x = 0 to 0.2), pentlandite, $(Fe,Ni)_9S_8$, and sometimes pyrite ($FeS_2$). Sulphide inclusions are also found in many xenoliths but those which are hosted by diamonds provide potentially the most pristine samples from the lithospheric mantle and deeper. Previous experiments indicate that oxygen partitions into sulphide melts and although sparse, some measurements of natural sulphide inclusions from mantle xenoliths indeed show measurable and in some cases relatively high oxygen concentrations. If the parameters that control sulphide oxygen concentration can be determined then they could be potentially used to understand conditions in the mantle and in particular in sublithospheric diamonds. The oxygen content of sulphides separating to the core during core formation could have also influenced the oxygen fugacity of the early mantle.
We have measured the oxygen contents of sulphide melts within experimentally produced mantle assemblages at high pressures and temperatures. A series of multi-anvil experiments were conducted to equilibrate a peridotite assemblage with molten sulphide (FeS) at pressures between 3 –11 GPa and temperatures of 1300 ˚C –1700 ˚C. The effects of pressure, temperature, oxygen fugacity and composition have been investigated. Oxygen fugacity was determined in some experiments by saturating the sulphide in Ir to produce a separate Ir-Fe metal alloy, for which the Fe content is a function of oxygen fugacity. The results show that sulphide melt oxygen contents can range up to 16 weight % FeO, at mantle conditions. Moreover, the content of oxygen in the sulphide is found to be not controlled by $fO_2$ or $fS_2$, which is in disagreement with previous experimental studies conducted at ambient pressure conditions. The experiments indicate that the oxygen concentration is mainly controlled by the FeO activity in coexisting silicates phases and the temperature, although further work is still required to calibrate effects of Ni and Cu. In order to fit the data and to account for the FeO dependence, we developed a thermodynamic model using an end-member equilibrium between olivine, pyroxene and FeO in the sulphide melt. The resulting relationship can be used as a geothermometer based on sulphide inclusion oxygen contents and could be particularly useful for determining diamond formation temperatures for sub lithospheric diamonds.

Degassing of volatile elements from the mantle to the atmosphere requires decompression melting, magma generation and degassing, and is therefore linked to mantle convection. Mantle convection is a physical process that tends to minimize temperature contrasts between the Earth's surface and the deep regions of the mantle. Hence its strength was variable through geological periods of time as it depended on heat generation within the Earth as well as heat dissipation to space. Convection of planetary mantles is a key driver of the evolution of planets and on Earth has been modulating the generation and stabilization of the continental crust. Still the thermal regime of the Earth, and notably the radiogenic/total heat production ratio (the Urey number) are not precisely known. It is related to the distribution of radioactive isotopes (mainly $^{238,235}$U, $^{232}$Th, $^{40}$K) among Earth's reservoirs which varied through time, on the latent heat of core crystallization, on the residual energy of accretion, and on the heat dissipation from the Earth's interior, which depends on mantle convection, a self-regulating process. Geological and geochemical observations have the potential to set constraints on variations of mantle convection in the distant time. Atmospheric xenon presents excesses in $^{129}$Xe, an isotope contributed by the decay of extinct iodine-129 ($T_{1/2}$ = 16 Ma). Part of this excess resulted from early degassing of the mantle and, possibily from contributions of comet to early Earth. Mantle degassing also contributed $^{129}$Xe to the atmosphere through time since the solid Earth is rich in $^{129}$Xe compared to the atmosphere. In agreement with this possibility, remnants of the Archean atmosphere trapped in fluid inclusions (Avice et al *Nature Comm*, 2017, GCA 2018) and in organic matter (Bekaert et al Science Adv 2018) show that xenon in Archean air was depleted in $^{129}$Xe compared to the modern composition (see Figure; error bars at 2 s; the grey area represents the reproducibility of air standards at the 2 slevel). However, this deficit cannot be accounted for by the modern degassing rate (as estimated from noble gas fluxes from the mantle), and requires degassing rates two orders of magnitude larger in the distant past than at present. This discrepancy implies a more vigorously convecting Archean-Proterozoic Earth, and suggests a potential impact on the composition of the Archean atmosphere. It also leads credence to models advocating a magmatic origin for drastic environmental changes like the great oxidation event.

# Investigating volatile cycles in the terrestrial mantle by incorporating He and Ar isotopes into geodynamical models of mantle convection

*Rosie Ellen Jones[1], Peter van Keken[2], Jonathan M Tucker[2], Chris J Ballentine[1]

1. Department of Earth Sciences, University of Oxford, Oxford, UK, 2. Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, USA

The dichotomy in $^{3}He/^{4}He$ isotopes ratios between mid ocean ridge and ocean island basalt samples (MORB and OIB) has provided a fundamental cornerstone in defining the need for a long-lived, volatile rich, and possibly primordial, geochemical reservoir within the deep mantle. However, this is somewhat at odds with evidence from other radiogenic isotope systems (e.g., U-Th-Pb, Lu-Hf, Sm-Nd, Rb-Sr), as well as geophysical evidence, for recycled surficial/crustal material in the deep mantle. Geodynamic models of mantle convection have been developed to incorporate earth-like phase and viscosity changes and can reproduce earth-like surface heat flow and plate motion. When such models take into account the higher density of the subducting oceanic crust, compared to the surrounding mantle, it provides a mechanism of retarding convection in the deepest mantle and reproduces observed geochemical distributions in multiple isotope systems (U-Th-Pb, Rb-Sr, Sm-Nd, Lu-Hf and Re-Os) that define the DMM, HIMU and EMI mantle endmembers (Brandenburg et al., 2008, Jones et al., 2017). Here we use a geodynamical model of mantle convection (Brandenburg et al., 2008), and combine it with geochemical input parameters, to investigate whether the subduction of dense eclogite can retard lower mantle convection sufficiently to explain the observed differences in $^{3}He/^{4}He$ obtained for MORB and OIB. We go on to analyse the effect of $^{3}He$ outgassing from the Earth's core and early recycling of extra-terrestrial material containing high $^{3}He$ (e.g., interplanetary dust particles (IDPs)) into the mantle. The K-Ar system is also incorporated into the model and earth-like $^{40}Ar$ planetary degassing from the mantle is reproduced. We explore the impact of $^{36}Ar$ recycling on the $^{40}Ar/^{36}Ar$ compositions of MORB and OIB. The results suggest recycling of atmospheric Ar can produce the observed $^{40}Ar/^{36}Ar$ compositions of the upper and lower mantle.

# Fluid circulation in the forearc mantle wedge inferred from the dihedral angle in an olivine-$H_2O$-NaCl system

*Yongsheng HUANG[1], Takayuki Nakatani[1], Michihiko Nakamura[1], Catherine McCammon[2]

1. Graduate School of Science, Tohoku University, 2. Byerisches Geoinstitut, University of Bayreuth

In subduction zones, the circulation of slab-released aqueous fluids is crucial to understand the generation of arc magma and recycle of materials, and further to constrain the global geodynamics. The infiltration of aqueous fluids plays an important role in controlling geophysical properties of the mantle wedge such as elasticity, permeability and electrical conductivity. Recently, magnetotellulic studies found a high electrical conductor beneath the fore-arc region which was interpreted as a storage of voluminous slab-derived fluid, implying the presence of permeable mantle wedge at fore-arc depths. By contrast, experimental constraints on dihedral (wetting) angle ( $\theta$ ) in the olivine-$H_2O$ system indicated the fluid is once trapped in isolated pores ( $\theta > 60^\circ$) within the down-dragging mantle matrixat fore-arc depths and finally released just beneath the arc volcano where $\theta < 60^\circ$. Here we present the precisely determined dihedral angles in the olivine and NaCl-bearing aqueous fluid (5–27.5 wt% NaCl) system at 1–4 GPa and 800–1100˚C to reveal the influence of NaCl on the fluid connectivity because the NaCl is now recognized to be an important constituent of subduction zone fluids. We found that NaCl significantly decreases $\theta$ down to below 60˚ at all the investigated temperature and pressure conditions even at 5 wt% NaCl. Our results suggest that released NaCl-bearing aqueous fluid begins to form an interconnected network in the mantle at relatively shallow depths of ~80 km and can partly penetrate the fore-arc crust without causing mantle melting, which could account for the high electrical conductivity anomalies beneath the for-are region. Our model also emphasizes that partial melting of peridotite triggered by the addition of aqueous fluid can occur more widely than that previously thought, and implies that the release depth of aqueous fluid is not a primary control on the volcanic front position. This work was supported by the JSPS Japanese-German Graduate Externship.

# The oxygen fugacity of serpentinites: implications for subduction zone redox evolution

*Lisa Eberhard[1], Dan Frost[1], Catherine McCammon[1]

1. BGI

At subduction zones $H_2O$ and $CO_2$ are returned to the Earth’ s mantle, bound within hydrous and carbonate minerals. Serpentinites are considered to be major carriers of $H_2O$ into the mantle but natural exposures indicate that some sections of serpentinized mantle also contain significant amounts of carbonate minerals. Determining the fate of so called ophicarbonate rocks presents an important challenge because it involves the interaction between both $H_2O$- and $CO_2$- bearing fluids. A further aspect however is that serpentine minerals also contain ferric in addition to ferrous iron. Natural serpentinites record in fact a very wide range of $Fe^{3+}/Fe^{tot}$ ratio but the effect of this ratio on the high pressure stability of serpentine and the relationship with the speciation of coexisting C-O-H fluid phases is unknown.

We have examined the stability of the serpentinite mineral antigorite within ophicabonate assemblages at subarc conditions as a function of P, T and $fO_2$. Multi-anvil experiments were performed both inside the stability field of antigorite, but also at conditions where antigorite starts to dehydrate. Natural serpentinites are used as starting materials with initially high and low $Fe^{3+}/Fe^{tot}$ ratios. Calcium carbonate was then added to these assemblages to simulate ophicarbonate composition. Iridium metal was added to some nominally unbuffered experiments to allow the oxygen fugacity to be determined, whereas in other experiments the oxygen fugacity was fixed using powders of Ru + $RuO_2$ and Re + $ReO_2$ distributed throughout the sample. Ferrous Fe is located in the octahedral site of antigorite whereas ferric Fe may additionally occupy the tetrahedral site of the trioctahedral 1:1 sheet silicates, providing charge balance. We have determined the location and speciation of the Fe atoms in serpentinites as a function of $fO_2$, P and T by using Mössbauer spectroscopy to examine the run products of the multi-anvil experiments.

The experiments were run for approximately 3 days during which it was possible to change the $Fe^{3+}/Fe^{tot}$ ratios of the starting materials to both higher and lower ratios depending on the redox buffers employed. We found that the relationship between the $Fe^{3+}/Fe^{tot}$ ratio of antigorite and the oxygen fugacity is very temperature dependent with antigorite $Fe^{3+}/Fe^{tot}$ ratios decreasing sharply at the same oxygen fugacity as dehydration commences. This behaviour should cause the oxygen fugacity within subducting lithosphere to increase as dehydration takes place, which will have important implications for fluid speciation. On the other hand the stabilisation of ferric iron in antigorite at high oxygen fugacities appears to have a minimal effect on the temperature of dehydration.

# Experimental study of the effect of composition on water solubility in natural silicate melts

*Shigeru Yamashita[1]

1. Institute for Planetary Materials, Okayama University

Water is the first dominant volatile dissolved in magmas. Oversaturation and exsolution of the water in magmas affects the buoyancy and excess vapor pressure of the system, and hence the water solubility in silicate melts is fundamental in controlling magma transport beneath volcanoes. Many experimental studies of the solubility for water in natural silicate melts are now available, but most of them were performed over a limited range of composition. For example, published solubility data for water are rather sparse for the natural silicate melts having moderate $SiO_2$ contents. This has resulted in insufficient data coverage of composition space, which makes difficult to precisely model if a melt is subject of compositional change due to partial crystallization, assimilation, or magma hybridization. This study presents results from experimental determinations of the solubility for water in a natural dacitic melt at near-the liquidus and the superheated conditions.

The starting material for the experiments was the natural subalkaline dacite JA1 (GSJ standard reference material, ~65 wt% $SiO_2$). A nominally anhydrous glass was prepared from the starting material, and the glass was equilibrated with water in an internally heated pressure vessel for ~24 hours at 1000-1200 ˚C and 100-200 MPa. Double capsule technique was employed to control the oxygen fugacity in the sample along Ni-NiO buffer during the experiments. The water content in the quenched glass was determined from the near infrared absorption intensities of the hydroxyl groups band at ~4500 $cm^{-1}$ and the molecular water band at ~5200 $cm^{-1}$ using the molar absorption coefficients of Ohlhost et al. (2001).

Results of this study are overall consistent with previous determinations of pressure- and temperature-dependence of water solubility in rhyolitic melts. Water solubility in the dacitic melt increases with pressure at a fixed temperature, and decreases with temperature at a fixed pressure. On the other hand, the water solubility in the dacitic melt was found to be 10-20 % (relative, on the mole fraction basis) greater than those previously determined by Holtz et al. (1992; 1995) and Yamashita (1999) for the rhyolitic melts when compared at the same pressure and temperature condition. This advocates that the effect of melt composition play a noticeable role in controlling the degree of water oversaturation during magmatic processes. When a hotter basaltic magma is injected to a colder rhyolitic magma body, a purely thermal effect on water solubility enhances formation of vapor bubbles in the rhyolitic magma (e.g., Yamashita, 1999). Once hybridization between the melt portions of the two magmas proceeds, the effect of melt composition on water solubility becomes important, i.e., already present, sub-millimeter size bubbles (thus their buoyant separation is limited) can be resorbed by the hybridized melt which has an intermediate composition.

# Deep mantle volatile cycle and plate tectonics: Impact to the climate evolution

*Takashi Nakagawa[1], Shintaro Kadoya[2], Eiichi Tajika[3]

1. Department of Earth Sciences, The University of Hong Kong, 2. Department of Earth and Space Sciences, University of Washington, 3. Department of Earth and Planetary Sciences, The University of Tokyo

We investigate the deep mantle volatile (water and carbon) cycle and its impact to plate tectonics and climate evolution in the numerical mantle convection simulations couping with the energy balance model of the surface climate model. To calculate the mantle water cycle, the storage capacity model of water in each mantle minerals as functions of temperature and pressure is incorporated into numerical mantle convection simulations so that the dehydration process can be included in the numerical model of mantle water cycling as well as the regassing and degassing processes. However, the decarbonation process cannot be included because the storage capacity model of carbon is not well-established. In three migration processes of mantle volatiles, the volcanic degassing plays a significant role because the volatile composition of the atmosphere-ocean system can be described as a balance between degassing flux and silicate weathering effects as uptake of the volatile components. As a result, the optical properties of the atmosphere-ocean system such as the Albedo and planetary radiation are changed with the volcanic degassing. Other two migration processes may be worked for regulating the volatile content stored in the deep planetary interior and inventory of surface volatile reservoir. The style of plate tectonics driven by mantle convection may strongly affect the style of climate evolution and inventory of surface volatile reservoir. In the stagnant lid mode of mantle convection, the snowball climate is dominated for over a few billion years because the strong radiative cooling is controlled due to less amount of volcanic degassing associated with the stagnant lid convection. Whereas, the continuous carbon degassing is expected in the continuous surface plate motions so that the mild climate can be found, which allows having the liquid water over a few billion years on the planetary surface. In order to preserve the amount of surface seawater on the planetary surface as the present-day amount of surface seawater on the Earth, the required amount of the water in the entire planetary system may be around 10 to 12 Ocean Masses of present-day Earth's water ocean. Therefore, the mantle volatile cycle concerning with the plate tectonics driven by mantle convection may control the habitability of the rocky planets such as the Earth.

# The nature of water induced small degree melts in the deep mantle

*Daniel James Frost[1], Pierre Condamine[3], Davide Novella[2], Rong Huang[1]

1. University of Bayreuth, 2. University of Cambridge, 3. Université de Lorraine

Slow S-wave velocities in the deep mantle have been used to argue for the presence of hydrous silicate melts. Small degree partial melts could potentially be formed due to a reduction in the $H_2O$ storage capacity of mantle minerals due to pressure induced phase transitions or as a result of redox processes. Hydrous melt layers could accumulate at certain depths in the mantle due to neutral buoyancy. Water concentrations in the ambient mantle are at most likely to lead to only small degrees of melting. Such incipient melts would be in equilibrium with a peridotite assemblage containing minerals that would be practically identical in major elements as the unmelted assemblage. The compositions of such melts are important because their water contents constrain the relationship between melt fraction and the bulk water content. Furthermore, the water content and the iron content would mainly determine their buoyancy. To assess if neutrally buoyant small degree hydrous melt layers exist in the mantle and to determine how much water would need to be present to create them requires experimental determination of their compositions.

Determining the chemical composition of low degree melts and particularly their water contents is experimentally very challenging. At pressures higher than 2 GPa melts no longer quench to form glasses and can therefore not be analyzed to determine water contents. Small melt fractions are very hard to analyze due to their very small volume and due to modification through reaction with solid phases during quenching. One way to overcome these problems and produce an analyzable portion of incipient melt composition is by performing sandwich experiments. In this method an initial first guess melt composition is equilibrated with a sub-equal proportion of peridotite. The resulting melt is then re- equilibrated with peridotite in a series of iterative experiments until a composition is obtained that is in equilibrium with the entire peridotite assemblage.

We have used this procedure to determine the compositions of incipient melts at depths equivalent to around 200 and 400 km in the mantle at adiabatic temperatures. The sandwich technique has to be modified in a number of ways when used at very high pressures, mainly to ensure that water contents can be accurately determined through mass balance. The resulting melts have affinities with the major classes of kimberlite magmas and their compositions can be used to assess their buoyancy in the deep mantle.

# Phase separation of hydrous Vesuvius melt: vesicle nucleation or spinodal decomposition?

*Anja Allabar[1], Marcus Nowak[1]

1. University of Tuebingen

The phase separation of $H_2O$ fluids from supersaturated hydrous silicate melts determines the starting point of explosive volcanic eruptions. The number of fluid vesicles per unit volume of silicate melt (*VND*) is a basic property that controls the efficiency of fluid-melt separation and as a result the acceleration of magma ascent. To simulate the phase separation of single phase hydrous silicate melts during ascent, continuous decompression experiments were performed at superliquidus temperatures with AD79 Vesuvius white pumice composition. This pumice buried Herculaneum and Pompeii and is representative of other catastrophic phonolitic and trachytic explosive eruptions like the violent 39 ka Campi Flegrei and the 1815 AD Tambora eruption.
Experiments were conducted in an internally heated pressure vessel equipped with a high-pressure valve that facilitates continuous decompression. 5.3 wt% $H_2O$ were dissolved in the melts at 200 MPa and 1523 K for 96 h. Subsequently, the slightly $H_2O$ undersaturated melts were isothermally decompressed at 1323 or 1373 K with rates of 0.024-1.7 MPa·s$^{-1}$. At final pressures ($P_{final}$) between 110 and 70 MPa, the samples were isobarically quenched with ~150 K·s$^{-1}$ to room temperature. The *VND* of the vitreous samples were determined with optical microscopy and quantitative backscattered electron image analysis combined with computational 2D to 3D transformation.
Homogeneously dispersed vesicles are observed in the samples decompressed to a $P_{final}$ ≦100 MPa which corresponds to a $\Delta P$ of ~95 MPa that is necessary to induce homogeneous phase separation. High log *VND*'*s* of ~5.2 (in mm$^{-3}$), corresponding to average vesicle distances of 10 $\mu$m, are observed irrespective of decompression rate within the investigated range. A nucleation theory based decompression rate meter (Toramaru, 2006), which is commonly used to estimate magma ascent velocity from *VND* of volcanic ejecta, fails to explain the experimentally observed decompression rate independent *VND*. Alternatively, decompression induced $H_2O$-silicate melt phase separation may be described by the theory of spinodal decomposition (Cahn, 1965) at the limit of thermodynamic stability. Critical behavior of hydrous silicate melt has already been evidenced experimentally by e.g. Shen and Keppler (1997) and is attributed to spinodal decomposition.
Irrespective of the phase separation mechanism, a decompression rate independent *VND* has profound consequences for the degassing dynamics of natural polyphase hydrous magma, that contain crystals and pre-existing fluid vesicles. During ascent, $H_2O$ supersaturation is decreased in melt shells surrounding pre-existing vesicles by $H_2O$ diffusion. Homogeneous phase separation occurs in interstitial melt volumes in which sufficient supersaturation is still preserved. If the decompression rate is fast enough to maintain such supersaturated volumes, the formation of vesicles with high log*VND* of 5.2 inevitably causes efficient melt degassing within seconds due to short $H_2O$ diffusion distances on a 10 $\mu$m scale from the melt into fluid vesicles. This causes rapid density decrease accompanied by sudden increase of magma buoyancy required for explosive volcanism.

# Role of water on dynamics in the lower mantle and core-mantle boundary regions

*Eiji Ohtani[1], Takayuki Ishii[2], Liang Yuan[1], Daijo Ikuta[1], Tomoo Katsura[2], Dan Frost[2]

1. Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University, 2. Bavarian Research Institute, University of Bayreuth

Recent experimental evidence indicated that the Earth’ s transition zone contains some amount of water at least locally. Subduction of the slabs into the lower mantle can transport water further into the lower mantle. One of the most important candidates of the water carrier into the lower mantle is hydrous phase delta-AlOOH and phase H-$MgSiO_4H_2$ solid solution. Our works on the stability of this solid solution revealed that it coexists with bridgmanite under the lower mantle conditions [1, 2].

We studied the hydrogen and aluminum partitioning between alumina and hydrogen between the delta-H solid solution and aluminous bridgmanite at high pressure and temperature. We observed that bridgmanite under the wet conditions depleted in aluminum, and it contains almost no water under the wet lower mantle conditions at 28 GPa and 800-1400°C. This partitioning of H and Al can provide significant effect on lower mantle dynamics through the change of the garnet-bridgmanite phase boundary, the pressure of the spin transition of both bridgmanite and delta-H solid solution, and bridganite-postperovskite transition.

The supply of water to the core-mantle boundary can create a reaction of water and iron in the core to produce $FeO_2H$ and its reaction product postperovskite $Fe_2O_3$. These phases together with the delta-H solid solution can play important roles at the bottom of the lower mantle. Physical properties of these phases can account for the sound velocity and density anomalies in the regions such as ULVZ (ultra-low velocity zone) and LLSVP (large low shear velocity province) [3].

# Stability of Fe-bearing hydrous phases and element partitioning in the system MgO-$Al_2O_3$-$Fe_2O_3$-$SiO_2$-$H_2O$ in Earth's lowermost mantle

*Hongsheng Yuan[1], Li Zhang[1], Eiji Ohtani[2], Yue Meng[3], Eran Greenberg[4], Vitali B. Prakapenka [4]

1. Center for High Pressure Science and Technology Advanced Research, 2. Department of Earth Science, Graduate School of Science, Tohoku University, 3. HPCAT, X-Ray Science Division, Argonne National Laboratory, 4. Center for Advanced Radiation Sources, University of Chicago

We performed experiments on a synthetic hydrous gel consisting of a model composition of subducted slabs in the MgO–$Al_2O_3$–$Fe_2O_3$–$SiO_2$–$H_2O$ system and containing ~7 wt.% water. The experiments were conducted in laser-heated diamond anvil cells under high pressure–temperature (*P-T*) conditions corresponding to the lowermost mantle using *in situ* synchrotron X-ray diffraction and *ex situ* transmission electron microscope techniques. The hydrous δ-phase AlOOH–FeOOH–$MgSiO_2(OH)_2$–$SiO_2$ (with an orthorhombic symmetry and the space group of *Pnnm*) coexists with bridgmanite (Bdg), post-perovskite (pPv), or both in a broad *P-T* range of 104–126 GPa and 1900–2500 K, whereas the pyrite-type (py) $FeOOH_x$ phase was only observed to coexist with the pPv phase by *in situ* XRD. Chemical analysis on recovered samples showed that (i) in the Bdg-bearing assemblage quenched from 104 GPa and 1900 K, the Bdg phase contains ~8 at.% Al and ~11 at.% Fe, and the coexisting hydrous δ-phase contains ~70 at.% Al and ~14 at.% Fe; (ii) in the pPv-bearing assemblage quenched from 117 GPa and 2050 K, the pPv phase contains ~7 at.% Al and ~16 at.% Fe, and the coexisting hydrous δ-phase contains ~81 at.% Al and ~9 at.% Fe. The considerable $Fe_2O_2(OH)_2$ (8–13 mol%) and $SiO_2$ (9–13 mol%) content in the δ-phase does not reduce its thermal stability; therefore, the Fe-bearing δ-phase can transport water to the lowermost mantle along the mantle geotherm. The dense py-phase may accumulate in the lowermost mantle in the presence of the pPv phase. In a hydrous system, $Al_2O_3$ depletion in both the Bdg and pPv phases can significantly reduce the width of the Bdg to pPv transition compared with the width in a dry system. On the other hand, significant Fe enrichment in pPv relative to the coexisting Bdg lowers the transition pressure to the depth of the D'' discontinuity. Accordingly, the depth and thickness of the Bdg to pPv transition in subducted hydrous basaltic crustal materials might explain the seismically detected D'' discontinuity. The formation of the dense hydrous py-phase in subducted slabs may contribute to chemical heterogeneities in the lowermost mantle.

# Laboratory Micro-Seismicity during Serpentinite Deformation as a Potential Analogue for Lower Wadati-Benioff Plane Seismicity

*Julien Gasc[1,3], Nadège Hilairet[2], Tony Yu[3], Yanbin Wang[3], Thomas P. Ferrand[1], Alexandre Schubnel[1]

1. Laboratoire de Géologie, CNRS - ENS, Paris, FRANCE, 2. Unité Matériaux et Transformations, CNRS - Lille University, Villeneuve d'Ascq, FRANCE, 3. GeoSoilEnviro-CARS, University of Chicago, Argonne IL, USA

The origin of intermediate-depth earthquakes, which occur at depths of 60-300 km along subducting slabs, remains somehow enigmatic. In the pressure and temperature conditions involved, rocks should indeed deform in a ductile fashion. Dehydration embrittlement, due to serpentine breakdown, was long considered a good candidate to explain lower Wadati-Benioff plane seismicity. However, unlike in the classic dehydration embrittlement theory, dehydration induced volume changes are negative at such depths and cannot trigger instabilities via pore pressure buildup. Accordingly, some experimental studies have shown that faulting of serpentinites related to dehydration, occurs in a stable and aseismic way (Chernak and Hirth, 2011; Gasc et al., 2011). Nevertheless, tremendous progress was recently made in understanding the mechanics of intermediate earthquakes, notably thanks to the combination of high pressure deformation experiments and in-situ synchrotron techniques. In order to assess the seismic potential of serpentinites, micro-seismicity was monitored during high pressure experiments by recording Acoustic Emissions (AE's) –or labquakes. A D-DIA apparatus was used to deform natural antigorite-rich samples at pressures of 1-5 GPa, both within and outside antigorite's stability field.

Below 400˚C, the deformation of fully hydrated serpentinite samples involves aseismic ductile cataclastic flow. Above 600˚C, despite conditions propitious to dehydration embrittlement (i.e., with fast strain rates and reaction kinetics), joint deformation and dehydration also lead to ductile shear, without generation of AE's. However, samples show a brittle temperature window around 500˚C that seems to correlate with the very onset of the mineral's breakdown, and is therefore not associated to significant release of water. In this latter case, AE's are consistently collected upon faulting and extremely sharp strain localization is observed (Gasc et al., 2017). In addition, brittle faulting of partly hydrated samples (a mixture of olivine and antigorite) can also occur with minor amounts of antigorite, due to stress percolation upon antigorite breakdown. Unlike for low-pressure dehydration embrittlement, faulting is also enabled here by the metastability of the solid phase rather than by fluid overpressure and dynamic fault propagation occurs concomitantly with the appearance of pseudotachylites along the fault plane (Ferrand et al., 2017).
Both brittle failure mechanisms identified in these studies share major similarities with the now-classic concept of transformational faulting (Burnley et al., 1991), often invoked for deep-focus earthquakes, and both may be a source of seismicity in subducting slabs. We provide evidence that destabilizing antigorite at mantle depths can initiate faulting and thus be involved in intermediate-depth earthquakes. However, analysis of the acoustic signal shows that it is relatively weaker than its real-earth counterpart, once scaled relative to standard brittle faulting. This suggests that other mechanisms are responsible for large intermediate-depth earthquakes, which may reflect fault propagation in the adjacent peridotitic mantle.

# Water transport and mixing in the whole-mantle scale convection

*Takeo Kaneko[1], Tomoeki Nakakuki[1], Masanori Kameyama[2], Hikaru Iwamori[3]

1. Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University, 2. Geodynamics Research Center, Ehime University, 3. Earthquake Research Institute, University of Tokyo

The subduction of oceanic plates transports sea water with the basaltic crust to the Earth’ s interior. High-pressures experiments reveal that nominally anhydrous minerals (NAMs) contain the water of a few thousands ppm in the weight fraction. On the other hand, numerical simulations show that the NAMs layer above the subducted slab plays an important role in water transport into the deep mantle. However, the details of the water circulation and distribution processes on the whole mantle has still not been understood well.
We perform numerical simulations of isoviscous mantle convection in a two-dimensional cylinder in which hydrous-mineral phase changes and the hydration-dehydration reaction are considered. We systematically examined the effects of parameters that control activity and mixing efficiency of the mantle convection, i.e., the Rayleigh number, the internal heating rate, and the water storage capacity of the lower mantle, on the water transport into the deep mantle.
The distribution and total amount of the water transported into the mantle strongly depends on the convection style. When the internal heating is absent, stable cellular flow dominates the mantle convection. The stable convection does not mix water well so that the water distributes only near the convection cell boundary. When the mantle has the internal heating, the mantle flow becomes strongly time-dependent by thermal boundary layer instabilities. Migration of the convection cell boundary enhances the mixing of the water into the whole mantle. In addition, mixing efficiency increases with the Rayleigh number, which is an index indicating convective vigor. When the water storage capacity of the lower mantle is much smaller than the NAMs, the ejected water forms the regional hydrous layer with high water content over the 660 km discontinuity near the downwellings. However, these hydrous regions are hindered from globally spreading to the mantle transition zone. The water content in most of the mantle rocks becomes equal to the smaller value among water storage capacities of the NAMs in the upper mantle and the lower mantle finally, though the upper mantle can accommodate more water. The amount of the water stored in the whole mantle rocks is, therefore, smaller than the summation of their capacities. As a result, the equilibrium of the water regassing and degassing is realized more rapidly than the whole mantle rocks are completely saturated.

Hydrothermal fluids and seawater are often entrapped in minerals as fluid inclusions in crustal/mantle materials, marine halites and even in rare meteorites [1, 2, 3, 4]. The chemical compositions of fluid inclusions and mineral inclusion therein are keys to decipher their origins and evolution of the geofulids. A laser-ablation inductively-coupled-plasma mass-spectrometry (LA-ICP-MS), a Raman spectrometry and an environmental SEM (cryo-SEM with EDS) are methods for chemical analysis of fluid inclusions, entrapped tiny minerals and gasses. For example, Kawamoto and coworkers recently determined Na/K ratio of fluid inclusions in olivine crystals from mantle xenoliths from the Pinatubo volcano by LA-ICP-MS in 20-$\mu$m spatial resolution [1]. The attempt successfully provided new insight on the fate of seawater subducting into the mantle in a plate convergent region. Lowenstein et al. investigated major chemistry of fluid inclusions from marine halites by a cryo-SEM with EDS system, and found systematic and oscillating changes in Phanerozoic seawater chemistry ($Na^+$ vs. $Cl^-$ and $Mg^{2+}$ vs. $Cl^-$) [3].

As unique sample preparation and analytical approach to a fluid inclusion, combined instrument of focused ion beam system and scanning electron microscope with a cryo sample stage (cryo-FIB-SEM) is recently utilized (e.g., Yoshida et al., 2018 [2]). Fluid inclusions can be exposed as ices in the vacuum sample chamber of cryo-FIB-SEM, and then the frozen fluids can be directly analyzed by EDS attached to SEM. Advantages of this approach are a direct access to fluid inclusions by precise sample milling with FIB, and simultaneous analysis for major elements with a relatively high spatial resolution (~5 $\mu$m). The method has been first applied to fluid inclusions in quartz [2].

A cryo-FIB-SEM approach is, however, time-consuming: entire processing and analysis with cryo-FIB-SEM requires several to few tens of hours for a several tens micrometer-sized sample. Descriptions of exact locations and spatial distribution of each fluid inclusion in host minerals will help to minimize a processing time with FIB. We, therefore, used a laboratory-based micro-focus XCT apparatus ($\mu$XCT) at the Center for Advanced Marine Core Research, Kochi University for acquiring an accurate three-dimensional characterization of fluid inclusions in minerals with a spatial resolution of 0.5 to 2.5 $\mu$m depending on sample size. In the present study, we aim to improve the throughput of the fluid inclusion analysis using cryo-FIB-SEM and establish a reasonable analytical flow. We have obtained spatial distributions of fluids in olivine from the Pinatubo xenoliths and those in halite in Sicilian rock by $\mu$XCT. Pretreatments for the samples have been carried out by micro-sampling system, and then microfabrication and chemical analysis of frozen fluids in the samples have been carried

©2019. Japan Geoscience Union. All Right Reserved. 

out by cryo-FIB-SEM.

In this talk, we will present the effectiveness of coordinated sample preparation utilizing cryo-FIB-SEM and $\mu$XCT, and a comprehensive microanalysis of fluid inclusions in addition to cryo-FIB-SEM. For instance, residues of fluid inclusions and associated minute minerals in FIB-processed samples can be further characterized in a higher spatial resolution by an analytical transmission electron microscope (TEM) and a secondary ion mass spectrometer (SIMS).

# Feasibility Study for Precise Particle Characterization of Fine Clay Particle Using An Automated Particle Image Analysis and Nanotrakcking Analysis.

*Daisuke Sasakura[1], Aiko Hayauchi[1], Sho Kimura[2]

1. MalvernPanalytical Japan ,Div of Spectris Co.Ltd,., 2. Faculty of Agriculture, University of the Ryukyu

## Introduction

Clay minerals are very common in soils, in fine-grained sedimentary rocks such as shale, mudstone, and siltstone and in fine-grained metamorphic slate and phyllite. Typical mechanism to generation of clay is alteration of the surface on mineral rock due to affected by transfer of water on the earth surface. Behavior of generation of clay is controlled by surface of minerals be forced to transform to other mineral component due to the moment contact with water. Particle size of clay minerals are usually ultrafine-grained, such as normally considered to be less than 2 micrometers in size on standard particle size distributions. Notable properties of clay are high-affinities with water, minerals due to unique properties of possible to make intercalation in crystal structure, and possibly disperse to anywhere with moving of water on earth surface due to fine particle size range. Therefore, to understand characteristics of clay is possible to consider as a maker index parameter of material transportation on the surface of earth. Especially particle characterization of clay is promising as fundamental parameter. Existing approaches to characterize of particle are such as an electron microscope (Scanning type: SEM, Transmission type :TEM) , an optical microscope (OM) , a laser diffraction (LD), an electro zone methods (coulter counter) and a dynamic light scattering (DLS) . However, drawbacks of these methods were such as indirect method, limited work on concentration determination, time consuming to measure over than several thousand particles and requirement to highly concentration (over than 3wt%) of ionized water. Complementally analytical approach using an automated particle image analysis (APIA) and Nanotracking analysis (NTA) are promising tools to as new flamework. In this report will be discuss for feasibility and technical discussion to applicable for fine clay using this flamework.

## Material and Methods.

As model samples for clay mineral, purchased Kaolin was used. To investigate purity and chemical components using crystal structure , XRD (Aereris , MalvernPanalytical , Almero, Netherlands) was used. Profile of XRD chart suggested diffraction peaks on 9.6, 19.3, 19.9, and 29.1 degrees. These peaks were significantly suggested as Pyrophyllite using library search.To characterize micrometer particles range, APIA analyses were conducted on a Morphologi G3SE as automated image analysis system (MalvernPanalytical Instruments, Worcestershire, UK). To characterize nanometer range, NTA analyses were conducted on a NS300 as nanotracking analyzing systems (MalvernPanalytical Instruments, Worcestershire, UK) with particle concentration.

# Crystal structure and local structures of natural perovskite-type (Na,REE,Ca)(Ti, Nb)$O_3$ loparite by single crystal diffraction and XAFS analyses

*Ginga Kitahara[1], Akira Yoshiasa[1], Makoto Tokuda[1], Kazumasa Sugiyama[2]

1. Kumamoto University, 2. Tohoku University

The perovskite type compound $ABX_3$ expresses various physical properties such as ferroelectricity and piezoelectricity, symmetry changes according to composition, pressure and temperature, and various deformations of framework constituted by $BX_6$ octahedral occur. Even in a solid solution, ferroelectricity, para electricity, superionic conductivity and the like are developed. Recently, it has attracted attention as a material for solar cells.

The perovskite-type minerals, which exist in the Earth’ s mantle, are one of the major host mineral of trace elements such as Th and REE. However, there are few detailed studies on rare earth elements and various heavy metals contained in naturally occurring perovskite-type minerals. In this study, we report on structural properties of solid solution, local structural characteristics of contained elements and irregularities due to radioactive elements, etc.

Analysis of chemical composition using SEM JSM-7001F manufactured by JEOL and EDS INCA SYSTEM manufactured by Oxford, and BL-9C and NW10A of KEK were used analysis of local structures and oxidation states by XAFS analysis and refinement of single crystal structure using Rigaku XtaLAB Super Nova.

The mineral produced from, Mt. Khibiny, Kola, Russia, which we treat as samples, is the solid solution with Lueshite $Na^{+}Nb^{5+}O_3$, Loparite $Na^{+}REE^{3+}Ti^{4+}{}_2O_6$, Perovskite $Ca^{2+}Ti^{4+}O_3$, Tausonite $Sr^{2+}Ti^{4+}O_3$ as end members. (Mitchell and Chakhmouradian 2000) SEM-EDS analysis reveal that there are albites mainly composed of $NaAlSi_3O_8$ at the rim. Therefore, we performed single crystal X-ray diffraction experiment with untwinned crystals picked up from the center.

Many discussions have been made on the crystal structure of Loparite. (Haggerty and Mariano 1983, Vlasov 1966, Mitchell 1996, Zubkova et al. 1998, Chakhmouradian et al. 1999, Mitchell et al. 2000) We attempted to analyze rhombohedral, tetragonal and tetragonal crystals which have been mentioned in previous research using this sample. Rhombohedral crystal: space group *R-3c*, a = 5.5077(2), c = 13.4906(5), Tetragonal crystal: space group *I4/mcm*, a = 5.5166(6), c = 7.7814(10), Ortho crystal Space group *Pbnm*, a = 5.5142(5), b = 5.5085(7), c = 7.7961(8) From more precise structural analysis, we will discuss the phase transition of Loparite structure etc.

From the shape of the XANES spectrum of Fe by spectral analysis, it turned out that the oxidation state of Fe contained is divalent, similar to the Ce-perovskite we investigated last time. In the Ti K-edge spectrum, it can be seen that the local distortion around Ti is considerably large from the peak intensity of pre-edge. With the substitution of Nb, the local strain of Ti at the octahedral site in the solid solution is larger than the $CaTiO_3$ end component, and the electron transition probability from 1s to 3d orbital is increasing. In the Th L3-edge spectrum, XANES is remarkable, and it can be interpreted that the actinoid element Th changes to U by causing radioactive decay, and irregularization corresponding to local metamictization

# Crystal Size Distributions based on crystal habit of groundmass pyroxene crystals in the ejecta of the Shinmoedake 2011 eruption

*Shota Okumura[1], Mayumi Mujin[2], Akira Tsuchiyama[1], Norimasa Shimobayashi[1], Akira Miyake[1]

1. Department of Geology and Mineralogy, Graduate School of Science, Kyoto University, 2. Division of Earth and Planetary Materials Science, Department of Earth Science, Tohoku University

The 2011 eruption of Shinmoedake, Kirishima volcano, Japan, is characterized by the transition of eruption styles and was preceded by magma mixing (e.g., Suzuki et al., 2013). However, the condition in the volcano has not fully clarified yet, thus clarification of the transition processes needs more information about the magma ascent process from the chamber to the shallow conduit. Meanwhile, Marsh (1988) has proposed that Crystal Size Distributions (CSDs) reflect the kinetic and physical processes affecting crystallization. Mujin and Nakamura (2014) and Mujin et al. (2017) have studied the CSDs of the groundmass crystals in the products of the eruption, and found that the CSD plots exhibit kinks which divide the groundmass crystals into two groups; the coarser ones with the gentler slope and the finer ones with the steeper slope. They proposed that the CSDs reflect the difference of the physicochemical conditions of magma depending on eruption styles. In this study, we focused on pyroxene crystals in groundmass to obtain the information about the physicochemical conditions during ascent in the conduit.

The samples used were the gray pumice of sub-Plinian eruptions and Vulcanian explosions of Shinmoedake 2011 eruption. We determined the miller indices of the pyroxene groundmass crystals by X-ray CT at SPring-8 (BL47XU) and an electron backscatter diffraction (EBSD), analyzed the size and shape of them with a field emission scanning electron microscope (FE-SEM), observed their microtextures with a transmission electron microscope (TEM), and performed composition analysis by a scanning TEM with an energy dispersive X-ray spectrometer (STEM-EDS).

We found that many of the crystals were in a hexagonal or octagonal prism. The former consisted of {010} and {110} prismatic faces and the latter had {100} faces. There were more hexagonal crystals than octagonal ones in the sub-Plinian pumice. In the Vulcanian pumice, by contrast, octagonal ones were dominant and there were only a few of hexagonal ones. In both eruption styles, the hexagonal ones were distributed in finer part than the octagonal ones. The slopes of the CSD also differed according to the habits; that is, the slopes of the hexagonal ones were steeper than that of the octagonal ones. The TEM observation showed that these pyroxene crystals in groundmass were composite crystals composed of orthopyroxene (Opx) and clinopyroxene (Cpx) which was attached to both {100} faces of the Opx, and that the Cpx parts on the both sides were occasionally in twin orientation relationship each other. Their microtextures were symmetric with respect to *c*-axis, which indicated the concentric spreads of the textures.

We found that the size distributions and slopes of the hexagonal and octagonal ones were similar to those of the finer group and the coarser group in Mujin and Nakamura (2014), respectively. Marsh (1988) proposed that CSD slope is a measure of the product of growth rate and residence time. Assuming that the growth rates were almost the same regardless of habits, residence times could be estimated from the CSD slopes as similar durations to the magma ascent durations in the conduit estimated from geophysical data (Kozono et al., 2013, Sato et al., 2013). In particular, the estimated residence time of the hexagonal ones in sub-Plinian pumice was similar to the ascend duration in sub-Plinian eruption. Hence, the hexagonal habit is assumed to reflect the relatively rapid magma ascent rate, which indicates that the

©2019. Japan Geoscience Union. All Right Reserved. 

habits of pyroxene groundmass crystals may reflect the ascent rates in the conduits. Moreover, the TEM observation suggests that microtextures of the crystals may record the temporal change of conditions during the ascent, which indicates the possibility that pyroxene groundmass crystals contribute to reveal the behavior of magma.

# Petrochemistry and zircon U-Pb age of ``lateritic'' metamorphic rocks from the Kitakami Mountains

*Nobutaka Tsuchiya[1], Yamato Kumagai[1], Tatsuro Adachi[2], Nobuhiko Nakano[2], Yasuhito Osanai[2]

1. Department of Geology, Faculty of Education, Iwate University, 2. Department of Earth Sciences, Faculty of Social and Cultural Studies, Kyushu University

Fe- and Al-rich metamorphic rocks were discovered from the Shinkama, Ofunato City, Kitakami Mountains, Japan. These metamorphic rocks underwent contact metamorphism during the intrusion of the lower Cretaceous Goyosan granitic rocks. The rocks from Shinkama are mainly composed of Pl, Bt, Ms, Grt, Crd(+/-), Kfs, Spl(+/-), Ilm, Ap. On the other hand, the rocks from Shinkama east are Pl, Bt, Ms, Grt(+/-), Crd, Kfs, Spl, And(+/-), Sil(+/-), Crn(+/-), Ilm, Ap. These rocks are characterized by low SiO2 contents (20--47%), high FeO* contents (12--33%) and high Al2O3 contents (18--38%). Bulk rock chemistry of the metamorphic rocks are resemble those from ``lateritic'' rocks from the Abukuma Metamorphic Belt. ``Lateritic'' rocks from the Abukuma Metamorphic Belt characteristically contains staurolite, however, metamorphic rocks from Shinkama does not include staurolite. This indicates the possibility that the metamorphic rocks in the Shinkama were probalbly metamorphosed under low pressure conditions than those from the Abukuma Metamorphic Belt.

U-Pb dating of zircons were carried out using Agilent 7500cx quadrupole inductively coupled plasma mass spectrometer (ICP-MS) with a New Wave Research UP-213 Nd-YAG UV (213 nm) laser ablation system (LA) installed at the Kyushu University. The operating parameters of analyses with LA-ICP-MS system are after Adachi et al. (2012). Zircon grains from the Shinkama metamorphic rocks are euhedral crystal (ca. 0.05mm) with remarkable oscillatory zoning, and define a concordant age of 126+/- 3Ma. On the other hand, zircon grains of subhedral crystal (larger than 0.1mm) with no oscillatory zoning, and define a concordant age of 326+/- 3Ma. The former age correspond to the contact metamorphism of Early Cretaceous, on the other hand, the latter corresopond to the hydrothermal alteration event of Carboniferous.

# How to make 'syn-plutonic dike' --- Another story from the Ryoke granitic province, Southwest Japan

*Takashi Nakajima[1], Hiroyuki Kamiyama[2], Ian S. Williams[3]

1. Geological Survey of Japan, 2. Ueyama-Shisui, Co. Ltd., 3. Australian National University

Syn-plutonic dike is interpreted to express a magma chamber process with intermingling silicic and mafic magmas in fluidal state.

In the Ryoke granitoids in Southwest Japan, mafic rocks often occur in so-called syn-plutonic dikes. They are pillow-like balls in the silicic matrix (pillow-type), and dikes intruding silicic matrix with silicic back-veins into them (dike-type). We found the 14-20Ma time discrepancies between mafic and silicic rocks in above both two types of syn-plutonic dikes in the Ryoke granitoids, 90-94Ma of silicic rocks and 70-75Ma of mafic rocks in zircon U-Pb ages. The time duration of 14-20Ma seems too long to imagine that these two components of the syn-plutonic dike was generated during a lifetime of a single magma chamber.

In a silicic rock of those syn-plutonic dike, we found a partly dissolved and re-grown intrastructure of a zircon grain in the CL image, with the ages of cc.70Ma in the re-grown part and cc.90Ma in the undissolved core. The mafic rocks of the syn-plutonic dike nearby gives cc.70Ma and the host Ryoke granitoids around them give 90-96Ma. So it could be interpreted that the syn-plutonic dike was formed with injection of the mafic magma at cc.70Ma into the already solidified 90-96Ma granitoids and partially melted them, which led the physical interaction of local silicic mushy melt and mafic magma. The partly dissolved and re-grown zircon described above could tell that story of forming syn-plutonic dike.

As this type of the “syn-plutonic dikes” occur widespread in a km-sized area in the Ryoke granitoids, that process may be regarded as local and partial revival of granitic magma chamber.

# Combined microspectroscopic characterization of a red-colored granite rock sample

*Katsuya Okada[1], Satoru Nakashima[1]

1. Department of Earth and Space Science, Graduate School of Science, Osaka University

Tenzan granite, Saga, Japan, has reddish color portions spreading from a grey prehnite vein over about 10 mm. However, origins of red coloration remain unclear. Combined microspectroscopic mapping have been conducted on a Tenzan granite sample by using an original visible/fluorescence/Raman microspectrometer together with a low vacuum scanning electron microscopy–energy dispersive spectrometry (SEM-EDS) without coating.

Visible darkfield reflectance spectra were converted to L*a*b* color values and Kubelka–Munk (KM) spectra. Large a* value (red) positions correspond to large band areas at 500–560 nm, possibly due to hematite-like iron oxide, while large b* value (yellow) positions to large band areas at 450–500 nm, due to epidote-like mineral. SEM-EDS analyses indicated that the reddish parts are Na and K-feldspars with low Fe contents (<0.5wt%). Raman microspectroscopy could not detect hematite-like minerals. Since some hematite-like minerals were identified by electron diffraction patterns under transmission electron microscope, they are considered to be submicron microcrystals disseminated in feldspar matrices.

The KM spectra for prehnite-like minerals show a weak broad band around 430 nm due possibly to a ligand field band of $Fe^{3+}$ without clear $Fe^{2+}$–$Fe^{3+}$ inter-valence charge transfer (IVCT) bands around 720nm. Therefore, Fe in prehnite is not considered to be present as hematite-like iron oxide, but can be mainly present as $Fe^{3+}$ replacing $Al^{3+}$ in the crystal structure.
Since determination of physicochemical states of Fe such as valence and coordination states ($Fe^{2+}$ or $Fe^{3+}$, oxide or in crystal lattice, etc.) and their distributions are extremely difficult, especially in complex colored rocks, the present combined microspectroscopic methods are useful for their nondestructive characterization.

# Crystal chemistry of synthetic mukhinite, V-analogue of clinozoisite, on the join $Ca_2Al_3Si_3O_{12}(OH)$-$Ca_2Al_2VSi_3O_{12}(OH)$

*Mariko Nagashima[1], Daisuke Nishio-Hamane[2], Nobuhiko Nakano[3], Toshisuke Kawasaki[4]

1. Graduate school of Sciences and Technology for Innovation, Yamaguchi University, 2. The institute for Solid State Physics, the University of Tokyo, 3. Department of Environmental Changes, Faculty of Social and Cultural Studies, Kyushu University, 4. Faculty of Science, Ehime University

This is the first report of the crystal structure of mukhinite, V-analogue clinozoisite, on the join $Ca_2Al_3Si_3O_{12}(OH)$-$Ca_2Al_2V^{3+}Si_3O_{12}(OH)$ synthesized at 1.5 GPa and 800 ºC (Run 20). The study was performed to clarify the distribution of $V^{3+}$ among structurally independent octahedral M1, M2 and M3 sites, and the effect of $V^{3+}$ on the crystal structure. Although epidote-supergroup minerals occur widely in low- to medium-grade metamorphic mafic rocks, and hydrothermally altered rocks, clinozoisite- and allanite-subgroup minerals rich in $V^{3+}$ are not common, and have been reported from restricted localities. Mukhinite from the Tashelginskoye iron ore deposit, southwestern Siberia, having the composition of $Ca_{2.0}(Al_{2.1}V_{0.8}Fe_{0.1})Si_{3.1}O_{12}(OH)$ has been regarded as a $V^{3+}$-analogue of clinozoisite (Shepel and Karpenko 1969). However, its crystal structure and $V^{3+}$ distribution among octahedra have not been investigated. Several syntheses and/or phase-equilibrium studies on clinozoisite-subgroup minerals have been performed. To the best of our knowledge, there has been no investigation of synthetic V-bearing epidote-supergroup minerals.

Syntheses were performed under the conditions of 1.2-1.5 GPa and 600-800 ºC, and run duration 89-261 hours. Mukhinite and $V^{3+}$-bearing clinozoisite (Czo) in all run products are associated with zoisite (Zo), and also coexist with V-bearing phases such as vanadomalayaite, goldmanite, V-oxides and unidentified Ca-Al-bearing vanadates. Czo and Zo were distinguished by using Raman spectra. As the result of submicroscopic texture observation by TEM, Zo in Run 19 product often contain Czo lamellae with several nm thickness, and they have epitaxial relationship as Zo[010]//Cz[010]. Czo and Zo in Run 20 product are generally separated, but in a few cases, they contact each other at boundaries. However, the phases in Run 20 do not have an epitaxial relationship, and Zo intergrowth with Czo is not observed. Mukhinite and $V^{3+}$-bearing clinozoisite crystallized in the Run 20 product show a compositional gap between 0.33-0.74 V atoms per formula unit (apfu), and the V content attains 1.14 apfu. The co-existence of low $V^{3+}$- and high $V^{3+}$-clinozoisites indicates the presence of a miscibility gap at 1.5 GPa and 800 ºC. Two mukhinite crystals with 0.75 and 0.83 $V^{3+}$ apfu were used for X-ray single-crystal structure analysis (hereafter, labelled as 20d and 20k). Structure refinements of the 20d and 20k crystals converged to $R_1$ values of 4.20% and 3.33%, respectively. The unit-cell parameters are $a$ = 8.8995(2), $b$ = 5.6299(1), $c$ = 10.1532(2) Å, beta = 115.327(1)º, and $V$ = 459.81(2) Å$^3$ for 20d, and $a$ = 8.8999(1), $b$ = 5.6357(1), $c$ = 10.1499(1) Å, beta = 115.306(1)º, and $V$ = 460.24(2) Å$^3$ for 20k. The resulting $V^{3+}$ occupancies among the octahedral sites of 20d and 20k are $^{M1}(Al_{0.894(6)}V_{0.106})^{M2}(Al_{0.976(6)}V_{0.024})^{M3}(V_{0.621(6)}Al_{0.379})$ and $^{M1}(Al_{0.868(4)}V_{0.132})^{M2}(Al_{0.957(4)}V_{0.043})^{M3}(V_{0.652(2)}Al_{0.348})$, respectively. Site preference of $V^{3+}$ at the octahedral sites is M3>M1>M2 as that of $Fe^{3+}$ and $Mn^{3+}$. The intracrystalline partition coefficient of $V^{3+}$ and $Al^{3+}$ between the M1 and M3 sites, $K_D = (V^{3+}/Al)^{M1}/(V^{3+}/Al)^{M3}$, is 0.07-0.08, which is greater than those of $Fe^{3+}$ and $Al^{3+}$ (0.03-0.05) and of $Mn^{3+}$ and $Al^{3+}$ (0.04-0.06). Variations of the unit-cell parameters are strongly related to the variations of the M3-O*i* and M1-O*i* distances. The unit-cell volumes of mukhinites are similar to those of $Ca_2(Al,Fe^{3+})_3Si_3O_{12}(OH)$-epidote. However, it is noticed that the *a*-dimension is longer, and the *c*-dimensions shorter. The b angles of the mukhinites are also different from those of epidotes, but similar to those of $Cr^{3+}$-clinozoisite. Although the behavior of $V^{3+}$ and its effect on the epidote-type structure are expected to be similar to those in the case of $Fe^{3+}$ due to their similar ionic radii, some structural

©2019. Japan Geoscience Union. All Right Reserved. 

variations cannot be explained only in terms of the similarity of ionic radii between $V^{3+}$ and $Fe^{3+}$.

# High temperature In-situ TEM observation of crystallization in Sakurajima volcanic glass

*Akira Miyake[1], Shota Okumura[1]

1. Department of Geology and Mineralogy, Graduate School of Science, Kyoto University

Recently, it attracts attention that the enviroment TEM (transmission electron microscope) holders using MEMS (Micro electro mechanical sysytem) tecunique, which is one of the integrated technologies of semiconductor circuit and It is possible to in-situ and nanometer-scale observe and analyze using these enviroment TEM holders, e.g., heating, biasing, gas and liquid conditions.
In the present study, in-stu heating TEM experiment was carried out to observe the crystallization in volcanic glass using in-situ heating TEM holder (Wildfire D6, DENS solutions). Sample is the volcanic glass from Sakurajima volcano.
Experiment condition is that at first heating 23 degC to 1600 degC, which shows the set value, at 1 degC/sec, nextly keeping the 1160 degC for around 24 min, and finally cooling 1160 degC to 23 degC at 1 degC/sec. Because our previous temperature calbration experiments indicated that the actual temperature had the about 200 degC lower value than the setting temperature, it is thought taht 1160 degC, the setting temperature in this study, showed about 950 degC.
Many minerals crstallized in volcanic glass were observed in the in-situ experiments, although we could not observe just crystallization from glass at first unfortunately. During keeping the 1160 degC, we could observe that mineral disappeared and re-crystallization. After cooling, we identified these minerals crystallized at high temperature, and these minerals were magnetite (Fe3O4) and clinopyroxene (space group: C2/c).

# Timing of intrusion and Sr isotopic composition of granodiorite porphyrites in the Noko Island, western part of northern Kyushu

*Masaki Yuhara[1], Yoshinobu Kawano[2], Osamu Okano[3]

1. Department of Earth System Science, Faculty of Science, Fukuoka University, 2. Department of Environment Systems, Faculty of Geo-environmental Science, Rissho University, 3. Department of Earth Sciences, Faculty of Science, Okayama University

The granodiorite porphyrite dykes are intruded into the Kitazaki Tonalite and metamorphic rocks distributed in Noko Island, western part of northern Kyushu. The petrological features of those dykes suggest that granodiorite porphyrite has been formed by mixing of tonalitic magma, which is differ from the Kitazaki Tonalite, and granitic magma (Yuhara, 2017).

The granodiorite porphyrite dyke includes lamprophyre (Yuhara et al., 2007), and the lamprophyre dyke cuts granodiorite porphyrite dyke. These occurrences imply that both dykes intruded at the same time. Ishibashi et al. (2007) reported K-Ar whole rock age of 90.7±1.2 Ma from lamprophyre dyke, and interpreted timing of intrusion. Thus, granodiorite porphyrite dykes intruded at about 90.7 Ma. Both dykes cut fine-grained granitic dykes intruded into the Kitazaki Tonalite.

Initial Sr isotopic ratios (SrI) of granodiorite porphyrites and mafic enclaves range from 0.70459 to 0.70487 and from 0.70430 to 0.70466, respectively. That of lamprophyre is 0.70414. Sr isotopic ratios calculated at 90.7 Ma of the Kitazaki Tonalite and fine-grained granites range from 0.70435 to 0.70480 and from 0.70512 to 0.70580, respectively. SrI of granodiorite porphyrites and mafic enclaves are lower than that of fine-grained granites, and in range of SrI of the Cretaceous granitic rocks in northern Kyusyu (Owada et al., 1999; Yuhara et al., 2005; Kawano and Yuhara, 2008). SrI of lamprophyre is lower than that of the Cretaceous granitic rocks in northern Kyusyu, but within that of the Shikanoshima basic rocks (Yuhara et al., 2016).

Keywords: granodiorite porphyrite, lamprophyre, Sr isotopic composition, Kitazaki Tonalite, Noko Island, Cretaceous granitic rocks in northern Kyusyu

# Petrological study of crystallization process of a composite dike in the Ryoke belt (Mie Prefecture, SW Japan)

*Ayu Yamazaki[1], Tetsuo Kawakami[1], Fumiko Higashino[2]

1. Department of Geology and Mineralogy, Graduate school of Science, Kyoto University , 2. Graduate school of Environmental Studies, Tohoku University

A composite dike with a width of about 3 m discordantly intrudes to the gneissose structure of pelitic and psammitic migmatites in Hakusan-cho, Mie Prefecture (Ryoke belt, SW Japan). This composite dike has silicic margin of about 15 cm in width and mafic rocks in its center in the form of discrete pillows of about 5-30 cm in width, representing coexistence of silicic and mafic magmas. This study aims to discuss how the composition of these magmas changed through magma mingling, magma mixing and chemical diffusion by observing microtextures indicative of magma mixing and spatial change of mineral compositions.

The silicic host rock more than 3 cm distant from the mafic pillow consists of plagioclase + biotite + quartz + K-feldspar + garnet. Silicic host rock in the vicinity of the mafic pillows shows the mineral assemblage of plagioclase + biotite + quartz ±K-feldspar with minor garnet. On the other hand, the mafic pillows mainly consist of two parts, hornblende-bearing and hornblende-free domains. The hornblende-bearing domain mainly consists of plagioclase + hornblende + biotite + quartz ±K-feldspar. The hornblende-free domain, commonly developed in between the hornblende-bearing domain and the silicic host, mainly consists of plagioclase + biotite + quartz ±K-feldspar.

Some microtextures indicative of magma mixing (e.g. acicular apatites, rapakivi feldspars, “anorthite spikes” in plagioclase) (Hibbard, 1991; Baxter and Feely, 2002) were found both from the mafic pillows and from the silicic host in the vicinity of them. Especially in felsic back veins developed in the mafic pillows, coarse-grained plagioclase shows a zonal inclusion arrangement of quartz and biotite. A number of acicular apatite crystals are included in and outside the inclusion arrangement, whereas no apatite inclusion is present inside the inclusion arrangement. This microtexture is considered as evidence of local magma mixing in felsic back veins.

When focusing on one pair of a discrete pillow and its silicic host, systematic change in mineral composition is observed in the silicic host and the mafic pillow as a distance from the mafic pillow: From the silicic host to the mafic pillow, anorthite value of fine-grained plagioclase, $Mg/(Mg+Fe_{total})$ ratio, Cl and $TiO_2$ concentrations of biotite gradually approach to the value observed in the mafic pillow. These chemical trends indicate that magma composition changed prior to the crystallization of these minerals. Observation of the sharp silicic host/mafic pillow boundary and rare occurrence of magma mixing textures both in silicic and mafic rocks suggests that chemical diffusion across the interface between the two magmas played an important role before mechanical mixing.

In a larger scale, 3 different mafic pillows in different positions of the vein (about 10 cm, 20 cm and 160 cm distant from the dike wall) show different $Mg/(Mg+Fe_{total})$ ratio of biotite and hornblende. The mafic pillow at 10 cm and that at 20 cm have similar $Mg/(Mg+Fe_{total})$ ratio of biotite and hornblende, whereas mafic pillow at 160 cm-distance has higher $Mg/(Mg+Fe_{total})$ ratio than them. This indicates the difference in the degree of chemical exchange between the silicic host and the mafic pillows as a distance from the vein wall.

# Petrography and Zircon U-Pb ages of the Ryoke Granitoids distributed in the Takanawa Peninsula, Ehime Prefecture.

*Kazuya Shimooka[1], Satoshi SAITO[1], Kenichiro Tani[2]

1. Graduate School of Science and Engineering, Ehime University, 2. Department of Geology and Paleontology, National Museum of Nature and Science

Various types of granitoids are widely distributed in the Ryoke Belt of Takanawa Peninsula, Ehime Prefecture. Based on geological and petrographic studies, Ochi (1982) has been classified the granitoids into three groups including (1) three tonalitic bodies, (2) four granodioritic bodies and (3) seven granitic bodies, and suggested that the tonalitic bodies intruded at the oldest stage, followed successively by the intrusion of the granodioritic and granitic bodies. In this study, we performed geological and petrographic investigation on the Ryoke granitoids in Takanawa Peninsula, and further obtained new zircon U-Pb ages for representative samples collected from the tonalitic, granodioritic and granitic bodies. The new zircon U-Pb ages are ca. 94 Ma for tonalite, ca. 89 Ma for granodiorite, and ca. 94 Ma for granite. The results suggest multiple intrusive activities in the study area including the older magmatism which has formed tonalites and granites at ca. 94 Ma and the younger granodiorite formation at ca. 89 Ma.

# Neoproterozoic arc magmatism and high-grade metamorphism of the basement rocks in southern Malawi

*Toshiaki Tsunogae[1], Sam Uthup[1], Mzee Wandembo Nyirongo[2], Md. Sazzadur Rahman[1], Yusuke Takamura[1], Kazuki Takahashi[1]

1. University of Tsukuba, 2. Malawi University of Science and Technology

The basement rocks in southern Malawi form part of the Mozambique Belt (or the southern Irumide Belt) that correspond a typical example of Neoproterozoic collisional orogens in southeastern Africa. The dominant lithologies in Lilongwe-Zomba-Blantyre area in southern Malawi are biotite gneiss (biotite + quartz + microcline + plagioclase), charnockite (orthopyroxene + K-feldspar + quartz + plagioclase + ilmenite + magnetite), and mafic granulite (plagioclase + clinopyroxene + garnet + calcic amphibole + quartz + orthopyroxene + ilmenite) which are intruded by syenite (K-feldspar + calcic amphibole + biotite + quartz + clinopyroxene) and granite (quartz + K-feldspar + plagioclase + biotite). Garnet in the mafic granulite is often mantled by plagioclase + orthopyroxene coronae, suggesting post-peak decompression. Phase equilibria modeling of the mafic granulite in the system NCKFMASHTO yielded the peak metamorphic condition of 800-920 °C and ~10 kbar with a clockwise *P-T* evolution. Major, minor, and REE geochemical data for selected felsic orthogneisses suggest arc-magmatic signatures of the rocks. The results of this study suggest that the orthogneisses in southern Malawi corresponds to a Neoproterozoic magmatic arc unit that was probably metamorphosed at high- to ultrahigh-temperature conditions during the latest Neoproterozoic East-African and Kuunga orogens.

# Geochemical features of Quaternary rhyolitic magma and xenolith from Hime-shima volcanic group

*Takehiro Hirayama[1], Tomoyuki Shibata[1], Masako Yoshikawa[1], Yasutaka Hayasaka[1], Keiji Takemura[2]

1. Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University, 2. Kyoto university

The Hime-shima volcanic group is composed of seven volcanoes; Oomi, Yahazudake, Kane, Ukisu, Shiroyama, Darumayama and Inazumi volcano, and is located offing of Kunisaki Peninsula, western Seto Inland Sea. The Philippine Sea Plate (PSP) is subducting under this island. It is thought that the volcanic rocks of the Himeshima volcanic groups were formed by magma mixing of dacite magma and rhyolitic magma, on the bases of disequilibrium amphibole in rhyolite and the linear trends of major element contents with the increasing in $SiO_2$ contents. According to their high Sr/Y ratios (some 100), low Y contents (< 14.3 ppm) and low $^{87}Sr/^{86}Sr$ rations (0.7037), the source material for dacitic endmember was inferred as partial melt of subducted PSP (Shibata et al. 2014). On the other hand, contributions of crustal materials are suggested from the existence of crustal xenoliths in the dacite (Shibata et al., 2014, 2016) and residual material of metapelite in the rhyolite (Hirayama et al., 2018). However, quantitative discussion for genesis of rhyolitic endmember have not been made. Therefore, we determined trace element compositions of rhyolites and major and trace element compositions of the crustal xenoliths in order to discuss the genesis of rhyolite magma. Additionally, we determined the U-Pb zircon age of the xenoliths to know their origin.

Trace element Primitive Mantle (PM)-normalized patterns of rhyolite from Hime-shima volcanic group is characterized by negative Sr, Zr and Eu anomalies and liner trend of Nb. According to their relationship between Sr/Y ratio and Y content, rhyolite from Hime-shima volcanic group have Sr/Y ratio ( < 10) and Y content ( < 15 ppm). Rhyolite from Hime-shima volcanic group cannot be classified as adakite and island-arc andesite-dacite-rhyolite. Geochemical features of the rhyolite have high Rb/Sr ratio (> 1.0), low Zr content (30 ppm) and high Nb content (15 ppm).

Petrography of xenoliths from Hime-shima volcanic group is similar to that of basement rocks of Ryoke metamorphic rocks and granites from Kunisaki peninsula. U-Pb ages of zircon grains from metapelite are ca. 100 –110 Ma. These ages show agreement with ages of U-Pb zircon in metamorphic rocks from Ryoke metamorphic belt. Geochemical features of these xenoliths have wide Zr contents (20 –100 ppm), low Nb contents ( < 10 ppm), high Y contents (> 15 ppm) and low Sr/Y ratios (< 40 ppm), although the xenolith of basaltic andesite shows high Sr/Y ratio of 90. As results of comparing the geochemical compositions between rhyolite and xenoliths from Hime-shima volcanic group, we think that there is no genetic relationship between the xenoliths and rhyolite.

We examined the genesis of xenoliths from Hime-shima volcanic group are from rocks composed with Ryoke metamorphic belt, because Ryoke metamorphic belt, which is composed of metamorphic rocks, diorites and granites, is under Hime-shima. We compared geochemical features of granites from Ryoke metamorphic belt (Ryoke granites, Yuhara, 1994) with rhyolites from Hime-shima. Trace element PM-normalized patterns of the granites have similar to those of rhyolite from Hime-shima volcanic group, which are characterized by negative Sr, Zr and Eu anomalies and liner trend of Nb. Geochemical compositions of the Ryoke granites have high Rb/Sr ratios (0.5 - 1.5), low Sr/Y ratios (10 - 20), wide

©2019. Japan Geoscience Union. All Right Reserved. 

composition range of Y contents (12 - 35 ppm) high Nb concentrations (10 - 20 ppm) and wide composition range of Zr contents (50 - 250 ppm). The chemical features of the rhyolite from Hime-shima volcanic group have high Nb (> 15 ppm), high Rb/Sr ratio (> 1.0), low Y content (< 10 ppm), low Sr/Y ratio (< 10) and low Zr content (< 50 ppm). These chemical features share rhyolites in Hime-shima volcanic group with the Ryoke granites. Therefore, it is interpreted that the rhyolites from Hime-shima volcanic group was derived from crustal material, which compositions is similar to the Ryoke granites.

# Petrological study on the intrusive contact of a Setouchi volcanic rock dike in the Nakajima Island, Ehime Prefecture

*Taiki Omori[1], Satoshi SAITO[2]

1. Department of Earth Science, Faculty of Science, Ehime University , 2. Department of Earth Science, Graduate Schoole of Science, Ehime University

We performed a detailed petrological study on the intrusive contact between a Setouchi andesitic dike and host Ryoke granitoids occurring in the Nakajima Island, Ehime Prefecture. At the intrusive contact, the andesite contains many fragments of host granitoids. The bulk $SiO_2$ contents of the marginal andesite at the intrusive contact are markedly higher than those of internal domain implying the mixing between the andesite intrusion and the host granitoids. Other bulk chemical compositions such as MgO, CaO, $Na_2O$, $K_2O$, Cr and Zr also imply mixing of the host granitoids into the andesite intrusion at the intrusive contact. However, the $Al_2O_3$ contents of the marginal andesite can not be explained by bulk mixing of the host granitoids and the andesite intrusion because the $Al_2O_3$ contents of the marginal andesite are higher than those of the host granites and internal domain of the andesite intrusion. Assuming that the marginal andesite with chilled margin texture retain original compositions of intrusive magma, we tested the major element mass-balance modeling to explain chemical compositions of internal domain of the andesite intrusion. The modeling reproduced the major element compositions of internal andesites by adding ~7 % of host granite components and ~12 % of mafic phenocryst minerals into the marginal andesite.

# Fundamental evaluation for making simulated sea bed floc

*AIKO HAYAUCHI[1], Daisuke Sasakura[1], Hisato Yasuda[2], Shinya Nakamura[3], Sho Kimura[3], Shohei Noda[4]

1. Malvern Panalytical division of Spectris Co., Ltd, 2. Kochi University, 3. UNIVERSITY OF THE RYUKYU, 4. TOKYO UNIVESITY OF SCIENCE

1. Introduction
Flock is an aggregate in which fine particles such as clay and silt gathered loosely. It exists in the seabed for example. Research on flocs has been carried out on site and/or real samples, and many are observational approaches. There we tried analysis from a micro viewpoint for making floc simulation samples and reported about relationship between sample particle feature and how ease to be floc last year.
But we didn’ t care flocculant concentration in that report. Flocculant concentration must be important factor to discuss with making a simulated floc. Therefore we focused on influence of flocculant concentration to floc characteristic in this study.

2. Material and method
Kaolin as a model sample and Eb-a(Hayashi Co., Ltd.) as a flocculant for simulated floc preparation were used. Eb-a water solution concentration was 0%, 0.1%, 0.01%, 0.01% and 0.0001%. 0.05% sample water solution was prepared with each Eb-a water solution.
One of famous parameter of solution stability evaluation is zeta potential. Zeta potential was measured with Zetasizer nano ZSP (Malvern Instruments). Particle size distribution (incl. floc size distribution) was measured with Mastersizer 3000 (Malvern Instruments) which is laser diffraction system. Mastersizer 3000 is circulation system. In other hand, Morphologi 4 (Malvern instruments) which is a statistical particle image analysis system was also used for measuring particle size distribution. Morphologi 4 is not circulation system, so we can know original floc size distribution and we can see floc as well because Morphologi 4 is imaging system.

3. Result
Zeta potential in each flocculant concentration is shown in Table 1. In general, the system is stable when the zeta potential absolute value is over 20mV. Zeta potential in Eb-a concentration 0%, 0.001% and 0.0001% were around -60mV. It means that these systems are very stable and it indicates that it is difficult to occur flocculation in these situations. In the other hand, zeta potential absolute value in Eb-a concentration 0.01%, 0.1% and 1% were under 10mV, so that these indicate easy to occur flocculation.
The floc size measured by Mastersizer3000 is shown in Table 2. At The size was measured with 1500rpm/stirring speed at first, then was measured with change to 2500rpm/stirring speed. Comparing each Dv90 on 1500rpm, higher Eb-a concentration showed bigger floc size. In terms of toughness of floc, comparing the ratio of Dv90 on 1500rpm to Dv90 on 2500rpm was 1% Eb-a (0.54), 0.1% Eb-a (65%) and 0.01% Eb-a (75%). This is a result indicating that 0.01% Eb - a was the least fragile among these three samples. Also interestingly, Dv10 on 2500rpm was 0.01% Eb-a (18um), 0.1% Eb-a (9.6um) and 1% Eb-a (5.1um).
The floc size was measured by Morphlogi 4 as well. These data will discuss indetail on that day.

©2019. Japan Geoscience Union. All Right Reserved. 

4. Conclusions

The results show flocculation concentration is one of important factor to make simulated floc. We will continue to study to make clear which factor important to make simulated floc.

Keywords: floc, flocculation, zeta potential, particle size distribution, imaging

| Eb-a(%) | 0 | 0.0001 | 0.001 | 0.01 | 0.1 | 1 |
|---|---|---|---|---|---|---|
| Zeta Potential (mV) | -58.0 | -59.4 | -57.9 | -9.62 | -1.03 | 0.119 |

Table 1: Zeta potential in each flocculant concentration

| Eb-a(%) | stirre speed | Dv10(μm) | Dv50(μm) | Dv90(μm) |
|---|---|---|---|---|
| 1 | 1500rpm | 14.6 | 62.5 | 155 |
| 1 | 2500rpm | 5.06 | 25.0 | 83.3 |
| 0.1 | 1500rpm | 12.4 | 42.4 | 106 |

# Petrology of the Morobe Granodiorite in the Kuper Range, Morobe Province, Papua New Guinea

Angela Lynett Bokuik[1], *Takashi Hoshide[1]

1. Faculty of International Resource Sciences, Akita University

The Morobe Granodiorite is a composite batholith comprising of monzodiorite, monzonite, quartz monzonite, granite, granodiorite, diorite and gabbro. Mafic Microgranular Enclaves (MME) are abundant in the intrusion. The mineral assemblage of the Morobe Granodiorite comprises of hornblende, biotite, plagioclase, alkali feldspar and quartz with accessory minerals of titanite, apatite, magnetite and ilmenite. The rocks have a variety of texture, such as poikilitic, cumulous and porphyritic. The MME also has a similar mineral assemblage and texture to its host however, it is abundant in mafic minerals hornblende and biotite.

Mineral compositions for amphibole of the granodiorite and MMEs are similar, implying similar magma environment. By the iteration calculation using a geobarometer (Anderson and Smith, 1995) and a geothermometer (Blundy and Holland, 1990), we estimated the crystallization temperature of 597-766˚C and the maximum crystallization pressure of 3.6 kbar. Crystallization conditions from the MME yield higher temperature (812˚C) and pressure (5.3 kbar) to its host, which implies MMEs represent the deeper hotter parts of the same magma chamber of which the MME and host formed.

The geochemical signature of the Morobe Granodiorite represent calc-alkaline and metaluminous nature typical of I-type granites. The variations of major elements in the Harker diagram can be best explained by fractionation mainly of hornblende and plagioclase. The interpretation is consistent with the textural variations of the rocks. Low $FeO^T/(FeO^T + MgO)$ ratios and high Mg-number for granodioritic rocks suggest magma originated from partial melting of the lower mafic crust. This magma was contaminated upon ascent wall rock assimilations of the host rock Owen Stanley Metamorphic. This can be seen as $Na_2O$ vs $SiO_2$ and $K_2O$ vs $SiO_2$ variation diagrams.

Keywords: Morobe Granodiorite, mafic microgranular enclaves, fractional crystallization

# Sr–Nd isotopic compositions of the San-yo Belt, Southwest Japan: Implications for the Cretaceous enriched mantle

*Shogo Kodama[1], Masaaki Owada[1], Teruyoshi Imaoka[1], Atsushi Kamei[2]

1. Yamaguchi University, 2. Shimane University

Cretaceous to Paleogene igneous rocks are widely exposed in the Inner Zone of Southwest Japan where the granitic rocks have been divided into the San-in, San-yo, and Ryoke Belts on the basis of their lithologies, geochemical compositions, magnetic susceptibility and associated ore deposits (Ishihara, 1971). The San-yo and Ryoke Belts belong to the ilmenite-series granitic rocks, but the San-in Belt corresponds to the magnetite-series ones (Ishihara, 1977). According to Sr isotopic compositions, Kagami et al. (1992) classified these granitic rocks into the North Zone , South Zone, and Transitional Zone situated between the North and South Zones. The granitic rocks from the Transitional and South Zones show negative eNdI values (Kagami et al., 1992); however, the isotopic compositions of granitic rocks would serve only as proof for the bulk of the continental crust (Jahn, 2010). This means that those data are unlikely to provide us with mantle signatures. Imaoka et al. (2014) described the Early Cretaceous lamprophyer (c. 105 Ma) from the Kyoto district. The Kyoto lamprophyres geochemically show enriched signatures with positive and negative eNdI values corrected to 105 Ma. In consideration of the geochemical signatures and tectonic setting, Imaoka et al. (2014) concluded that the Kyoto lamprophyre was derived from heterogenous enriched mantle created by the subduction of the oceanic crust. Aspects of the existence of enriched mantle, however, are still unclear, such as in regard to its regional extension and duration for the Cretaceous magma activities of the Inner Zone of Southwest Japan.

Late Cretaceous igneous rocks are widely exposed in the western part of Honshu Island. These igneous rocks consist mainly of granitic rocks and felsic to intermediate volcanic rocks. We newly found a small gabbro stock (c. 1 km in diameter) with relatively primitive compositions in the central part of Yamaguchi Prefecture. The gabbro stock accompanies the Susuma-Nagaho granodiorite as coeval intrusive rocks. Therefore, we refer to both granodiorite and gabbro as the Susuma-Nagaho Plutonic Complex (SNPC, hereafter). The gabbro can be subdivided into fine-grained gabbro (Fn-gabbro) and coarse-grained cumulus gabbro (Co-gabbro). The Fn-gabbro has a high Mg-number similar to primitive basalt with negative eNd values corrected to 92 Ma although Cr and Ni contents are relatively low, which indicates that the basaltic magma may have been derived from enriched mantle. In consideration of the geochemical signatures including the Sr and Nd isotopic compositions, the enriched mantle characterized by negative eNd isotopic values would have existed underneath the Inner Zone of Southwest Japan during the Cretaceous.

# Lithological variation of massive serpentinites in marginal zone of serpentinite body in Kamuikotan belt, Hokkaido, Japan: Analysis of advanced-boring cores for tunnel construction

*Shusaku Yamazaki[1], Kenji Okazaki[1], Toshiyuki Kurahashi[1]

1. Civil Engineering Research Institute for Cold Region, Public Works Research Institute, National Research and Development Agancy

Serpentinite body associated with high-pressure metamorphic rocks such as Kamuikotan belt in Hokkaido is very important as a key to understand a deep subduction process in subduction zone. In the field of marine geology, recent advances of sampling and analytical techniques contribute to understand of serpentinization process of abyssal peridotites. On the other hand, terrestrial serpentinite body still remain a lot of unexplained processes such as variation of serpentinization, uplifting mechanism and formation of internal structure, because of poor sampling by its fragile and fragmented rock conditions on earth surface conditions. There are over 30 tunnel construction cases drilling into a serpentinite body in Japan. Geoengineering investigation including description of tunnel drilling face, measurement of physical properties and making cross section of the tunnel route were operated in each tunnel. However, a detailed geological information such as types of source rock and degree and aspect of serpentinization has been less understood from the construction records. In addition, even in recent yeses with developed drilling technology, excavation of serpentinites often encounters serious trouble such as tunnel collapse. It indicates that more detailed classification of serpentinites for tunnel construction is necessary using recent geological insights and technique.

The authors focus on reconstruction of the tunnel geological section and the detailed classification of serpentinites of a tunnel with 1241 m into Takadomari serpentinite body of Horokanai area in Kamuikotan belt in Hokkaido, Japan. In this study, massive serpentinites, which were sampled from advanced-boring core at 50 to 100 m intervals along tunnel route, were conduct to description of core and thin section and XRD analysis to investigate lithological variation around the marginal zone of the serpentinite body contact with Kamuikotan metamorphic rocks.

The research by Igarashi et al. (1985) revealed that serpentinites of the Takadomari body were classified into massive, foliated and clay serpentinites and their source rocks were mostly harzburgite and partly dunite as band in harzburgite. There are large number of “micordiorite” and micro gabbro dikes in the body. As a result of this study, advanced-boring cores from the tunnel also have same variation of massive, foliated and clay serpentinites. The source rock types of massive serpentinites from the marginal zone are also mainly harzburgite with minor band of dunite. All samples were completely serpentinized and only Cr-spinel is survived as primary mineral. Original texture of the massive serpentinite is classified into dunitic texture without pyroxenes, harzburgitic texture with orthopyroxene, cumulate texture with euhedral orthopyroxene and foliation of spinel allay. Serpentine types in the massive serpentinites are antigorite that replaced olivine and orthopyroxene and lately formed asbestos chrysotile vein. Minor amount of brucite also appears through the tunnel. As a notable feature in the marginal zone of the body, three zones of difference serpentinization were observed. In the center of the tunnel, the serpentinites well remain the original harzburgitic and dunitic texture. In the west side with amphibolites, the massive serpentinites contain magnesite veins and patches as metasomatism. In the east side with the contact to greenschists, the original texture is completely disappeared with greenish large antigorite and massive of

©2019. Japan Geoscience Union. All Right Reserved. 

grains of magnetite with brucite. The difference of texture and mineralogy of the serpentinites in this tunnel could possibly be explained that the serpentinization process in subduction zone is difference in the both sides of marginal zone in the association with the types of the Kamuikotan metamorphic rocks.

[SCG52-P13] Lithological variation of massive serpentinites in marginal zone of serpentinite body in Kamuikotan belt, Hokkaido, Japan: Analysis of advanced-boring cores for tunnel construction

*Shusaku Yamazaki[1], Kenji Okazaki[1], Toshiyuki Kurahashi[1] (1.Civil Engineering Research Institute for Cold Region, Public Works Research Institute, National Research and Development Agency)

# Combined microspectroscopic characterization of a red-colored granite rock sample

*Katsuya Okada[1], Satoru Nakashima[1]

1. Department of Earth and Space Science, Graduate School of Science, Osaka University

Tenzan granite, Saga, Japan, has reddish color portions spreading from a grey prehnite vein over about 10 mm. However, origins of red coloration remain unclear. Combined microspectroscopic mapping have been conducted on a Tenzan granite sample by using an original visible/fluorescence/Raman microspectrometer together with a low vacuum scanning electron microscopy–energy dispersive spectrometry (SEM-EDS) without coating.

Visible darkfield reflectance spectra were converted to L*a*b* color values and Kubelka–Munk (KM) spectra. Large a* value (red) positions correspond to large band areas at 500–560 nm, possibly due to hematite-like iron oxide, while large b* value (yellow) positions to large band areas at 450–500 nm, due to epidote-like mineral. SEM-EDS analyses indicated that the reddish parts are Na and K-feldspars with low Fe contents (<0.5wt%). Raman microspectroscopy could not detect hematite-like minerals. Since some hematite-like minerals were identified by electron diffraction patterns under transmission electron microscope, they are considered to be submicron microcrystals disseminated in feldspar matrices.

The KM spectra for prehnite-like minerals show a weak broad band around 430 nm due possibly to a ligand field band of $Fe^{3+}$ without clear $Fe^{2+}$–$Fe^{3+}$ inter-valence charge transfer (IVCT) bands around 720nm. Therefore, Fe in prehnite is not considered to be present as hematite-like iron oxide, but can be mainly present as $Fe^{3+}$ replacing $Al^{3+}$ in the crystal structure.
Since determination of physicochemical states of Fe such as valence and coordination states ($Fe^{2+}$ or $Fe^{3+}$, oxide or in crystal lattice, etc.) and their distributions are extremely difficult, especially in complex colored rocks, the present combined microspectroscopic methods are useful for their nondestructive characterization.

# Crystal chemistry of synthetic mukhinite, V-analogue of clinozoisite, on the join $Ca_2Al_3Si_3O_{12}(OH)$-$Ca_2Al_2VSi_3O_{12}(OH)$

*Mariko Nagashima[1], Daisuke Nishio-Hamane[2], Nobuhiko Nakano[3], Toshisuke Kawasaki[4]

1. Graduate school of Sciences and Technology for Innovation, Yamaguchi University, 2. The institute for Solid State Physics, the University of Tokyo, 3. Department of Environmental Changes, Faculty of Social and Cultural Studies, Kyushu University, 4. Faculty of Science, Ehime University

This is the first report of the crystal structure of mukhinite, V-analogue clinozoisite, on the join $Ca_2Al_3Si_3O_{12}(OH)$-$Ca_2Al_2V^{3+}Si_3O_{12}(OH)$ synthesized at 1.5 GPa and 800 ºC (Run 20). The study was performed to clarify the distribution of $V^{3+}$ among structurally independent octahedral M1, M2 and M3 sites, and the effect of $V^{3+}$ on the crystal structure. Although epidote-supergroup minerals occur widely in low- to medium-grade metamorphic mafic rocks, and hydrothermally altered rocks, clinozoisite- and allanite-subgroup minerals rich in $V^{3+}$ are not common, and have been reported from restricted localities. Mukhinite from the Tashelginskoye iron ore deposit, southwestern Siberia, having the composition of $Ca_{2.0}(Al_{2.1}V_{0.8}Fe_{0.1})Si_{3.1}O_{12}(OH)$ has been regarded as a $V^{3+}$-analogue of clinozoisite (Shepel and Karpenko 1969). However, its crystal structure and $V^{3+}$ distribution among octahedra have not been investigated. Several syntheses and/or phase-equilibrium studies on clinozoisite-subgroup minerals have been performed. To the best of our knowledge, there has been no investigation of synthetic V-bearing epidote-supergroup minerals.

Syntheses were performed under the conditions of 1.2-1.5 GPa and 600-800 ºC, and run duration 89-261 hours. Mukhinite and $V^{3+}$-bearing clinozoisite (Czo) in all run products are associated with zoisite (Zo), and also coexist with V-bearing phases such as vanadomalayaite, goldmanite, V-oxides and unidentified Ca-Al-bearing vanadates. Czo and Zo were distinguished by using Raman spectra. As the result of submicroscopic texture observation by TEM, Zo in Run 19 product often contain Czo lamellae with several nm thickness, and they have epitaxial relationship as Zo[010]//Cz[010]. Czo and Zo in Run 20 product are generally separated, but in a few cases, they contact each other at boundaries. However, the phases in Run 20 do not have an epitaxial relationship, and Zo intergrowth with Czo is not observed. Mukhinite and $V^{3+}$-bearing clinozoisite crystallized in the Run 20 product show a compositional gap between 0.33-0.74 V atoms per formula unit (apfu), and the V content attains 1.14 apfu. The co-existence of low $V^{3+}$- and high $V^{3+}$-clinozoisites indicates the presence of a miscibility gap at 1.5 GPa and 800 ºC. Two mukhinite crystals with 0.75 and 0.83 $V^{3+}$ apfu were used for X-ray single-crystal structure analysis (hereafter, labelled as 20d and 20k). Structure refinements of the 20d and 20k crystals converged to $R_1$ values of 4.20% and 3.33%, respectively. The unit-cell parameters are $a$ = 8.8995(2), $b$ = 5.6299(1), $c$ = 10.1532(2) Å, beta = 115.327(1)º, and $V$ = 459.81(2) Å$^3$ for 20d, and $a$ = 8.8999(1), $b$ = 5.6357(1), $c$ = 10.1499(1) Å, beta = 115.306(1)º, and $V$ = 460.24(2) Å$^3$ for 20k. The resulting $V^{3+}$ occupancies among the octahedral sites of 20d and 20k are $^{M1}(Al_{0.894(6)}V_{0.106})^{M2}(Al_{0.976(6)}V_{0.024})^{M3}(V_{0.621(6)}Al_{0.379})$ and $^{M1}(Al_{0.868(4)}V_{0.132})^{M2}(Al_{0.957(4)}V_{0.043})^{M3}(V_{0.652(2)}Al_{0.348})$, respectively. Site preference of $V^{3+}$ at the octahedral sites is M3>M1>M2 as that of $Fe^{3+}$ and $Mn^{3+}$. The intracrystalline partition coefficient of $V^{3+}$ and $Al^{3+}$ between the M1 and M3 sites, $K_D = (V^{3+}/Al)^{M1}/(V^{3+}/Al)^{M3}$, is 0.07-0.08, which is greater than those of $Fe^{3+}$ and $Al^{3+}$ (0.03-0.05) and of $Mn^{3+}$ and $Al^{3+}$ (0.04-0.06). Variations of the unit-cell parameters are strongly related to the variations of the M3-O*i* and M1-O*i* distances. The unit-cell volumes of mukhinites are similar to those of $Ca_2(Al,Fe^{3+})_3Si_3O_{12}(OH)$-epidote. However, it is noticed that the *a*-dimension is longer, and the *c*-dimensions shorter. The b angles of the mukhinites are also different from those of epidotes, but similar to those of $Cr^{3+}$-clinozoisite. Although the behavior of $V^{3+}$ and its effect on the epidote-type structure are expected to be similar to those in the case of $Fe^{3+}$ due to their similar ionic radii, some structural

©2019. Japan Geoscience Union. All Right Reserved. 

variations cannot be explained only in terms of the similarity of ionic radii between $V^{3+}$ and $Fe^{3+}$.

# High temperature In-situ TEM observation of crystallization in Sakurajima volcanic glass

*Akira Miyake[1], Shota Okumura[1]

1. Department of Geology and Mineralogy, Graduate School of Science, Kyoto University

Recently, it attracts attention that the enviroment TEM (transmission electron microscope) holders using MEMS (Micro electro mechanical sysytem) tecunique, which is one of the integrated technologies of semiconductor circuit and It is possible to in-situ and nanometer-scale observe and analyze using these enviroment TEM holders, e.g., heating, biasing, gas and liquid conditions.
In the present study, in-stu heating TEM experiment was carried out to observe the crystallization in volcanic glass using in-situ heating TEM holder (Wildfire D6, DENS solutions). Sample is the volcanic glass from Sakurajima volcano.
Experiment condition is that at first heating 23 degC to 1600 degC, which shows the set value, at 1 degC/sec, nextly keeping the 1160 degC for around 24 min, and finally cooling 1160 degC to 23 degC at 1 degC/sec. Because our previous temperature calbration experiments indicated that the actual temperature had the about 200 degC lower value than the setting temperature, it is thought taht 1160 degC, the setting temperature in this study, showed about 950 degC.
Many minerals crstallized in volcanic glass were observed in the in-situ experiments, although we could not observe just crystallization from glass at first unfortunately. During keeping the 1160 degC, we could observe that mineral disappeared and re-crystallization. After cooling, we identified these minerals crystallized at high temperature, and these minerals were magnetite (Fe3O4) and clinopyroxene (space group: C2/c).

# Timing of intrusion and Sr isotopic composition of granodiorite porphyrites in the Noko Island, western part of northern Kyushu

*Masaki Yuhara[1], Yoshinobu Kawano[2], Osamu Okano[3]

1. Department of Earth System Science, Faculty of Science, Fukuoka University, 2. Department of Environment Systems, Faculty of Geo-environmental Science, Rissho University, 3. Department of Earth Sciences, Faculty of Science, Okayama University

The granodiorite porphyrite dykes are intruded into the Kitazaki Tonalite and metamorphic rocks distributed in Noko Island, western part of northern Kyushu. The petrological features of those dykes suggest that granodiorite porphyrite has been formed by mixing of tonalitic magma, which is differ from the Kitazaki Tonalite, and granitic magma (Yuhara, 2017).

The granodiorite porphyrite dyke includes lamprophyre (Yuhara et al., 2007), and the lamprophyre dyke cuts granodiorite porphyrite dyke. These occurrences imply that both dykes intruded at the same time. Ishibashi et al. (2007) reported K-Ar whole rock age of 90.7±1.2 Ma from lamprophyre dyke, and interpreted timing of intrusion. Thus, granodiorite porphyrite dykes intruded at about 90.7 Ma. Both dykes cut fine-grained granitic dykes intruded into the Kitazaki Tonalite.

Initial Sr isotopic ratios (SrI) of granodiorite porphyrites and mafic enclaves range from 0.70459 to 0.70487 and from 0.70430 to 0.70466, respectively. That of lamprophyre is 0.70414. Sr isotopic ratios calculated at 90.7 Ma of the Kitazaki Tonalite and fine-grained granites range from 0.70435 to 0.70480 and from 0.70512 to 0.70580, respectively. SrI of granodiorite porphyrites and mafic enclaves are lower than that of fine-grained granites, and in range of SrI of the Cretaceous granitic rocks in northern Kyusyu (Owada et al., 1999; Yuhara et al., 2005; Kawano and Yuhara, 2008). SrI of lamprophyre is lower than that of the Cretaceous granitic rocks in northern Kyusyu, but within that of the Shikanoshima basic rocks (Yuhara et al., 2016).

Keywords: granodiorite porphyrite, lamprophyre, Sr isotopic composition, Kitazaki Tonalite, Noko Island, Cretaceous granitic rocks in northern Kyusyu

# Petrological study of crystallization process of a composite dike in the Ryoke belt (Mie Prefecture, SW Japan)

*Ayu Yamazaki[1], Tetsuo Kawakami[1], Fumiko Higashino[2]

1. Department of Geology and Mineralogy, Graduate school of Science, Kyoto University , 2. Graduate school of Environmental Studies, Tohoku University

A composite dike with a width of about 3 m discordantly intrudes to the gneissose structure of pelitic and psammitic migmatites in Hakusan-cho, Mie Prefecture (Ryoke belt, SW Japan). This composite dike has silicic margin of about 15 cm in width and mafic rocks in its center in the form of discrete pillows of about 5-30 cm in width, representing coexistence of silicic and mafic magmas. This study aims to discuss how the composition of these magmas changed through magma mingling, magma mixing and chemical diffusion by observing microtextures indicative of magma mixing and spatial change of mineral compositions.

The silicic host rock more than 3 cm distant from the mafic pillow consists of plagioclase + biotite + quartz + K-feldspar + garnet. Silicic host rock in the vicinity of the mafic pillows shows the mineral assemblage of plagioclase + biotite + quartz ±K-feldspar with minor garnet. On the other hand, the mafic pillows mainly consist of two parts, hornblende-bearing and hornblende-free domains. The hornblende-bearing domain mainly consists of plagioclase + hornblende + biotite + quartz ±K-feldspar. The hornblende-free domain, commonly developed in between the hornblende-bearing domain and the silicic host, mainly consists of plagioclase + biotite + quartz ±K-feldspar.

Some microtextures indicative of magma mixing (e.g. acicular apatites, rapakivi feldspars, “anorthite spikes” in plagioclase) (Hibbard, 1991; Baxter and Feely, 2002) were found both from the mafic pillows and from the silicic host in the vicinity of them. Especially in felsic back veins developed in the mafic pillows, coarse-grained plagioclase shows a zonal inclusion arrangement of quartz and biotite. A number of acicular apatite crystals are included in and outside the inclusion arrangement, whereas no apatite inclusion is present inside the inclusion arrangement. This microtexture is considered as evidence of local magma mixing in felsic back veins.

When focusing on one pair of a discrete pillow and its silicic host, systematic change in mineral composition is observed in the silicic host and the mafic pillow as a distance from the mafic pillow: From the silicic host to the mafic pillow, anorthite value of fine-grained plagioclase, $Mg/(Mg+Fe_{total})$ ratio, Cl and $TiO_2$ concentrations of biotite gradually approach to the value observed in the mafic pillow. These chemical trends indicate that magma composition changed prior to the crystallization of these minerals. Observation of the sharp silicic host/mafic pillow boundary and rare occurrence of magma mixing textures both in silicic and mafic rocks suggests that chemical diffusion across the interface between the two magmas played an important role before mechanical mixing.

In a larger scale, 3 different mafic pillows in different positions of the vein (about 10 cm, 20 cm and 160 cm distant from the dike wall) show different $Mg/(Mg+Fe_{total})$ ratio of biotite and hornblende. The mafic pillow at 10 cm and that at 20 cm have similar $Mg/(Mg+Fe_{total})$ ratio of biotite and hornblende, whereas mafic pillow at 160 cm-distance has higher $Mg/(Mg+Fe_{total})$ ratio than them. This indicates the difference in the degree of chemical exchange between the silicic host and the mafic pillows as a distance from the vein wall.

# Petrography and Zircon U-Pb ages of the Ryoke Granitoids distributed in the Takanawa Peninsula, Ehime Prefecture.

*Kazuya Shimooka[1], Satoshi SAITO[1], Kenichiro Tani[2]

1. Graduate School of Science and Engineering, Ehime University, 2. Department of Geology and Paleontology, National Museum of Nature and Science

Various types of granitoids are widely distributed in the Ryoke Belt of Takanawa Peninsula, Ehime Prefecture. Based on geological and petrographic studies, Ochi (1982) has been classified the granitoids into three groups including (1) three tonalitic bodies, (2) four granodioritic bodies and (3) seven granitic bodies, and suggested that the tonalitic bodies intruded at the oldest stage, followed successively by the intrusion of the granodioritic and granitic bodies. In this study, we performed geological and petrographic investigation on the Ryoke granitoids in Takanawa Peninsula, and further obtained new zircon U-Pb ages for representative samples collected from the tonalitic, granodioritic and granitic bodies. The new zircon U-Pb ages are ca. 94 Ma for tonalite, ca. 89 Ma for granodiorite, and ca. 94 Ma for granite. The results suggest multiple intrusive activities in the study area including the older magmatism which has formed tonalites and granites at ca. 94 Ma and the younger granodiorite formation at ca. 89 Ma.

# Neoproterozoic arc magmatism and high-grade metamorphism of the basement rocks in southern Malawi

*Toshiaki Tsunogae[1], Sam Uthup[1], Mzee Wandembo Nyirongo[2], Md. Sazzadur Rahman[1], Yusuke Takamura[1], Kazuki Takahashi[1]

1. University of Tsukuba, 2. Malawi University of Science and Technology

The basement rocks in southern Malawi form part of the Mozambique Belt (or the southern Irumide Belt) that correspond a typical example of Neoproterozoic collisional orogens in southeastern Africa. The dominant lithologies in Lilongwe-Zomba-Blantyre area in southern Malawi are biotite gneiss (biotite + quartz + microcline + plagioclase), charnockite (orthopyroxene + K-feldspar + quartz + plagioclase + ilmenite + magnetite), and mafic granulite (plagioclase + clinopyroxene + garnet + calcic amphibole + quartz + orthopyroxene + ilmenite) which are intruded by syenite (K-feldspar + calcic amphibole + biotite + quartz + clinopyroxene) and granite (quartz + K-feldspar + plagioclase + biotite). Garnet in the mafic granulite is often mantled by plagioclase + orthopyroxene coronae, suggesting post-peak decompression. Phase equilibria modeling of the mafic granulite in the system NCKFMASHTO yielded the peak metamorphic condition of 800-920 °C and ~10 kbar with a clockwise *P-T* evolution. Major, minor, and REE geochemical data for selected felsic orthogneisses suggest arc-magmatic signatures of the rocks. The results of this study suggest that the orthogneisses in southern Malawi corresponds to a Neoproterozoic magmatic arc unit that was probably metamorphosed at high- to ultrahigh-temperature conditions during the latest Neoproterozoic East-African and Kuunga orogens.

# Geochemical features of Quaternary rhyolitic magma and xenolith from Hime-shima volcanic group

*Takehiro Hirayama[1], Tomoyuki Shibata[1], Masako Yoshikawa[1], Yasutaka Hayasaka[1], Keiji Takemura[2]

1. Department of Earth and Planetary Systems Science, Graduate School of Science, Hiroshima University, 2. Kyoto university

The Hime-shima volcanic group is composed of seven volcanoes; Oomi, Yahazudake, Kane, Ukisu, Shiroyama, Darumayama and Inazumi volcano, and is located offing of Kunisaki Peninsula, western Seto Inland Sea. The Philippine Sea Plate (PSP) is subducting under this island. It is thought that the volcanic rocks of the Himeshima volcanic groups were formed by magma mixing of dacite magma and rhyolitic magma, on the bases of disequilibrium amphibole in rhyolite and the linear trends of major element contents with the increasing in $SiO_2$ contents. According to their high Sr/Y ratios (some 100), low Y contents (< 14.3 ppm) and low $^{87}Sr/^{86}Sr$ rations (0.7037), the source material for dacitic endmember was inferred as partial melt of subducted PSP (Shibata et al. 2014). On the other hand, contributions of crustal materials are suggested from the existence of crustal xenoliths in the dacite (Shibata et al., 2014, 2016) and residual material of metapelite in the rhyolite (Hirayama et al., 2018). However, quantitative discussion for genesis of rhyolitic endmember have not been made. Therefore, we determined trace element compositions of rhyolites and major and trace element compositions of the crustal xenoliths in order to discuss the genesis of rhyolite magma. Additionally, we determined the U-Pb zircon age of the xenoliths to know their origin.

Trace element Primitive Mantle (PM)-normalized patterns of rhyolite from Hime-shima volcanic group is characterized by negative Sr, Zr and Eu anomalies and liner trend of Nb. According to their relationship between Sr/Y ratio and Y content, rhyolite from Hime-shima volcanic group have Sr/Y ratio ( < 10) and Y content ( < 15 ppm). Rhyolite from Hime-shima volcanic group cannot be classified as adakite and island-arc andesite-dacite-rhyolite. Geochemical features of the rhyolite have high Rb/Sr ratio (> 1.0), low Zr content (30 ppm) and high Nb content (15 ppm).

Petrography of xenoliths from Hime-shima volcanic group is similar to that of basement rocks of Ryoke metamorphic rocks and granites from Kunisaki peninsula. U-Pb ages of zircon grains from metapelite are ca. 100 –110 Ma. These ages show agreement with ages of U-Pb zircon in metamorphic rocks from Ryoke metamorphic belt. Geochemical features of these xenoliths have wide Zr contents (20 –100 ppm), low Nb contents ( < 10 ppm), high Y contents (> 15 ppm) and low Sr/Y ratios (< 40 ppm), although the xenolith of basaltic andesite shows high Sr/Y ratio of 90. As results of comparing the geochemical compositions between rhyolite and xenoliths from Hime-shima volcanic group, we think that there is no genetic relationship between the xenoliths and rhyolite.

We examined the genesis of xenoliths from Hime-shima volcanic group are from rocks composed with Ryoke metamorphic belt, because Ryoke metamorphic belt, which is composed of metamorphic rocks, diorites and granites, is under Hime-shima. We compared geochemical features of granites from Ryoke metamorphic belt (Ryoke granites, Yuhara, 1994) with rhyolites from Hime-shima. Trace element PM-normalized patterns of the granites have similar to those of rhyolite from Hime-shima volcanic group, which are characterized by negative Sr, Zr and Eu anomalies and liner trend of Nb. Geochemical compositions of the Ryoke granites have high Rb/Sr ratios (0.5 - 1.5), low Sr/Y ratios (10 - 20), wide

©2019. Japan Geoscience Union. All Right Reserved. 

composition range of Y contents (12 - 35 ppm) high Nb concentrations (10 - 20 ppm) and wide composition range of Zr contents (50 - 250 ppm). The chemical features of the rhyolite from Hime-shima volcanic group have high Nb (> 15 ppm), high Rb/Sr ratio (> 1.0), low Y content (< 10 ppm), low Sr/Y ratio (< 10) and low Zr content (< 50 ppm). These chemical features share rhyolites in Hime-shima volcanic group with the Ryoke granites. Therefore, it is interpreted that the rhyolites from Hime-shima volcanic group was derived from crustal material, which compositions is similar to the Ryoke granites.

# Petrological study on the intrusive contact of a Setouchi volcanic rock dike in the Nakajima Island, Ehime Prefecture

*Taiki Omori[1], Satoshi SAITO[2]

1. Department of Earth Science, Faculty of Science, Ehime University , 2. Department of Earth Science, Graduate Schoole of Science, Ehime University

We performed a detailed petrological study on the intrusive contact between a Setouchi andesitic dike and host Ryoke granitoids occurring in the Nakajima Island, Ehime Prefecture. At the intrusive contact, the andesite contains many fragments of host granitoids. The bulk $SiO_2$ contents of the marginal andesite at the intrusive contact are markedly higher than those of internal domain implying the mixing between the andesite intrusion and the host granitoids. Other bulk chemical compositions such as MgO, CaO, $Na_2O$, $K_2O$, Cr and Zr also imply mixing of the host granitoids into the andesite intrusion at the intrusive contact. However, the $Al_2O_3$ contents of the marginal andesite can not be explained by bulk mixing of the host granitoids and the andesite intrusion because the $Al_2O_3$ contents of the marginal andesite are higher than those of the host granites and internal domain of the andesite intrusion. Assuming that the marginal andesite with chilled margin texture retain original compositions of intrusive magma, we tested the major element mass-balance modeling to explain chemical compositions of internal domain of the andesite intrusion. The modeling reproduced the major element compositions of internal andesites by adding ~7 % of host granite components and ~12 % of mafic phenocryst minerals into the marginal andesite.

# Fundamental evaluation for making simulated sea bed floc

*AIKO HAYAUCHI[1], Daisuke Sasakura[1], Hisato Yasuda[2], Shinya Nakamura[3], Sho Kimura[3], Shohei Noda[4]

1. Malvern Panalytical division of Spectris Co., Ltd, 2. Kochi University, 3. UNIVERSITY OF THE RYUKYU, 4. TOKYO UNIVESITY OF SCIENCE

1. Introduction
Flock is an aggregate in which fine particles such as clay and silt gathered loosely. It exists in the seabed for example. Research on flocs has been carried out on site and/or real samples, and many are observational approaches. There we tried analysis from a micro viewpoint for making floc simulation samples and reported about relationship between sample particle feature and how ease to be floc last year.
But we didn’ t care flocculant concentration in that report. Flocculant concentration must be important factor to discuss with making a simulated floc. Therefore we focused on influence of flocculant concentration to floc characteristic in this study.

2. Material and method
Kaolin as a model sample and Eb-a(Hayashi Co., Ltd.) as a flocculant for simulated floc preparation were used. Eb-a water solution concentration was 0%, 0.1%, 0.01%, 0.01% and 0.0001%. 0.05% sample water solution was prepared with each Eb-a water solution.
One of famous parameter of solution stability evaluation is zeta potential. Zeta potential was measured with Zetasizer nano ZSP (Malvern Instruments). Particle size distribution (incl. floc size distribution) was measured with Mastersizer 3000 (Malvern Instruments) which is laser diffraction system. Mastersizer 3000 is circulation system. In other hand, Morphologi 4 (Malvern instruments) which is a statistical particle image analysis system was also used for measuring particle size distribution. Morphologi 4 is not circulation system, so we can know original floc size distribution and we can see floc as well because Morphologi 4 is imaging system.

3. Result
Zeta potential in each flocculant concentration is shown in Table 1. In general, the system is stable when the zeta potential absolute value is over 20mV. Zeta potential in Eb-a concentration 0%, 0.001% and 0.0001% were around -60mV. It means that these systems are very stable and it indicates that it is difficult to occur flocculation in these situations. In the other hand, zeta potential absolute value in Eb-a concentration 0.01%, 0.1% and 1% were under 10mV, so that these indicate easy to occur flocculation.
The floc size measured by Mastersizer3000 is shown in Table 2. At The size was measured with 1500rpm/stirring speed at first, then was measured with change to 2500rpm/stirring speed. Comparing each Dv90 on 1500rpm, higher Eb-a concentration showed bigger floc size. In terms of toughness of floc, comparing the ratio of Dv90 on 1500rpm to Dv90 on 2500rpm was 1% Eb-a (0.54), 0.1% Eb-a (65%) and 0.01% Eb-a (75%). This is a result indicating that 0.01% Eb - a was the least fragile among these three samples. Also interestingly, Dv10 on 2500rpm was 0.01% Eb-a (18um), 0.1% Eb-a (9.6um) and 1% Eb-a (5.1um).
The floc size was measured by Morphlogi 4 as well. These data will discuss indetail on that day.

©2019. Japan Geoscience Union. All Right Reserved. 

4. Conclusions

The results show flocculation concentration is one of important factor to make simulated floc. We will continue to study to make clear which factor important to make simulated floc.

# Petrology of the Morobe Granodiorite in the Kuper Range, Morobe Province, Papua New Guinea

Angela Lynett Bokuik[1], *Takashi Hoshide[1]

1. Faculty of International Resource Sciences, Akita University

The Morobe Granodiorite is a composite batholith comprising of monzodiorite, monzonite, quartz monzonite, granite, granodiorite, diorite and gabbro. Mafic Microgranular Enclaves (MME) are abundant in the intrusion. The mineral assemblage of the Morobe Granodiorite comprises of hornblende, biotite, plagioclase, alkali feldspar and quartz with accessory minerals of titanite, apatite, magnetite and ilmenite. The rocks have a variety of texture, such as poikilitic, cumulous and porphyritic. The MME also has a similar mineral assemblage and texture to its host however, it is abundant in mafic minerals hornblende and biotite.

Mineral compositions for amphibole of the granodiorite and MMEs are similar, implying similar magma environment. By the iteration calculation using a geobarometer (Anderson and Smith, 1995) and a geothermometer (Blundy and Holland, 1990), we estimated the crystallization temperature of 597-766˚C and the maximum crystallization pressure of 3.6 kbar. Crystallization conditions from the MME yield higher temperature (812˚C) and pressure (5.3 kbar) to its host, which implies MMEs represent the deeper hotter parts of the same magma chamber of which the MME and host formed.

The geochemical signature of the Morobe Granodiorite represent calc-alkaline and metaluminous nature typical of I-type granites. The variations of major elements in the Harker diagram can be best explained by fractionation mainly of hornblende and plagioclase. The interpretation is consistent with the textural variations of the rocks. Low $FeO^T/(FeO^T + MgO)$ ratios and high Mg-number for granodioritic rocks suggest magma originated from partial melting of the lower mafic crust. This magma was contaminated upon ascent wall rock assimilations of the host rock Owen Stanley Metamorphic. This can be seen as $Na_2O$ vs $SiO_2$ and $K_2O$ vs $SiO_2$ variation diagrams.

# Sr–Nd isotopic compositions of the San-yo Belt, Southwest Japan: Implications for the Cretaceous enriched mantle

*Shogo Kodama[1], Masaaki Owada[1], Teruyoshi Imaoka[1], Atsushi Kamei[2]

1. Yamaguchi University, 2. Shimane University

Cretaceous to Paleogene igneous rocks are widely exposed in the Inner Zone of Southwest Japan where the granitic rocks have been divided into the San-in, San-yo, and Ryoke Belts on the basis of their lithologies, geochemical compositions, magnetic susceptibility and associated ore deposits (Ishihara, 1971). The San-yo and Ryoke Belts belong to the ilmenite-series granitic rocks, but the San-in Belt corresponds to the magnetite-series ones (Ishihara, 1977). According to Sr isotopic compositions, Kagami et al. (1992) classified these granitic rocks into the North Zone , South Zone, and Transitional Zone situated between the North and South Zones. The granitic rocks from the Transitional and South Zones show negative eNdI values (Kagami et al., 1992); however, the isotopic compositions of granitic rocks would serve only as proof for the bulk of the continental crust (Jahn, 2010). This means that those data are unlikely to provide us with mantle signatures. Imaoka et al. (2014) described the Early Cretaceous lamprophyer (c. 105 Ma) from the Kyoto district. The Kyoto lamprophyres geochemically show enriched signatures with positive and negative eNdI values corrected to 105 Ma. In consideration of the geochemical signatures and tectonic setting, Imaoka et al. (2014) concluded that the Kyoto lamprophyre was derived from heterogenous enriched mantle created by the subduction of the oceanic crust. Aspects of the existence of enriched mantle, however, are still unclear, such as in regard to its regional extension and duration for the Cretaceous magma activities of the Inner Zone of Southwest Japan.

Late Cretaceous igneous rocks are widely exposed in the western part of Honshu Island. These igneous rocks consist mainly of granitic rocks and felsic to intermediate volcanic rocks. We newly found a small gabbro stock (c. 1 km in diameter) with relatively primitive compositions in the central part of Yamaguchi Prefecture. The gabbro stock accompanies the Susuma-Nagaho granodiorite as coeval intrusive rocks. Therefore, we refer to both granodiorite and gabbro as the Susuma-Nagaho Plutonic Complex (SNPC, hereafter). The gabbro can be subdivided into fine-grained gabbro (Fn-gabbro) and coarse-grained cumulus gabbro (Co-gabbro). The Fn-gabbro has a high Mg-number similar to primitive basalt with negative eNd values corrected to 92 Ma although Cr and Ni contents are relatively low, which indicates that the basaltic magma may have been derived from enriched mantle. In consideration of the geochemical signatures including the Sr and Nd isotopic compositions, the enriched mantle characterized by negative eNd isotopic values would have existed underneath the Inner Zone of Southwest Japan during the Cretaceous.

# Lithological variation of massive serpentinites in marginal zone of serpentinite body in Kamuikotan belt, Hokkaido, Japan: Analysis of advanced-boring cores for tunnel construction

*Shusaku Yamazaki[1], Kenji Okazaki[1], Toshiyuki Kurahashi[1]

1. Civil Engineering Research Institute for Cold Region, Public Works Research Institute, National Research and Development Agancy

Serpentinite body associated with high-pressure metamorphic rocks such as Kamuikotan belt in Hokkaido is very important as a key to understand a deep subduction process in subduction zone. In the field of marine geology, recent advances of sampling and analytical techniques contribute to understand of serpentinization process of abyssal peridotites. On the other hand, terrestrial serpentinite body still remain a lot of unexplained processes such as variation of serpentinization, uplifting mechanism and formation of internal structure, because of poor sampling by its fragile and fragmented rock conditions on earth surface conditions. There are over 30 tunnel construction cases drilling into a serpentinite body in Japan. Geoengineering investigation including description of tunnel drilling face, measurement of physical properties and making cross section of the tunnel route were operated in each tunnel. However, a detailed geological information such as types of source rock and degree and aspect of serpentinization has been less understood from the construction records. In addition, even in recent yeses with developed drilling technology, excavation of serpentinites often encounters serious trouble such as tunnel collapse. It indicates that more detailed classification of serpentinites for tunnel construction is necessary using recent geological insights and technique.

The authors focus on reconstruction of the tunnel geological section and the detailed classification of serpentinites of a tunnel with 1241 m into Takadomari serpentinite body of Horokanai area in Kamuikotan belt in Hokkaido, Japan. In this study, massive serpentinites, which were sampled from advanced-boring core at 50 to 100 m intervals along tunnel route, were conduct to description of core and thin section and XRD analysis to investigate lithological variation around the marginal zone of the serpentinite body contact with Kamuikotan metamorphic rocks.

The research by Igarashi et al. (1985) revealed that serpentinites of the Takadomari body were classified into massive, foliated and clay serpentinites and their source rocks were mostly harzburgite and partly dunite as band in harzburgite. There are large number of “micordiorite” and micro gabbro dikes in the body. As a result of this study, advanced-boring cores from the tunnel also have same variation of massive, foliated and clay serpentinites. The source rock types of massive serpentinites from the marginal zone are also mainly harzburgite with minor band of dunite. All samples were completely serpentinized and only Cr-spinel is survived as primary mineral. Original texture of the massive serpentinite is classified into dunitic texture without pyroxenes, harzburgitic texture with orthopyroxene, cumulate texture with euhedral orthopyroxene and foliation of spinel allay. Serpentine types in the massive serpentinites are antigorite that replaced olivine and orthopyroxene and lately formed asbestos chrysotile vein. Minor amount of brucite also appears through the tunnel. As a notable feature in the marginal zone of the body, three zones of difference serpentinization were observed. In the center of the tunnel, the serpentinites well remain the original harzburgitic and dunitic texture. In the west side with amphibolites, the massive serpentinites contain magnesite veins and patches as metasomatism. In the east side with the contact to greenschists, the original texture is completely disappeared with greenish large antigorite and massive of

©2019. Japan Geoscience Union. All Right Reserved. 

grains of magnetite with brucite. The difference of texture and mineralogy of the serpentinites in this tunnel could possibly be explained that the serpentinization process in subduction zone is difference in the both sides of marginal zone in the association with the types of the Kamuikotan metamorphic rocks.

## [S-CG53] Environment formed and maintained by active faults

convener:Naoji Koizumi(School of Environmental Science,the University of Shiga Prefecture), Makoto Yamano(Earthquake Research Institute, the University of Tokyo), Takafumi Kasaya(Japan Agency for Marine-Earth Science and Technology), Hideki Hamamoto(Center for Environmental Science in Saitama), Chairperson:NAOJI KOIZUMI, TADANORI GOTO(Graduate School of Engineering, Kyoto University)

An active fault causes a large earthquake at a very low frequency such as once every several thousand to tens of thousands years and destroys the surrounding environment. On the other hand, during the period when the large earthquake or the fault movement does not occur, the unique environments such as mountains, basins, structural lakes, hot springs and mineral deposits are formed and maintained by the topography and hydrogeological structure made by the accumulation of the fault movement. In general, the presence of active faults is recognized as a factor of environmental destruction, but it is also necessary to understand the active faults as a factor of environmental formation and maintenance. In this session, we welcome wide-ranging topics on the role of active faults as a factor for the formation and maintenance of the environment and how to investigate it.

# Effect of the Hanaore fault and Biwako-seigan fault on the water quality of the Ado river in Shiga Prefecture

*Naoji Koizumi[1], Masahiro Ueda[1], Shinsuke Minote[1], Tatsuya Tanaka[1], Masahiro Maruo[1], Kanto Mitani[2]

1. School of Environmental Science,the University of Shiga Prefecture, 2. Daikokuten Bussan Co., Ltd.

1.Introduction
Along a fault plain, there is a fractured damage zone, which has high permeability. This zone is often become groundwater path from deep to shallow (Faulkner et al., 2010). As a result, the fault-related groundwater stably supplies heat and chemical materials including water itself, which make some effect on the environment in and around the fault zone. For example, hot and mineral springs tends to distribute in and around fault zones. This fault-related groundwater should also have some effect on the river in the case that the river runs along or across the fault.

The Ado river, which is located in the western part of Shiga Prefecture, is the second longest in the rivers which flow into Lake Biwa, which is the largest lake in Japan. The catchment area of the Ado river is also the largest in the rivers which flow into Lake Biwa. In the part of the upstream and most of the midstream, the Ado river runs along the Hanaore fault. In the downstream the Ado river cross the Biwako-seigan fault (Fig.1). Both of the faults are the main active faults in the western part of the Shiga Prefecture. Therefore the Ado river is suitable for investigating the effect of active faults on the river water quality.

2.Observation
We surveyed the Ado river during the period from August 12 to August 14 in 2018 (Fig.1) , which is named the spatial survey. Before this period there had been no precipitation for thirteen days at IMZ and MNM. Therefore it is considered that the river water was mainly composed of the base flow, which supplies from groundwater to river. We also surveyed the Ado river at RYD, HRS, ADG and KTG about once a month from April, 2018, which is named the temporal survey.

3.Result
In the spatial survey the water quality type was Ca-HCO3 at all the sampling points. The ion concentrations were gradually increased from AD7 to TKI although there were no systematic change in the ion concentrations at the other sampling points. Between HRS and ADG, where the Ado river crosses the Biwako-seigan fault, there was no change in the ion concentrations. In the temporal survey, there was also no no change in the ion concentrations between HRS and ADG. This shows that the Hanaore fault has some effect on the water quality of the Ado river although the Biwako-seigan fault has little effect on it.

Fig.1 The solid circles show the sampling points of the Ado river during the period from August 12 to August 14 in 2018. The solid triangles denote meteorological observation points of Japan Meteorologidal Agency. This is modified from the figure of the active fault database of Japan (Geological Survey of Japan, AIST, 2019). The background map is from Geographycal Information Authority of Japan (2019).

# Hydrothermal vents in the deep basin of Lake Biwa

*Michio Kumagai[1]

1. Ritsumeikan University

The autonomous underwater vehicle (AUV) “Tantan” was constructed and first deployed in the year 2000, as the world’s first AUV conceived for lake ecosystem exploration and monitoring. Tantan (meaning “freshwater surveillance” in Japanese) was designed to move along bottom slopes keeping a constant distance above the sediments, with a payload that includes two high-definition video cameras, a digital camera, a submersible microscope and various sensors. In December 2009, Tantan identified turbid water ebullition on the deep area in the North Basin of Lake Biwa, which is a larger basin with maximum depth 104 m and 99% water volume, and follow-up investigations were conducted in April, December 2010 and January 2012. This study confirmed the existence of hydrothermal vents, and provided the evidence that their vent numbers per unit area on the lake bottom have increased from 1.0 $km^{-2}$ vent in 2009 to 54.0 vents $km^{-2}$ in 2012. We also found that those discovered vents located along the ridge of sunken mountains which form the basement of Lake Biwa with covered sediments. Some back-up investigations have been performed with a remotely operated vehicle (ROV) and several kinds of sonar devices, and all of the outputs support the existence of vents found by Tantan.

# Heat flow anomalies observed on the seafloor in the vicinity of faults: indication of fluid flow

*Makoto Yamano[1], Shusaku Goto[2], Yoshifumi Kawada[3], Hideki Hamamoto[4]

1. Earthq. Res. Inst., Univ. Tokyo, 2. Geol. Surv. Japan, AIST, 3. IRIDeS, Tohoku Univ., 4. Center Environ. Sci. Saitama

Active fluid flow along faults may yield temperature or surface heat flow anomalies because advective heat transport by fluid flow is much more efficient than conductive transport. On land, it is rather difficult to observe such anomalies as temperature profile measurement in deep boreholes is required. On the other hand, we can conduct dense heat flow measurements on seafloor if surface sediment is soft enough to allow penetration of temperature probes. Heat flow and/or temperature anomalies in the vicinity of faults have been reported in some accretionary prisms, e.g., Cascadia and Barbados subduction zones. In this presentation, we show examples of heat flow anomalies associated with faults on the seafloor in the Nankai Trough area.

Accretionary prism developed landward of the Nankai Trough is extensively faulted in a compressional stress field due to subduction of the Philippine Sea plate. At the toe of the prism off Muroto, eastern Shikoku, closely-spaced heat flow measurements were made with a ROV and conspicuous high anomalies were found around the second frontal thrust, indicating that pore fluid flows upward along the fault (Kawada et al., 2014). Off the Kii peninsula, a large thrust fault system termed the megasplay cuts through the entire prism and its branches reach the seafloor. Yamano et al. (2014) conducted heat flow measurements with a surface ship across a branch of the megasplay and observed high heat flow values on the lower part of a fault scarp. Goto et al. (2008) made measurements with a submersible around biological communities along another branch of the megasplay and showed a sharp heat flow variation in a scale of several meters. These observations demonstrate that fluid flow along faults in various spatial scales can be detected by surface heat flow measurements.

The velocity or flux of vertical fluid flow may be estimated through long-term monitoring of temperature distribution in surface sediment. Temporal variation of the bottom water temperature propagates downward through sediment by thermal diffusion. Since this propagation process is affected by vertical fluid flow, analysis of long-term record of temperatures at multiple depths allows us to estimate fluid flow velocity (Goto et al., 2005). This method was applied to temperature records obtained in and around a biological community located a tip of the megasplay branch fault and the result indicates the existence of upward fluid flow (Kawada et al., 2013).

# How can we quantify the hydraulic permeability of fault based on geophysical survey?

*Tada-nori Goto[1], Sota Kawaguchi[1]

1. Graduate School of Engineering, Kyoto University

For understanding impacts of faults/fractures to the Earth's environment, evaluation of hydraulic permeability along fault and fractures are required because they hydrogeologically play a role of pathway of deep groundwater and gas. Previous studies have obtained the hydraulic characteristics using boreholes and rock samples. However, such information is only valid in a local scale, and it is basically considered to be difficult to estimate the hydraulic permeability at several-hundred meter scales or more. In this study, we try to estimate the permeability in and around fractures in typical bedrocks (e.g., granitic rocks) based on the geophysical explorations: resistivity, seismic velocity and so on. The geophysical logging experiment (e.g., cross-hole tomography) can indicate both local and larger scale geophysical information. More large-scaled information can be obtained by land-surface geophysical surveys. For evaluation of permeability of large-scale fault, a rock physical modeling will be helpful since it can connect geophysical property to the hydraulic property theoretically or numerically.
Prior to the challenge of large-scale permeability estimation, we applied the rock physical modeling to the small-scale geophysical measurements. We measured DC resistivity and elastic properties (Young modulus) on the exposed fresh granite at the Mizunami Underground Research Laboratory, Japan Atomic Energy Agency. Based on the simple rock physical model, we estimated the permeability of granite with less fracturing. The in-situ permeability measurements confirmed that the estimated values are enough close to the measured ones (within the difference of half of order). The technique is also valid to the permeability measurements by pumping test at wells. We succeeded that the observed permeability obtained at Mizunami can be reproduced by only using geophysical logging data such as resistivity and seismic P-wave velocity.
Then, we applied this rock physical model to the large-scale geophysical images based on the magnetotellurics and seismic tomography. Although it is a preliminary result, the estimated permeability structure by our method is not realistic one unfortunately. In this study, we discuss on the additional information and technique how the accuracy of estimated permeability is improved.

# Healing process of the Nojima Fault zone after 1995 Hyogo-ken Nanbu earthquake

*Hideki Murakami[1], Naoto Oshiman[2], Ryokei Yoshimura[2], Tsutomu Miura[2], Masato Kamo[2]

1. Research and Education Faculty,Kochi University, 2. Disaster Prevention Research Institute,Kyoto University

Two faults of the Nojima Fault and the Higashiura Fault exist in the northeastern part of Awaji Island. Repeated activities of these faults have formed the topography of Awaji Island. In this study, we report the result of the Nojima water injection experiment of 2018 and the healing process of the Nojima Fault zone estimated from self-potential variations associated with water injection experiments. The water injection experiments were conducted 8 times between 1997 and 2018 in an 1800 m long borehole near the Nojima Fault, which is the surface earthquake fault of 1995 Hyogo-ken Nanbu earthquake, to investigate the recovery process of the fault zone after the large earthquake. We have estimated the time evolution of hydraulic parameters from self-potential variations associated with water injection. It is expected that hydraulic parameters will decrease as the healing process of the fault zone progresses. Though the Nojima Fault has repeatedly moved at a recurrence interval of ca. 2,000 years during the Late Quaternary, it is estimated from the experiment results that the healing process of the fault zone is progressing in several years after the earthquake shorter than the recurrence interval.

# Heat flow measurement in Lake Biwa

*Hideki Hamamoto[1], Makoto Yamano[2]

1. Center for Environmental Science in Saitama, 2. Earthquake Research Institute, University of Tokyo

Active venting of water and gas has been observed in the vicinity of a fault on the bottom of Lake Biwa. Heat flow measurement is a useful tool for investigation of such fluid flow. Previous studies reported heat flow values at two stations in Lake Biwa: one is 50 $mW/m^2$ in a borehole on the bottom of the lake and the other is 44 $mW/m^2$ in a borehole located at the lakeshore. Taking account of values measured in the surrounding area, heat flow in the Lake Biwa area not disturbed by fluid flow is estimated to be about 50 $mW/m^2$.

We conducted heat flow measurement at five stations in a deep basin in the northwestern part of Lake Biwa in 2010 using a research vessel “Hakken-gou”, which was operated by Lake Biwa Environmental Research Institute at that time. We used a conventional heat flow probe for measurement on deep seafloor. The length of probe is 1.5 or 3.0 m and seven temperature sensors are mounted along the probe. The maximum water depth of Lake Biwa is about 100 m, and bottom water temperature (BWT) variation with a large amplitude has been observed. Subsurface temperature within a few meters of the lake bottom must be affected by BWT variation. The temperature profiles we measured with the heat flow probe were apparently disturbed by BWT variations. At one station in close vicinity to fluid vents, we obtained an extremely large temperature gradient (approximately 300 mK/m). It means that heat flow at this station is anomalously high, whatever disturbance by BWT variation the temperature profile suffered. The observed high heat flow is attributable to upward fluid flow through sediment, since advective heat transport by fluid flow is very efficient.

However, we cannot measure heat flow precisely with conventional heat flow probes in shallow water areas with significant BWT variations. For obtaining reliable heat flow values, we should conduct long-term temperature monitoring and analyze the data considering influence of BWT variations. Analysis of long-term temperature data may also provide information on fluid flow velocity. We need to conduct reliable and high-density heat flow measurements for investigation of fluid flow related to faults on the bottom of Lake Biwa.

Keywords: Heat flow, Lake Biwa, Bottom water temperature variation

# Shallow Resistivity Structure across the Futagawa-Fault Nishihara Area and the Reliability

*Tada-nori Goto[1], Hisatoshi Koji[1], Sota Kawaguchi[1], Satoru Yamaguchi[2], Yuto Yamalaka[2], Daigo Furukawa[2], Koki Aizawa[3]

1. Graduate School of Engineering, Kyoto University, 2. Graduate School of Science, Osaka City University, 3. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University

At the 2016 Kumamoto earthquake, Japan, many surface ruptures occurred. They are distributed along the Futagwa fault already known as an active fault. In the Nishihara area, Kumamoto prefecture, the Futagwa fault consists of two parallel sub-faults with E-W strike, and large displacements were observed along the southern one. The analysis of InSAR data, a large deformation zone is presumed in the area between the two sub-faults (Fujiwara et al., 2016). InSAR results also showed a linear surface rupture located south of the Futagwa fault, which is not equivalent to the known active faults. Thus, the distribution of ground displacement/rupture at the 2016 Kumamoto earthquake is complicated, and the reason should be due to the complexity of the geological structure along the active fault. However, the shallow structure around the Futagwa fault has not been estimated in this area.

In this study, electromagnetic survey (AMT exploration) was carried out in the Nishihara area for exploration of the shallow resistivity structure. The equipment used is MTU-5A by Phoenix Geophysics. The total number of AMT sites is 14, arranged on a N-S survey profile across the Futagwa fault. High-quality AMT responses were obtained at 11 site, and a inversion scheme by Uchida and Ogawa (1993) for estimation of two-dimensional resistivity model was applied. In the correction of static shift, we focused on the spatial smoothness of Zssq phase, and applied the spatial filtering to observed apparent resistivity.

The obtained resistivity structure indicated two buried low-resistive zones along the two sub-faults, with depth from 0m to 500m or more. One of the low resistive zone along the northern one of sub-faults has a north dip with about 60 degrees, consistent with the previous geological survey. On the other hand, another low resistivity zone along the south sub-faults has a larger width (about 400 m) than the northern one, and has a south dip. The reliability of the low resistive zones was evaluated based on the principal component analysis method and the Markov chain Monte Carlo method (Koji and Goto, 2019). As a result, the sensitivity of southern low-resistive zone is high enough. The two parallel low-resistive zones, one of which has a south dip, were not reported in the previous geophysical and geological studies. However, such features are consistent with the InSAR results. As a conclusion, geophysical explorations for evaluating of shallow structure at active faults are effective to understand and predict the ground displacement and shaking at earthquakes.

# Detailed topography and sub-surface structure around the 2016 Fukushima Earthquake

*Takafumi Kasaya[1], Toshiya Fujiwara[1], Toshiya Kanamatsu[1], Katsunori FUJIKURA[1]

1. Japan Agency for Marine-Earth Science and Technology

The large earthquake of M7.4 was occurred off Fukushima Prefecture on 22 Nov. 2017. This earthquake was not a interpolate earthquake, but normal fault type earthquake occurred in the land-side plate. However, a tsunami with a maximum wave height of 1.4 m was observed around the coastal area of Tohoku distinct. When this earthquake occurred, R/V Shinseimaru and R//V Yokosuka were under the scientific survey mission of other purpose near the focal region of this earthquake. JAMSTEC decided to carry out the immediate survey using both vessels. As the results, some small cliffs were detected. In order to obtain the further information of the succession of cliffs and sea floor condition, including the distribution of benthos, we carried out the visual observation using ROV Hyper-Dolphin (HPD) and detailed survey using the multi narrow echo-sounder and sub-bottom profiler at the KS-17-J04 cruise conducted by the project “Tohoku Ecosystem-Associated Marine Sciences”. We carried out two dives and could detect the flesh topographical cliff of about 1-2 m height difference around the cliff detected by the immediate observation. The uppermost layer under the seafloor is a soft mud layer containing concentrated layer of shells. The lower layer is formed of consolidated sedimentary layer. In near the cliff and the bottom of fissure, some white discoloration zones considered as bacteria mats were observed. At the northernmost fissure where we could arrive, the populations of benthos were observed. Furthermore, we conducted the detailed dense bathymetric survey, sub-surface structure, and the observation using a sidescan sonar with 400 kHz. As these results, we could obtain the distribution of the lineaments and faults around the focal area.

## [S-CG53] Environment formed and maintained by active faults

convener:Naoji Koizumi(School of Environmental Science,the University of Shiga Prefecture), Makoto Yamano(Earthquake Research Institute, the University of Tokyo), Takafumi Kasaya(Japan Agency for Marine-Earth Science and Technology), Hideki Hamamoto(Center for Environmental Science in Saitama)

An active fault causes a large earthquake at a very low frequency such as once every several thousand to tens of thousands years and destroys the surrounding environment. On the other hand, during the period when the large earthquake or the fault movement does not occur, the unique environments such as mountains, basins, structural lakes, hot springs and mineral deposits are formed and maintained by the topography and hydrogeological structure made by the accumulation of the fault movement. In general, the presence of active faults is recognized as a factor of environmental destruction, but it is also necessary to understand the active faults as a factor of environmental formation and maintenance. In this session, we welcome wide-ranging topics on the role of active faults as a factor for the formation and maintenance of the environment and how to investigate it.

# Heat flow measurement in Lake Biwa

*Hideki Hamamoto[1], Makoto Yamano[2]

1. Center for Environmental Science in Saitama, 2. Earthquake Research Institute, University of Tokyo

Active venting of water and gas has been observed in the vicinity of a fault on the bottom of Lake Biwa. Heat flow measurement is a useful tool for investigation of such fluid flow. Previous studies reported heat flow values at two stations in Lake Biwa: one is 50 $mW/m^2$ in a borehole on the bottom of the lake and the other is 44 $mW/m^2$ in a borehole located at the lakeshore. Taking account of values measured in the surrounding area, heat flow in the Lake Biwa area not disturbed by fluid flow is estimated to be about 50 $mW/m^2$.

We conducted heat flow measurement at five stations in a deep basin in the northwestern part of Lake Biwa in 2010 using a research vessel “Hakken-gou”, which was operated by Lake Biwa Environmental Research Institute at that time. We used a conventional heat flow probe for measurement on deep seafloor. The length of probe is 1.5 or 3.0 m and seven temperature sensors are mounted along the probe. The maximum water depth of Lake Biwa is about 100 m, and bottom water temperature (BWT) variation with a large amplitude has been observed. Subsurface temperature within a few meters of the lake bottom must be affected by BWT variation. The temperature profiles we measured with the heat flow probe were apparently disturbed by BWT variations. At one station in close vicinity to fluid vents, we obtained an extremely large temperature gradient (approximately 300 mK/m). It means that heat flow at this station is anomalously high, whatever disturbance by BWT variation the temperature profile suffered. The observed high heat flow is attributable to upward fluid flow through sediment, since advective heat transport by fluid flow is very efficient.

However, we cannot measure heat flow precisely with conventional heat flow probes in shallow water areas with significant BWT variations. For obtaining reliable heat flow values, we should conduct long-term temperature monitoring and analyze the data considering influence of BWT variations. Analysis of long-term temperature data may also provide information on fluid flow velocity. We need to conduct reliable and high-density heat flow measurements for investigation of fluid flow related to faults on the bottom of Lake Biwa.

# Shallow Resistivity Structure across the Futagawa-Fault Nishihara Area and the Reliability

*Tada-nori Goto[1], Hisatoshi Koji[1], Sota Kawaguchi[1], Satoru Yamaguchi[2], Yuto Yamalaka[2], Daigo Furukawa[2], Koki Aizawa[3]

1. Graduate School of Engineering, Kyoto University, 2. Graduate School of Science, Osaka City University, 3. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University

At the 2016 Kumamoto earthquake, Japan, many surface ruptures occurred. They are distributed along the Futagwa fault already known as an active fault. In the Nishihara area, Kumamoto prefecture, the Futagwa fault consists of two parallel sub-faults with E-W strike, and large displacements were observed along the southern one. The analysis of InSAR data, a large deformation zone is presumed in the area between the two sub-faults (Fujiwara et al., 2016). InSAR results also showed a linear surface rupture located south of the Futagwa fault, which is not equivalent to the known active faults. Thus, the distribution of ground displacement/rupture at the 2016 Kumamoto earthquake is complicated, and the reason should be due to the complexity of the geological structure along the active fault. However, the shallow structure around the Futagwa fault has not been estimated in this area.

In this study, electromagnetic survey (AMT exploration) was carried out in the Nishihara area for exploration of the shallow resistivity structure. The equipment used is MTU-5A by Phoenix Geophysics. The total number of AMT sites is 14, arranged on a N-S survey profile across the Futagwa fault. High-quality AMT responses were obtained at 11 site, and a inversion scheme by Uchida and Ogawa (1993) for estimation of two-dimensional resistivity model was applied. In the correction of static shift, we focused on the spatial smoothness of Zssq phase, and applied the spatial filtering to observed apparent resistivity.

The obtained resistivity structure indicated two buried low-resistive zones along the two sub-faults, with depth from 0m to 500m or more. One of the low resistive zone along the northern one of sub-faults has a north dip with about 60 degrees, consistent with the previous geological survey. On the other hand, another low resistivity zone along the south sub-faults has a larger width (about 400 m) than the northern one, and has a south dip. The reliability of the low resistive zones was evaluated based on the principal component analysis method and the Markov chain Monte Carlo method (Koji and Goto, 2019). As a result, the sensitivity of southern low-resistive zone is high enough. The two parallel low-resistive zones, one of which has a south dip, were not reported in the previous geophysical and geological studies. However, such features are consistent with the InSAR results. As a conclusion, geophysical explorations for evaluating of shallow structure at active faults are effective to understand and predict the ground displacement and shaking at earthquakes.

# Estimation of fault models of the short-term SSE using groundwater pressures at the Hokusei observation site

*Yuichi Kitagawa[1], Norio Matsumoto[1]

1. Tectono-Hydrology Research Group, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

One of the problems is the lack of high quality crustal deformation/groundwater observation sites in the western part of Aichi prefecture and the northern part of Mie prefecture around Ise Bay, in terms of the estimation of short-term slow slip events (SSEs) occurring at the plate boundary of the Nankai Trough. One of the causes is that unconsolidated sedimentary layers such as the Tokai Group are thickly deposited in this area. In May 2016, the inner pipe of the observation well at the Hokusei observation site located in the northern part of Mie prefecture was sealed with a packer in order to improve the response of groundwater level to crustal deformation. Because the permeability of the target aquifer at this site is low, the groundwater level before the sealing was poor in response to crustal strain changes before the sealing. The groundwater pressure is observed after sealing, then tidal fluctuation clearly appeared in the groundwater pressure, therefore we found the response of the groundwater pressure to crustal deformation to be clearly improved. The response of the groundwater pressure to crustal strain after sealing improved about 10 times than that of the groundwater level before the sealing. By eliminating the tidal component, barometric pressure response, and rain response from the groundwater pressure data, short-term SSEs were detected by the changes in groundwater pressure in July 2016, November 2017 and April 2018. And then slips of the short-term SSEs were estimated to be spread to Northern Ise Bay by the data of strain, tilt and groundwater pressure. In the area around Northern Ise Bay where deep low frequency tremors are not active, it is shown that short-term SSEs repeatedly occurred. In soft sedimentary layer which is unsuitable for observation of crustal deformation by strain meter and tilt meter, it is showed that the measurement of groundwater level (pressure) is a powerful means of crustal deformation observation.

# Groundwater level changes during the 2018 Hokkaido Eastern Iburi earthquake

*Tomo Shibata[1], Ryo Takahashi[2], Hiroaki Takahashi[3], Takanori Kagoshima[4], Yuji Sano[4], Daniele Pinti[5]

1. Graduate School of Science, Kyoto University, 2. Geological Survey of Hokkaido, Hokkaido Research Organization, 3. Graduate School of Science, Hokkaido University, 4. Atmosphere and Ocean Research Institute, The University of Tokyo, 5. GEOTOP, Université du Québec

Groundwater table level in wells can fluctuate under stress provoked by earthquakes located even thousands of kilometers away. The mechanisms of changes in groundwater level can be explained by hydrological changes such as pore-pressure response to coseismic static elastic strain, permeability changes caused by seismic waves and fluid migration along seismogenic dilatant cracks or crustal ruptures. The Geological Survey of Hokkaido, Hokkaido Research Organization (HRO), has been monitoring groundwater tables in several wells after the 2018 Hokkaido Eastern Iburi earthquake. The wells were drilled for exploiting hot spring water but have not been used in the last 20 years. The groundwater level was measured by pressure gauges with resolution about 5-10 mm in 10-minute intervals in each monitored well. After the Hokkaido Eastern Iburi earthquake, we were able to find a step-like decrease in groundwater levels in three wells. These wells are located within the region where tensile changes of the quake-induced volumetric strain can be calculated by using the fault model, suggesting that the changes in groundwater levels are qualitatively consistent with those in volumetric strain. The observed groundwater level changes are also affected by tidal and barometric effects, and we can estimate the response of groundwater level for tidal components. The tidal responses in all the wells have not changed before and after the earthquake.

# Postseismic streamflow changes after the 2016 Kumamoto earthquake

*Naoji Koizumi[1], Shinsuke Minote[1], Tatusya Tanaka[1]

1. School of Environmental Science,the University of Shiga Prefecture

It has been well known that large earthquakes sometimes cause hydrological changes widely in and around the region of strong ground motion. In several cases of those changes, stream flow and spring flow increases in lowland and water table drops in highland. It has often been explained by permeability enhancement in the region of strong ground motion (Rojstaczer et al. ,1995; Wang and Manga, 2004). Since Japan is relatively rich in water resources, people may have not paid much attention to these earthquake-related hydrological changes. But those hydrological changes are clearly one of the seismic risks and should also be examined in Japan because those changes sometimes continue for a period of several months to years (Rojstaczer et al. ,1995) .

The 2016 Kumamoto Earthquake, which occurred mainly in Kumamoto Prefecture, Japan in April 2016, caused severe damages in and around Kumamoto Prefecture. It also caused many changes in stream water and groundwater (Ichiyanagi and Ando, 2017; Sato et al., 2017). The region of strong ground motion of the main shock spreads from the coastal plain to the Aso caldera.

We analyzed the data of streamflow at fourteen flow rate observation stations of three major rivers in Kumamoto prefecture during the period from 1990s to 2017. After the 2016 Kumamoto earthquake, streamflow was increased at four of the fourteen observation stations, where the rivers flow from the Aso caldera or the foot of Mt.Aso. However the streamflow was not increased just after the 2016 Kumamoto earthquake. It was increased 2 months after the Kumamoto earthquake, when a heavy rainfall occurred. In addition it is found that (flood frow rate/precipitation amount) ratio tends to be increased when the precipitation amount is large after the 2016 Kumamoto earthquake. This can be explained not by permeability enhancement but by decrease of the soil moisture retention capacity. In and around the region of the strong ground motion of the 2016 Kumamoto earthquake there were many mudslides and landslides, which could reduce the soil moisture retention capacity. The earthquake-related decrease of the soil moisture retention capacity could have caused the streamflow increase in and around the region of the strong ground motion of the 2016 Kumamoto earthquake.

We have developed a radium concentration monitoring system in order to analyze a radium concentration in soil samples based on a gamma-ray spectrum. A gamma-ray spectrum of a soil sample was measured by a $SrI_2$ solid scintillator equipped by a multi-pixel photon counter (hereinafter a detector). The detector was shielded by 5cm-thick lead brocks, because 214-bismuth, which is a daughter elements of radium contained in cement materials, emits strong gamma-ray. We have achieved 80% background reduction. We prepared a calibration curve in order to determine a soil radium concentration by a peak area of 214-bismuth in a gamma-ray spectrum of JG-1 geochemical reference sample (AIST, GSJ). We are going to have a discussion to improve problems of this system.

# $^{222}$Rn concentration distribution in Yatsushiro Sea

*Kuniyo Kawabata[1], Fumiaki Tsunomori[2], Yujin Kitamura[1], Hakuho-Maru K18-3 scientists

1. Graduate School of Science and Engineering, KAGOSHIMA UNIVERSITY, 2. Geochemical Research Center, Graduate School of Science, University of Tokyo

Radon concentrations in Yatsushiro sea were surveyed to examine relationship with the submarine sediments and geological structure such as submarine active faults.

$^{222}$Rn is a radioactive noble gas and occurs naturally in earth’ s crust as an intermediate step in the normal radioactive decay chain of uranium series. Radon shows high solubility for water and thus high mobility through groundwater and fluids in earth’ s crust. Concentration of radon in crustal fluid and groundwater can provide a clue to understand geology of the aquifer and state of crustal deformation as crack formation and change in strain state, because its release rate depends mainly on rock surface area. Recently location of active faults and its activity have been examined by using the method (e.g. Malgrange and Gleeson, 2014, Tsunomori et al., 2017).

A bunch of submarine active faults underlies in Yatsushiro area sea. These faults compose the Futagawa-Hinagu Fault zone which was activated at the 2016 Kumamoto earthquake. To evaluate records of submarine landslides and changes in submarine circumstances due to historical earthquakes, R/V Hakuho-Maru sailed for research expedition (KH-1803) in Yatsushiro sea from 27th to 30th July, 2018. We collected bottom water from obtained multiple cores and piston cores, and pore waters from piston cores for the measurement of the radon concentration in the sample water on board.
The results of radon concentration distribution from multiple cores, (MC 1-12), show that higher concentration along the Line Y18a. The radon concentrations from bottom water of piston cores (PC 1-11) also show similar results while the values are larger than the results from multiple cores. A higher radon concentration is attributed to difference in (1) Radium concentration in sediments, and/or (2) properties of sediments such as porosity and/or surface area of grains which are caused by difference in types of sediment or fault activity in sediments. The Line Y18a extends across a major submarine active fault (FA1, Tanoura-Tsunagi-oki-faults) (Kagohara et al., 2011). Such a geological setting suggests that the radon concentration distribution in Yatsushiro sea might reflect the current fault activity. We discuss the contributing factor of the higher radon concentration by comparison with Ra concentration in sediment, sediment properties in each site and geological structure in Yatsushiro sea.

# Application of slug test model to earthquake-related groundwater-level change in the Oi well Kanagawa Prefecture, Center Japan

*Yang Li[1], Motoo Ukawa[1], Kazuhiro Itadera[2], Masatake Harada[2]

1. Nihon University, 2. Hot Spring Research Institute of Kanagawa Prefecture

The sustained groundwater level changes following earthquake have been reported since the early twentieth century, and several mechanisms have been proposed for these phenomena. In this study, we applied slug test model in order to explain time constants of the sustained uplifts observed in the Ohi well, center Japan. The Ohi observation well, 300 m in depth, is one of the deep wells belonging to groundwater level monitoring system established by Hot Springs Research Institute of Kanagawa Prefecture (HSRI). The groundwater level is recorded by pressure gauge in 1 Hz sampling. In the Oi well the groundwater level changes in exponential sustained increase following earthquakes has been documented by HSRI. We selected the events in which groundwater level increased over 5 cm were observed in the period from 2011 to 2016. By fitting these changes with exponential decay function, the time constant of the Ohi well is ranging 100 to 400 s. We show, by applying slug test model, that this time constant range of the uplift of groundwater level is explained by the time constant of the system consisting of the well and the surrounding aquifer. The success of application of the slug test model strongly suggests that the pore-pressure rapidly increased just after the arrival of seismic waves. This time constant rang means the hydraulic permeability almost no change by earthquake.

# Changes in groundwater level and borehole strain data associated with the 2018 Osaka Hokubu earthquake (M6.1) at the Takarazuka observatory

*Norio Matsumoto[1], Tsutomu Kiguchi[1]

1. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST)

Groundwater level sensor and the Sakata-type three-component borehole strainmeter was deployed at the Takarazuka observation well in 1996. We observed changes in groundwater level and borehole strain data associated with the 2018 Osaka Hokubu earthquake (M6.1) at the Takarazuka observatory, which is located 26 km away from the epicenter of the earthquake. Observed groundwater level change was 14 cm decrease just after the earthquake, then, we observed rapid increase: 25 cm increase after one hour and 4.2 m increase after 8 days of the earthquake. These changes in groundwater level cannot be explained by the static strain change associated with the earthquake. We compare these changes with the changes in groundwater level and borehole strain data associated with the other distant and local earthquakes in these 20 years.

Static stress change caused by the megathrust slip of the 2011 $M_w$ 9.0 Tohoku-Oki earthquake considerably affected the seismicity pattern in inland areas, resulting in the occurrence of numerous earthquakes along several active faults in Japan. On June 30, 2011, the $M_j$ 5.4 central Nagano earthquake occurred at a shallow depth of 5 km, indicating the reactivation of the Gofukuji fault in Central Japan. This study was undertaken to elucidate spatial and temporal changes of $^{3}He/^{4}He$ ratios around a source region before and after an inland earthquake using both new and existing helium isotope data from hot spring and drinking water wells. Most gas samples near the seismic source region are characterized by increase in postseismic $^{3}He/^{4}He$ ratios. In contrast, the postseismic ratios decrease by up to about 30 % away from the seismic source region. Episodic faulting could release accumulated crustal (radiogenic) helium from host rocks, or enhance the transfer of mantle volatiles through permeable fault zones, such that subsequent fluid flow proximal to the source region could then explain the spatio-temporal variations in $^{3}He/^{4}He$ ratios.

## [S-CG55] Crustal fluids and deformation

convener:Yuichi Kitagawa(Tectono-Hydrology Research Group, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology), Naoji Koizumi(School of Environmental Science,the University of Shiga Prefecture), Koji Umeda(Hirosaki University), Fumiaki Tsunomori(Geochemical Research Center, Graduate School of Science, University of Tokyo)

We will provide an opportunity to discuss about observation and modeling of crustal fluids. Topics of interests include, but not limited to (1) a field of physics and chemistry of fault fluids, which is related to earthquake occurrences and researches physical and chemical changes of the fluids caused by crustal deformation including earthquakes, (2) a field of earthquake hydrology, which estimates crustal deformation from level, pressure and chemistry of groundwater using poroelastic theory, and (3) a field of chemistry of crustal fluids, which concerns chemical and isotopic features of the crustal fluids and try to estimate the flux of them.

The sustained groundwater level changes following earthquake have been reported since the early twentieth century, and several mechanisms have been proposed for these phenomena. In this study, we applied slug test model in order to explain time constants of the sustained uplifts observed in the Ohi well, center Japan. The Ohi observation well, 300 m in depth, is one of the deep wells belonging to groundwater level monitoring system established by Hot Springs Research Institute of Kanagawa Prefecture (HSRI). The groundwater level is recorded by pressure gauge in 1 Hz sampling. In the Oi well the groundwater level changes in exponential sustained increase following earthquakes has been documented by HSRI. We selected the events in which groundwater level increased over 5 cm were observed in the period from 2011 to 2016. By fitting these changes with exponential decay function, the time constant of the Ohi well is ranging 100 to 400 s. We show, by applying slug test model, that this time constant range of the uplift of groundwater level is explained by the time constant of the system consisting of the well and the surrounding aquifer. The success of application of the slug test model strongly suggests that the pore-pressure rapidly increased just after the arrival of seismic waves. This time constant rang means the hydraulic permeability almost no change by earthquake.

Groundwater level sensor and the Sakata-type three-component borehole strainmeter was deployed at the Takarazuka observation well in 1996. We observed changes in groundwater level and borehole strain data associated with the 2018 Osaka Hokubu earthquake (M6.1) at the Takarazuka observatory, which is located 26 km away from the epicenter of the earthquake. Observed groundwater level change was 14 cm decrease just after the earthquake, then, we observed rapid increase: 25 cm increase after one hour and 4.2 m increase after 8 days of the earthquake. These changes in groundwater level cannot be explained by the static strain change associated with the earthquake. We compare these changes with the changes in groundwater level and borehole strain data associated with the other distant and local earthquakes in these 20 years.

1. Tectono-Hydrology Research Group, Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology (AIST)

Since 1994 groundwater level has been observed at the Kusanagi observation well. Changes in groundwater level associated with the middle –large local earthquakes and the large distant earthquakes were observed. All groundwater level changes associated with these earthquakes were increase. The relationship between these changes in groundwater level and distant and local earthquakes in these 20 years is discussed.

## [S-CG58] Brittle-Ductile Transition and Supercritical Geofluids for Crustal Energy in Island Arc

convener:Noriyoshi Tsuchiya(Graduate School of Environmental Studies, Tohoku University), Hiroshi Asanuma(AIST), Yasuo Ogawa(Volcanic Fluid Research Center, School of Science, Tokyo Institute of Technology), Shigemi Naganawa(Akita University)

Nature of rock mass below the brittle-ductile transition (BDT) is of great scientific interest to understand various phenomenon in the Earth's crust. We will review and discuss current understanding of characteristics the rock mass below the BDT, including composites, stress, failure mechanism induced by liquid injection and associates earthquake generation mechanism, and water rock interaction, considering engineered geothermal development in the BDT. Discussions on the possible phenomena in the geothermal development in the BDT will be followed in this session. <br/> New drilling technology is key of issues. This session will cover advanced drilling technology under high temperature conditions for energy extraction.<br/><br/>

# Mechanical and hydrological properties of granite under supercritical fluid conditions

*Manami Kitamura[1], Miki Takahashi[1]

1. National Institute of Advanced Industrial Science and Technology

To extract geothermal energy effectively and safely from magma and/or adjacent hot rock, we need to tackle many issues which require new technology development. One of them we are targeting on is to develop a technology to mitigate induced-earthquakes. It is required to understand roles of factors on occurrences of the induced-earthquake (e.g., strength, crack density, and fluid-rock reaction) and their intercorrelations (e.g., *Asanuma* et al., 2012).

Our purpose of this series of experiments is to clarify a relationship between the rock strength and the fracture density under hydrothermally supercritical conditions. We conducted triaxial deformation test on intact granite rock strength under high-temperature (250 –750˚C), high-pressure (104 MPa) condition at a constant load velocity (0.1 μm/sec) using a gas-rig at GSJ, AIST. We used Oshima granite, which has initially ~0.55% of the porosity, 4.95±1.01 km/s in Vp at dry condition (dry). All experimental products showed brittle feature having several oblique fracture surfaces, but both value of peak stress and amount of stress drop became smaller at higher temperature. Additionally, Young’s modulus decreases with increasing the temperature from 57.4 GPa at 250˚C to 32.3 GPa at 750˚C. At 400˚C, the stress drop accelerated the deformation with ~98 times faster velocity than that at load-point. In contrast, at 650˚C and 750˚C, the velocity during stress drop kept the same order of the load-point velocity. Therefore, the deformation feature may start to be of ductile when the temperature exceeds 650˚C. The microstructures of samples deformed at 400˚C and 550˚C showed the shear zone with the grain reduction. In contrast, for the samples deformed at 650˚C and 750˚C, we partly observed the sintered structure at grain boundaries among feldspar gouge. The sintered structure at >650°C might be the cause of the slow stress drop. Highly dense cracked granite specimens were formed by a rapid decompression test (RDT) using an autoclave settled at Tohoku University (*Kitamura & Takahashi*, 2017AGU; *Takagi* et al., 2017GRC Trans.), caused by a reduction of the fluid pressure within 2 seconds from vapor/supercritical state pressure (10 –48 MPa, 550 ˚C) to ambient pressure. X-ray CT scanning on the specimens after RDT showed that numerous microcracks were generated in them (see details in *Takahashi & Kitamura*, 2018, annual meeting of Geological Soc. Japan). The RDT imposed the porosity increasing towards 3.91 % and Vp decreasing towards 1.46±0.22 km/s (dry). We conducted the permeability measurement on fractured granites after RDT with the porosity of 2.1 –2.7% under a combined condition of 400 ˚C in temperature, 104 MPa in confining pressure, 39 –99 MPa in pore fluid pressure ($P_p$). Permeability measured by pore pressure oscillation method decreases from $1.3\times10^{-16}$ $m^2$ at $P_p$ of 99 MPa to $2.6\times10^{-18}$ $m^2$ at $P_p$ of 39 MPa for the permeable case. Permeability on fractured granite of 2.1% in porosity at room temperature (RT) show relatively lower permeability than those at 400°C except for at $P_p$ of 99 MPa. Permeability at RT rapidly decreases from $1.0\times10^{-15}$ $m^2$ at $P_p$ of 99 MPa to $1.0\times10^{-18}$ $m^2$ at $P_p$ of 84 MPa, and then reaches $5.8\times10^{-19}$ $m^2$ at $P_p$ of 99 MPa. In the meeting, we will show additional results of permeability tests on fractured granites under various high temperature conditions.

# Three-dimensional electrical resistivity structure of kuju Volcano, Central Kyushu, Japan revealed by Magnetotelluric survey data

*Sabry Abdallah[1], Mitsuru Utsugi [1], Koki Aizawa[2], Makoto Uyeshima[3], Wataru Kanda[4], Takao Koyama[3]

1. Institute of geothermal science, Faculty of Science, Kyoto University, 2. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, 3. Earthquake Research Institute, The University of Tokyo, 4. Volcanic Fluid Research Center, School of Science, Tokyo Institute of Technology

The Kuju volcano is located in south western part of Oita prefecture, Japan , and is one of the important geothermal areas in Japan. It has began to erupt on October 11,1995 at the eastern flank of Mt. Hossho, which is in the central part of Kuju volcano. Second eruption started again in the middle of December, 1995, producing an ash volume of about 5000 $m^3$. Iwoyama is the central part Kuju Volcano and considered to be one of the most hydrothermal active hydrothermal field in Japan. Geothermal areas beneath active volcanoes may have an important role in geothermal energy development in the future. so it is important to monitor and clarify the thermal and hydrologic processes occurring beneath volcanoes. Magnetotelluric (MT) investigation is an important tool to identify the subsurface resistivity structure using natural variation in the electromagnetic field, therefore it is convenient to for the hydrothermal system investigation. We applied a Wide-band MT survey method to identify the structures associated with the hydrothermal systems beneath Kuju volcano. MT field survey data were collected at 63 observation points around the Kuju volcano from September to October 2015. Fourier Transform(FT) applied to the collected data to reduce the background noise associated with Power supply of 60 Hz and other noises associated with higher frequencies. Inverse FT was applied to the data to transform from frequency-domain to time-domain data. The 3-D resistivity structure model is obtained by inverting the MT impedance using ModEM code (Kelbert, A. et al., 2014). The primary 3-D resistivity structure model clarified that, a resistive structure (100-300 Ω.m) prevail the most of Kuju Volcano area. A very conductive structure (~1Ω.m) exists around Iowyama-Kuju area and extends with the depth towards the south-east part of Iowyama. In comparison with the previous studies, the resistive structure can be interpreted as lava and pyroclastic deposits, whereas the conductive structure around Iowyama-Kuju area is maybe corresponds to aquifers and altered layers.

# Preliminary Report on Themoluminescence Geothermal Exploration in Northern Area of Mt. Kurikoma (Akayumata-River), NE Japan.

*Hiroki Okano[1], Nobuo Hirano[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies Tohoku University

Thermoluminescence (TL) is a method to evaluate radiation dose accumulated in minerals by heating minerals and analyzing luminescence. We can evaluate geothermal manifestation through analyzing the variation of Paleodose in minerals caused by geothermal activities. In this study, geological survey waa performed around Mt. Takamatsudake in the northern area of Mt. Kurikoma, and We estimated geothermal structure of the area and relation between TL distribution and geothermal structure.

In the exploration area, the Takamatsudake lava is distributed around Mt. Takamatsudake, and in the lower part, Torageyama tuff formation is distributed , and also Doroyu fomation composed of mudstone is distributed in the lower part of the Torageyama tuff fomation. 33 samples were collected from Torageyama tuff and Doroyu fomation.

As a result of TL analysis, TL anomalies were confirmed downstream of Akayumata-river hot springs. However, no significant TL anomalies was observed around Yunomata hot springs. In Akayumata H.S(hot spring), boiling water are discharging from a few places, whereas Yunomata H.S are only spouted from one point at 50 ℃. In the earthquake hypocentral distribution from 1985 to 2015, hypocentral clusters are confirmed at shallow part arounf 2 ~ 7 km beneath Akayumata and Yunomata H.S, and it may suggest the existence of a fluid. Around Akayumata H.S, the mud layer is exposed with a local anticline structure. We suggest that hot water discharge to the surface along with cracks and faults associated with these geological structure.

As a result of alteration mineral analysis, both the Torageyama F. and the Doroyu F. were confirmed to have a Green Tuff alteration due to chlorite and sericite. In addition, kaolinite was found near the Akayumata H.S, and laumontite was found around Yunomata H.S. and upstream of Akayumata-river. TL anomaly is harmonious with the distribution of kaolinite, but the weakly related to the distribution of laumontite. From this point of view, it is predicted that TL has information on the temperature-time effect, which is different from altered minerals. By investigating more detailed underground structures in the future and conducting quantitative analysis on the temperature dependency of TL, it is expected that the accuracy of information given by the surface TL data can be improved.

# Experimental Study of Critical Point Determination for Multicomponent Fluids using light-scattering Spectroscopic Method

*Nobuo Hirano[1], Yuta Oshima[1], Atsushi Okamoto[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental studies, Tohoku University

Geofluid is a multicomponent fluid by reaction with various crustal materials, and it is in a supercritical state under high temperature and high pressure conditions inside the Earth. It is very important to know the critical point (CP) and phase state of a geo-fluid in order to know the fluid-rock reaction mechanism under high temperature and high pressure conditions. However, it is difficult to directly determine CP of multicomponent fluid such as geological fluid and sea water by calculation using state equation (EOS) using fluid components, and it is necessary to decide experimentally.
Molecules in the supercritical fluid are unevenly distributed and are known to form both high density and sparse molecular regions in the fluid. Such nonuniformity of molecular distribution is called density fluctuation, and this degree becomes maximum at CP of fluid.
Therefore, for pure material such as H 2 O and CO 2, the critical opalescence is spectroscopically observed at the subcritical to supercritical transition. Therefore, if the density variation of the multicomponent fluid can be observed by a spectroscopic method, it is possible to determine the CP value.
The objective of this study is to establish a new measurement technique / procedure for easily determining CP of multicomponent fluid using spectroscopic observation of subcritical / supercritical transition state.

# Transport and Reaction Behavior of Supercritical Geofluid Revealed by Porphyry Copper Deposit

*Geri Agroli[1], Noriyoshi Tsuchiya[1]

1. Tohoku University

Supercritical geothermal reservoir (SCGR) is a novel system in the geothermal field. Recently this geothermal system got a lot of attention from scholar since the successful of IDDP that encountered the supercritical fluid in Reykjanes and Krafla geothermal field. SCGR is promising exploited geothermal resource in the near future with several benefits in the economic and technical aspect. However the limited access to geological properties of SCGR system to optimize the potential of the system as well as to address the issue of the system lead us to investigate the natural analog that suitable with this system, Instead of we spend huge money for drilling activity. Porphyry copper deposit is a suitable candidate for SCGR analog where magma ascent from deep mantle and fluid infiltrate a ductile rock mass at ~600˚C, and stock work fracture as an important fluid pathway developed intensively.

The research was conducted on the largest porphyry copper deposit in northern Mongolia called Erdenet deposit. We used 700m depth drill core samples from an open pit. Based on texture and mineralogy, lithology of Erdenet comprises of quartz porphyry and granodiorite porphyry at shallow and deep level consecutively. Mineral assemblages of Quartz porphyry are qtz-ser-py-cp±cal and chl-plg-qtz±kfs for Granodiorite porphyry. Stockwork vein system can be well observed on certain samples and Er-22 (569.9m) reveal distinct vein generation process and evolution based on cross-cutting relationship. Qtz-Mo vein precipitated at the beginning of the process followed by the formation qtz-py±cp vein and those 2 vein type cut by qtz±cal vein. Fluid activity was investigated by several analytical techniques to measure mineral composition to further obtain thermodynamics properties (P-T conditions). Host rock crystallize at temperature 389-861˚C (measurement point from core to rim) using Ti-in-Quartz geothermometer under lithostatic pressure derived from a cotectic line in the Qz-Ab-Or ternary diagram. The similar methods perform to obtain quartz precipitation temperature of qtz-mo vein and the result show vein was precipitated at 323-678˚C (measurement point from core to rim). Fluid inclusion is a useful technique to determine the precipitation of the other two vein type. Qtz-py±cp vein homogenizes at temperature 147.8-358.9˚C with median 251.9˚C but the pressure regime and salinity of fluid are difficult to measure due to most of the inclusion size is less than 5 $\mu$m. The last fluid activity marked by the presence of qtz±cal that cut all of the previous veins. The homogenization temperature is less than 200˚C.

The distribution of vein in the granodiorite porphyry system in Erdenet revealed the evolution of fluid in order to understand the geological properties of a supercritical geothermal reservoir. The emplacement of granodiorite at >600˚C followed by formation of qtz-mo vein that interpreted to have formed in the supercritical regime at 500-600˚C under lithostatic pressure and subsequent pressure drop to hydrostatic condition induce qtz-py±cp vein formation due to drop of silica solubility. Lithostatic to hydrostatic pressure shifting indicate by the presence of pervasive sericite alteration imply meteoric water had circulated into the system. The temperature of the system keeps decrease and precipitation of qtz±cal occurred as the last product on this system. Erdenet Cu-Mo provides a lesson regarding on fluid process and development of supercritical geothermal activity and strong candidate as a natural analog for advanced scientific studied in the future.

# Characteristics of precipitation of amorphous silica and its influences on permeability of fractured granite in superhot geothermal environments

*Hikaru Abe[1], Noriaki Watanabe[1], Kengo Nakamura[1], Atsushi Okamoto[1], Takeshi Komai[1]

1. Graduate School of Environmental Studies, Tohoku University

Superhot geothermal environments (above ca. 400˚C) represent a new geothermal energy frontier. However, the networks of permeable fractures capable of storing and transmitting fluids are likely to sealed by a rapid precipitation of amorphous silica in response to an occurrence of high-level of supersaturation for amorphous silica due to a phase change between liquid water, steam, and supercritical water. Here we report results of two sets of hydrothermal precipitation experiments at 400-500˚C and 20-35 MPa, which were respectively conducted to investigate characteristics of precipitation of amorphous silica and its influences on permeability of fractured granite in superhot geothermal environments. In the first set of the precipitation experiments, liquid water with a prescribed Si concentration, which was prepared from water that dissolved granite at 360 ˚C and 35 MPa, was injected to a stainless-steel pipe, in which amorphous silica was precipitated at a prescribed combination of temperature (400-500˚C), pressure (20-35 MPa) and degree of saturation (1.5-2.5). As a result, spherical particles of amorphous silica of <10 μm (typically, 0.2-1.0 μm) were precipitated at all conditions. These particles tended to become smaller and aggregated with increasing temperature or degree of saturation (i.e., with increasing rate of nucleation), while there was no significant influence of pressure. Based on this finding, the second set of the precipitation experiments to investigate influences of the amorphous silica particles on permeability of fractured granite was conducted at 450°C, 25 MPa, and different degrees of saturation. The above-mentioned liquid water with a prescribed Si concentration was injected into a thermally fractured granite containing multiple fractures at an effective confining stress of 10 MPa, where initial permeability of the fractured granite was relatively high (ca. $10^{-16}$ $m^2$) because of the presence of fractures having relatively large apertures of >10 μm. As a result, permeability did not decrease with time at both conditions for the formations of larger and dispersed particles, and smaller and aggregated particles. This finding indicates that precipitation of amorphous silica does not always reduce permeability of fractured granite immediately, and silica particles will move to other locations after its formation. Therefore, in producing superhot geothermal energy, amorphous silica particles will be produced via a production well or will be trapped within fractured granite having a relatively lower initial permeability, therefore relatively smaller apertures. Although the present study has not been completed yet, it is suggested that in case of a superhot geothermal reservoir with permeability aperture large enough to transmit the amorphous silica particle, the permeability may not be destroyed even if precipitation of amorphous silica occurs rapidly.

# Evolution and The Total Budget of Fluid in Granitic Magma through Magmatism and Volcanism in The Subduction Zone, NE Japan

*Fajar Febiani Amanda[1], Ryoichi Yamada[2], Satoshi Okumura[2], Masaoki Uno[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University, 2. Graduate School of Science, Tohoku University

Fluids (especially water) are carried by oceanic plates which are subducted into the depth of the mantle and released through the dehydration process. Water migrates upward and contributes to the melting of the mantle wedge in the formation of an arc magma. The formation of volcanoes and igneous rocks as plutons in the arc magma produces geothermal energy sources and the formation of ore mineral deposits. Throughout its migration within the crust, the fluid evolves both in temperature and pressure, composition and amount. These fluid traces can be found among the minerals as melt and/or fluid inclusions in volcanic products, igneous plutons, and the veinlets. In this study, water budget estimated on the crust by determining the condition of P-T and composition of fluids in the volcanic rocks and igneous plutons including the host rock and veinlets.

Samples were taken from caldera fill sediment and porphyry copper deposits in NE Japan region. The P-T condition and fluid composition are measured from the melt inclusion in quartz from the caldera fill sediments and fluid inclusions in the granite intrusion and the veinlets. The sample is divided into several types, namely volcanic rock samples from caldera fill sediment, granite from porphyry copper deposits, and the veinlets contained in the granite body including quartz vein, glassy vein, and hydrothermal breccia vein. In volcanic rock samples, quartz crystals were picked, encased in resin and polished for major element and water content analysis. In granite samples and veinlets, the rock thin sections were made for fluid inclusion microthermometry analysis and fluid diffusion analysis using apatite mineral. Water budget in the upper crust is estimated from caldera fill sediments to be 2.3–7.6 t /yr/m. Water budget in the deeper part of the crust can then be determined from porphyry copper deposits.

# Porosity generation during feldspar replacement as the mark of potassium-rich supercritical fluids on the top of granitic intrusion

*Astin Nurdiana[1], Atsushi Okamoto[1], Masaoki Uno[1], Kenta Yoshida[2], Noriyoshi Tsuchiya[1]

1. Tohoku University, 2. Japan Agency for Marine-earth Science and Technology

Feldspar replacement is prevalent process within the crust which has been studied for decades. In particular, it is known that feldspar is texturally sensitive to an interaction with fluids, and the process often results in by the pore generation. Recently, Plümper, et al. (2017) proposed that such reaction-induced nanoporosity plays significant roles in pervasive fluid flow in the crusts, yet it is still unclear until what extent nanoporosity commonly presents and is affected by the feldspar replacement. In this study, we report novel pore structures that have been produced during feldspar replacement in the hornblende schist around the granitoid body.

The Kinkasan Island, which is part of southern Kitakami Mountains, mainly consists of the Cretaceous granitoid bodies with abundant pegmatite dikes, and metamorphic sequences, including hornblende (Hbl) schists and biotite schists. Quartz diorite, as the host plutonic body, and metamorphic rocks were formed under the conditions estimated to be 700-750˚C and 610-660˚C in 0.37-0.42 GPa, respectively. The Hbl schists are often cut by thin alkali feldspar veins in direction perpendicular to the foliation. In the matrix, primordial plagioclase grains (An48Ab52Or0) are generally replaced by patchy grains of albite (An4Ab94Or2) and alkali feldspar (An0Ab1Or99). The mass balance analyses of the plagioclase and alteration products show the gains of Si, K, and fewer Na, also loss of Ca and Al, indicating that feldspar replacement was induced by infiltration of the potassium-rich fluids (the K/Na molar ratio of 3). The detail observations by FIB-SEM reveal that the replacement process yields extensive amount of pore with throat size of ~0.1 –5 $\mu$m. These pores preferentially formed along the grain boundaries of newly-produced albite. Generally, the pores distribute throughout all the plagioclase grains without preference for matrix grain boundary, and formed 3D pore network that seems barely to continue. However, it increased the porosity of the rock up to ~2%. These features of pores related to the feldspar replacement suggests the importance of the reactive fluid infiltration through low-permeability metamorphic rocks, likewise give a new insight on how fluid propagation generate micro-to nano-scale porosity.

# Quantitative evaluation of fracture distribution in granite and the relationship between fracture distribution and physical properties

*Manami Kadono[1], Shin-ichi Uehara[2], Miki Takahashi[3], Manami Kitamura[3]

1. Department of Environment Systems, Graduate School of frontier Science, The University of Tokyo, 2. Department of Enviroment Science, Faculty of Science, Toho University, 3. National Institute of Advanced Industrial Science and Technology

Recently, geothermal uses in the depth below the brittle-ductile boundary have been considered for collecting geothermal energy more efficiently than conventional geothermal uses [1]. One of them is supercritical geothermal power generation, which uses supercritical fluid of higher temperature and pressure than conventional type, and therefore output per power plant is expected to be increased [2]. In this geothermal development, there is a plan to artificially create geothermal reservoirs when the geothermal fluid enough for the power generation capacity does not exist in the rock. These artificial reservoirs are planned to be created through processes such as cooling rocks by water injection, emergence of brittle region, causing hydraulic fracturing, and then emergence of high permeability region. Here, crack generation and propagation by injecting water and cooling rock have some possibility of inducing earthquakes. Therefore, it is important to elucidate properties of crack generation and propagation in the rock in this situation. However, these properties have not been understood enough. In addition, clarifying the relationship between properties of crack distributions and elastic wave velocities, which is not established so far, may be of useful for investigating the crack distributions at actual geothermal development sites by elastic wave explorations.
In this study, we generate cracks in granite specimens by heating them up to 550℃ then cooling, and we clarified the relationship between the cooling rate and the conditions of crack distributions in the specimens. We also tried to clarify the relation between the crack conditions and physical properties such as (elastic wave velocity, porosity and elastic properties derived from the elastic wave velocities) .
Cylindrical specimens (20 mm in the diameter and 40 mm in the length) of granite from Oshima, Ehime Prefecture (initial porosity: <0.38 %, P and S wave velocity ($V_P$), ($V_S$) under water saturated condition: 5.96±0.14, 3.10±0.10 km/s, respectively) were used for the experiments. After being heated the specimens, were cooled in three ways with different cooling rates for the surface temperature (approximately 3.3 ℃/min, 17.7℃/min, and 516 ℃/sec). Observations of X-ray CT images revealed that microscopic cracks were generated in the specimens after the heating-cooling processes. Cracks were extracted from this CT images and the number of cracks was measured. The number of cracks per image (20 mm×40 mm) $N$ was $600 < N < 2600$, and the faster the cooling rate was, the larger $N$ per unit area was. This is probably because faster cooling rate causes the greater temperature difference between the center and surface of specimens, which causes larger difference in the degree of shrinkage of the minerals constituting the specimens, and then the minerals are easier to be separated from each other. When $N$ is lager, the porosity is larger (0.60 - 0.82%), and $V_P$ and $V_S$ are smaller (4.63 - 4.86 and 1.69 - 2.15 km/s, respectively). Bulk modulus and shear modulus were decreased from 61 - 65 to 45 - 48 GPa and 24 - 26 to 7 - 13 GPa, respectively, through the heating-cooling processes. In the presentation, we will investigate the relationship between $p$, a parameter representing the distribution propability of cracks defined by Hestir & Long [3], and physical properties.

## [S-CG58] Brittle-Ductile Transition and Supercritical Geofluids for Crustal Energy in Island Arc

convener:Noriyoshi Tsuchiya(Graduate School of Environmental Studies, Tohoku University), Hiroshi Asanuma(AIST), Yasuo Ogawa(Volcanic Fluid Research Center, School of Science, Tokyo Institute of Technology), Shigemi Naganawa(Akita University)

Nature of rock mass below the brittle-ductile transition (BDT) is of great scientific interest to understand various phenomenon in the Earth's crust. We will review and discuss current understanding of characteristics the rock mass below the BDT, including composites, stress, failure mechanism induced by liquid injection and associates earthquake generation mechanism, and water rock interaction, considering engineered geothermal development in the BDT. Discussions on the possible phenomena in the geothermal development in the BDT will be followed in this session. <br/> New drilling technology is key of issues. This session will cover advanced drilling technology under high temperature conditions for energy extraction.<br/><br/>

# Mechanical and hydrological properties of granite under supercritical fluid conditions

*Manami Kitamura[1], Miki Takahashi[1]

1. National Institute of Advanced Industrial Science and Technology

To extract geothermal energy effectively and safely from magma and/or adjacent hot rock, we need to tackle many issues which require new technology development. One of them we are targeting on is to develop a technology to mitigate induced-earthquakes. It is required to understand roles of factors on occurrences of the induced-earthquake (e.g., strength, crack density, and fluid-rock reaction) and their intercorrelations (e.g., *Asanuma* et al., 2012).

Our purpose of this series of experiments is to clarify a relationship between the rock strength and the fracture density under hydrothermally supercritical conditions. We conducted triaxial deformation test on intact granite rock strength under high-temperature (250 –750˚C), high-pressure (104 MPa) condition at a constant load velocity (0.1 μm/sec) using a gas-rig at GSJ, AIST. We used Oshima granite, which has initially ~0.55% of the porosity, 4.95±1.01 km/s in Vp at dry condition (dry). All experimental products showed brittle feature having several oblique fracture surfaces, but both value of peak stress and amount of stress drop became smaller at higher temperature. Additionally, Young’s modulus decreases with increasing the temperature from 57.4 GPa at 250˚C to 32.3 GPa at 750˚C. At 400˚C, the stress drop accelerated the deformation with ~98 times faster velocity than that at load-point. In contrast, at 650˚C and 750˚C, the velocity during stress drop kept the same order of the load-point velocity. Therefore, the deformation feature may start to be of ductile when the temperature exceeds 650˚C. The microstructures of samples deformed at 400˚C and 550˚C showed the shear zone with the grain reduction. In contrast, for the samples deformed at 650˚C and 750˚C, we partly observed the sintered structure at grain boundaries among feldspar gouge. The sintered structure at >650°C might be the cause of the slow stress drop. Highly dense cracked granite specimens were formed by a rapid decompression test (RDT) using an autoclave settled at Tohoku University (*Kitamura & Takahashi*, 2017AGU; *Takagi* et al., 2017GRC Trans.), caused by a reduction of the fluid pressure within 2 seconds from vapor/supercritical state pressure (10 –48 MPa, 550 ˚C) to ambient pressure. X-ray CT scanning on the specimens after RDT showed that numerous microcracks were generated in them (see details in *Takahashi & Kitamura*, 2018, annual meeting of Geological Soc. Japan). The RDT imposed the porosity increasing towards 3.91 % and Vp decreasing towards 1.46±0.22 km/s (dry). We conducted the permeability measurement on fractured granites after RDT with the porosity of 2.1 –2.7% under a combined condition of 400 ˚C in temperature, 104 MPa in confining pressure, 39 –99 MPa in pore fluid pressure ($P_p$). Permeability measured by pore pressure oscillation method decreases from $1.3\times10^{-16}$ $m^2$ at $P_p$ of 99 MPa to $2.6\times10^{-18}$ $m^2$ at $P_p$ of 39 MPa for the permeable case. Permeability on fractured granite of 2.1% in porosity at room temperature (RT) show relatively lower permeability than those at 400°C except for at $P_p$ of 99 MPa. Permeability at RT rapidly decreases from $1.0\times10^{-15}$ $m^2$ at $P_p$ of 99 MPa to $1.0\times10^{-18}$ $m^2$ at $P_p$ of 84 MPa, and then reaches $5.8\times10^{-19}$ $m^2$ at $P_p$ of 99 MPa. In the meeting, we will show additional results of permeability tests on fractured granites under various high temperature conditions.

# Three-dimensional electrical resistivity structure of kuju Volcano, Central Kyushu, Japan revealed by Magnetotelluric survey data

*Sabry Abdallah[1], Mitsuru Utsugi [1], Koki Aizawa[2], Makoto Uyeshima[3], Wataru Kanda[4], Takao Koyama[3]

1. Institute of geothermal science, Faculty of Science, Kyoto University, 2. Institute of Seismology and Volcanology, Faculty of Sciences, Kyushu University, 3. Earthquake Research Institute, The University of Tokyo, 4. Volcanic Fluid Research Center, School of Science, Tokyo Institute of Technology

The Kuju volcano is located in south western part of Oita prefecture, Japan , and is one of the important geothermal areas in Japan. It has began to erupt on October 11,1995 at the eastern flank of Mt. Hossho, which is in the central part of Kuju volcano. Second eruption started again in the middle of December, 1995, producing an ash volume of about 5000 $m^3$. Iwoyama is the central part Kuju Volcano and considered to be one of the most hydrothermal active hydrothermal field in Japan. Geothermal areas beneath active volcanoes may have an important role in geothermal energy development in the future. so it is important to monitor and clarify the thermal and hydrologic processes occurring beneath volcanoes. Magnetotelluric (MT) investigation is an important tool to identify the subsurface resistivity structure using natural variation in the electromagnetic field, therefore it is convenient to for the hydrothermal system investigation. We applied a Wide-band MT survey method to identify the structures associated with the hydrothermal systems beneath Kuju volcano. MT field survey data were collected at 63 observation points around the Kuju volcano from September to October 2015. Fourier Transform(FT) applied to the collected data to reduce the background noise associated with Power supply of 60 Hz and other noises associated with higher frequencies. Inverse FT was applied to the data to transform from frequency-domain to time-domain data. The 3-D resistivity structure model is obtained by inverting the MT impedance using ModEM code (Kelbert, A. et al., 2014). The primary 3-D resistivity structure model clarified that, a resistive structure (100-300 Ω.m) prevail the most of Kuju Volcano area. A very conductive structure (~1Ω.m) exists around Iowyama-Kuju area and extends with the depth towards the south-east part of Iowyama. In comparison with the previous studies, the resistive structure can be interpreted as lava and pyroclastic deposits, whereas the conductive structure around Iowyama-Kuju area is maybe corresponds to aquifers and altered layers.

# Preliminary Report on Themoluminescence Geothermal Exploration in Northern Area of Mt. Kurikoma (Akayumata-River), NE Japan.

*Hiroki Okano[1], Nobuo Hirano[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies Tohoku University

Thermoluminescence (TL) is a method to evaluate radiation dose accumulated in minerals by heating minerals and analyzing luminescence. We can evaluate geothermal manifestation through analyzing the variation of Paleodose in minerals caused by geothermal activities. In this study, geological survey waa performed around Mt. Takamatsudake in the northern area of Mt. Kurikoma, and We estimated geothermal structure of the area and relation between TL distribution and geothermal structure.

In the exploration area, the Takamatsudake lava is distributed around Mt. Takamatsudake, and in the lower part, Torageyama tuff formation is distributed , and also Doroyu fomation composed of mudstone is distributed in the lower part of the Torageyama tuff fomation. 33 samples were collected from Torageyama tuff and Doroyu fomation.

As a result of TL analysis, TL anomalies were confirmed downstream of Akayumata-river hot springs. However, no significant TL anomalies was observed around Yunomata hot springs. In Akayumata H.S(hot spring), boiling water are discharging from a few places, whereas Yunomata H.S are only spouted from one point at 50 ℃. In the earthquake hypocentral distribution from 1985 to 2015, hypocentral clusters are confirmed at shallow part arounf 2 ~ 7 km beneath Akayumata and Yunomata H.S, and it may suggest the existence of a fluid. Around Akayumata H.S, the mud layer is exposed with a local anticline structure. We suggest that hot water discharge to the surface along with cracks and faults associated with these geological structure.

As a result of alteration mineral analysis, both the Torageyama F. and the Doroyu F. were confirmed to have a Green Tuff alteration due to chlorite and sericite. In addition, kaolinite was found near the Akayumata H.S, and laumontite was found around Yunomata H.S. and upstream of Akayumata-river. TL anomaly is harmonious with the distribution of kaolinite, but the weakly related to the distribution of laumontite. From this point of view, it is predicted that TL has information on the temperature-time effect, which is different from altered minerals. By investigating more detailed underground structures in the future and conducting quantitative analysis on the temperature dependency of TL, it is expected that the accuracy of information given by the surface TL data can be improved.

# Experimental Study of Critical Point Determination for Multicomponent Fluids using light-scattering Spectroscopic Method

*Nobuo Hirano[1], Yuta Oshima[1], Atsushi Okamoto[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental studies, Tohoku University

Geofluid is a multicomponent fluid by reaction with various crustal materials, and it is in a supercritical state under high temperature and high pressure conditions inside the Earth. It is very important to know the critical point (CP) and phase state of a geo-fluid in order to know the fluid-rock reaction mechanism under high temperature and high pressure conditions. However, it is difficult to directly determine CP of multicomponent fluid such as geological fluid and sea water by calculation using state equation (EOS) using fluid components, and it is necessary to decide experimentally.
Molecules in the supercritical fluid are unevenly distributed and are known to form both high density and sparse molecular regions in the fluid. Such nonuniformity of molecular distribution is called density fluctuation, and this degree becomes maximum at CP of fluid.
Therefore, for pure material such as H 2 O and CO 2, the critical opalescence is spectroscopically observed at the subcritical to supercritical transition. Therefore, if the density variation of the multicomponent fluid can be observed by a spectroscopic method, it is possible to determine the CP value.
The objective of this study is to establish a new measurement technique / procedure for easily determining CP of multicomponent fluid using spectroscopic observation of subcritical / supercritical transition state.

# Transport and Reaction Behavior of Supercritical Geofluid Revealed by Porphyry Copper Deposit

*Geri Agroli[1], Noriyoshi Tsuchiya[1]

1. Tohoku University

Supercritical geothermal reservoir (SCGR) is a novel system in the geothermal field. Recently this geothermal system got a lot of attention from scholar since the successful of IDDP that encountered the supercritical fluid in Reykjanes and Krafla geothermal field. SCGR is promising exploited geothermal resource in the near future with several benefits in the economic and technical aspect. However the limited access to geological properties of SCGR system to optimize the potential of the system as well as to address the issue of the system lead us to investigate the natural analog that suitable with this system, Instead of we spend huge money for drilling activity. Porphyry copper deposit is a suitable candidate for SCGR analog where magma ascent from deep mantle and fluid infiltrate a ductile rock mass at ~600˚C, and stock work fracture as an important fluid pathway developed intensively.

The research was conducted on the largest porphyry copper deposit in northern Mongolia called Erdenet deposit. We used 700m depth drill core samples from an open pit. Based on texture and mineralogy, lithology of Erdenet comprises of quartz porphyry and granodiorite porphyry at shallow and deep level consecutively. Mineral assemblages of Quartz porphyry are qtz-ser-py-cp±cal and chl-plg-qtz±kfs for Granodiorite porphyry. Stockwork vein system can be well observed on certain samples and Er-22 (569.9m) reveal distinct vein generation process and evolution based on cross-cutting relationship. Qtz-Mo vein precipitated at the beginning of the process followed by the formation qtz-py±cp vein and those 2 vein type cut by qtz±cal vein. Fluid activity was investigated by several analytical techniques to measure mineral composition to further obtain thermodynamics properties (P-T conditions). Host rock crystallize at temperature 389-861˚C (measurement point from core to rim) using Ti-in-Quartz geothermometer under lithostatic pressure derived from a cotectic line in the Qz-Ab-Or ternary diagram. The similar methods perform to obtain quartz precipitation temperature of qtz-mo vein and the result show vein was precipitated at 323-678˚C (measurement point from core to rim). Fluid inclusion is a useful technique to determine the precipitation of the other two vein type. Qtz-py±cp vein homogenizes at temperature 147.8-358.9˚C with median 251.9˚C but the pressure regime and salinity of fluid are difficult to measure due to most of the inclusion size is less than 5 $\mu$m. The last fluid activity marked by the presence of qtz±cal that cut all of the previous veins. The homogenization temperature is less than 200˚C.

The distribution of vein in the granodiorite porphyry system in Erdenet revealed the evolution of fluid in order to understand the geological properties of a supercritical geothermal reservoir. The emplacement of granodiorite at >600˚C followed by formation of qtz-mo vein that interpreted to have formed in the supercritical regime at 500-600˚C under lithostatic pressure and subsequent pressure drop to hydrostatic condition induce qtz-py±cp vein formation due to drop of silica solubility. Lithostatic to hydrostatic pressure shifting indicate by the presence of pervasive sericite alteration imply meteoric water had circulated into the system. The temperature of the system keeps decrease and precipitation of qtz±cal occurred as the last product on this system. Erdenet Cu-Mo provides a lesson regarding on fluid process and development of supercritical geothermal activity and strong candidate as a natural analog for advanced scientific studied in the future.

# Characteristics of precipitation of amorphous silica and its influences on permeability of fractured granite in superhot geothermal environments

*Hikaru Abe[1], Noriaki Watanabe[1], Kengo Nakamura[1], Atsushi Okamoto[1], Takeshi Komai[1]

1. Graduate School of Environmental Studies, Tohoku University

Superhot geothermal environments (above ca. 400˚C) represent a new geothermal energy frontier. However, the networks of permeable fractures capable of storing and transmitting fluids are likely to sealed by a rapid precipitation of amorphous silica in response to an occurrence of high-level of supersaturation for amorphous silica due to a phase change between liquid water, steam, and supercritical water. Here we report results of two sets of hydrothermal precipitation experiments at 400-500˚C and 20-35 MPa, which were respectively conducted to investigate characteristics of precipitation of amorphous silica and its influences on permeability of fractured granite in superhot geothermal environments. In the first set of the precipitation experiments, liquid water with a prescribed Si concentration, which was prepared from water that dissolved granite at 360 ˚C and 35 MPa, was injected to a stainless-steel pipe, in which amorphous silica was precipitated at a prescribed combination of temperature (400-500˚C), pressure (20-35 MPa) and degree of saturation (1.5-2.5). As a result, spherical particles of amorphous silica of <10 μm (typically, 0.2-1.0 μm) were precipitated at all conditions. These particles tended to become smaller and aggregated with increasing temperature or degree of saturation (i.e., with increasing rate of nucleation), while there was no significant influence of pressure. Based on this finding, the second set of the precipitation experiments to investigate influences of the amorphous silica particles on permeability of fractured granite was conducted at 450°C, 25 MPa, and different degrees of saturation. The above-mentioned liquid water with a prescribed Si concentration was injected into a thermally fractured granite containing multiple fractures at an effective confining stress of 10 MPa, where initial permeability of the fractured granite was relatively high (ca. $10^{-16}$ $m^2$) because of the presence of fractures having relatively large apertures of >10 μm. As a result, permeability did not decrease with time at both conditions for the formations of larger and dispersed particles, and smaller and aggregated particles. This finding indicates that precipitation of amorphous silica does not always reduce permeability of fractured granite immediately, and silica particles will move to other locations after its formation. Therefore, in producing superhot geothermal energy, amorphous silica particles will be produced via a production well or will be trapped within fractured granite having a relatively lower initial permeability, therefore relatively smaller apertures. Although the present study has not been completed yet, it is suggested that in case of a superhot geothermal reservoir with permeability aperture large enough to transmit the amorphous silica particle, the permeability may not be destroyed even if precipitation of amorphous silica occurs rapidly.

# Evolution and The Total Budget of Fluid in Granitic Magma through Magmatism and Volcanism in The Subduction Zone, NE Japan

*Fajar Febiani Amanda[1], Ryoichi Yamada[2], Satoshi Okumura[2], Masaoki Uno[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University, 2. Graduate School of Science, Tohoku University

Fluids (especially water) are carried by oceanic plates which are subducted into the depth of the mantle and released through the dehydration process. Water migrates upward and contributes to the melting of the mantle wedge in the formation of an arc magma. The formation of volcanoes and igneous rocks as plutons in the arc magma produces geothermal energy sources and the formation of ore mineral deposits. Throughout its migration within the crust, the fluid evolves both in temperature and pressure, composition and amount. These fluid traces can be found among the minerals as melt and/or fluid inclusions in volcanic products, igneous plutons, and the veinlets. In this study, water budget estimated on the crust by determining the condition of P-T and composition of fluids in the volcanic rocks and igneous plutons including the host rock and veinlets.

Samples were taken from caldera fill sediment and porphyry copper deposits in NE Japan region. The P-T condition and fluid composition are measured from the melt inclusion in quartz from the caldera fill sediments and fluid inclusions in the granite intrusion and the veinlets. The sample is divided into several types, namely volcanic rock samples from caldera fill sediment, granite from porphyry copper deposits, and the veinlets contained in the granite body including quartz vein, glassy vein, and hydrothermal breccia vein. In volcanic rock samples, quartz crystals were picked, encased in resin and polished for major element and water content analysis. In granite samples and veinlets, the rock thin sections were made for fluid inclusion microthermometry analysis and fluid diffusion analysis using apatite mineral. Water budget in the upper crust is estimated from caldera fill sediments to be 2.3–7.6 t /yr/m. Water budget in the deeper part of the crust can then be determined from porphyry copper deposits.

Keywords: water budget, fluid evolution, melt inclusion, fluid inclusion

# Porosity generation during feldspar replacement as the mark of potassium-rich supercritical fluids on the top of granitic intrusion

*Astin Nurdiana[1], Atsushi Okamoto[1], Masaoki Uno[1], Kenta Yoshida[2], Noriyoshi Tsuchiya[1]

1. Tohoku University, 2. Japan Agency for Marine-earth Science and Technology

Feldspar replacement is prevalent process within the crust which has been studied for decades. In particular, it is known that feldspar is texturally sensitive to an interaction with fluids, and the process often results in by the pore generation. Recently, Plümper, et al. (2017) proposed that such reaction-induced nanoporosity plays significant roles in pervasive fluid flow in the crusts, yet it is still unclear until what extent nanoporosity commonly presents and is affected by the feldspar replacement. In this study, we report novel pore structures that have been produced during feldspar replacement in the hornblende schist around the granitoid body.

The Kinkasan Island, which is part of southern Kitakami Mountains, mainly consists of the Cretaceous granitoid bodies with abundant pegmatite dikes, and metamorphic sequences, including hornblende (Hbl) schists and biotite schists. Quartz diorite, as the host plutonic body, and metamorphic rocks were formed under the conditions estimated to be 700-750˚C and 610-660˚C in 0.37-0.42 GPa, respectively. The Hbl schists are often cut by thin alkali feldspar veins in direction perpendicular to the foliation. In the matrix, primordial plagioclase grains (An48Ab52Or0) are generally replaced by patchy grains of albite (An4Ab94Or2) and alkali feldspar (An0Ab1Or99). The mass balance analyses of the plagioclase and alteration products show the gains of Si, K, and fewer Na, also loss of Ca and Al, indicating that feldspar replacement was induced by infiltration of the potassium-rich fluids (the K/Na molar ratio of 3). The detail observations by FIB-SEM reveal that the replacement process yields extensive amount of pore with throat size of ~0.1 –5 $\mu$m. These pores preferentially formed along the grain boundaries of newly-produced albite. Generally, the pores distribute throughout all the plagioclase grains without preference for matrix grain boundary, and formed 3D pore network that seems barely to continue. However, it increased the porosity of the rock up to ~2%. These features of pores related to the feldspar replacement suggests the importance of the reactive fluid infiltration through low-permeability metamorphic rocks, likewise give a new insight on how fluid propagation generate micro-to nano-scale porosity.

# Quantitative evaluation of fracture distribution in granite and the relationship between fracture distribution and physical properties

*Manami Kadono[1], Shin-ichi Uehara[2], Miki Takahashi[3], Manami Kitamura[3]

1. Department of Environment Systems, Graduate School of frontier Science, The University of Tokyo, 2. Department of Enviroment Science, Faculty of Science, Toho University, 3. National Institute of Advanced Industrial Science and Technology

Recently, geothermal uses in the depth below the brittle-ductile boundary have been considered for collecting geothermal energy more efficiently than conventional geothermal uses [1]. One of them is supercritical geothermal power generation, which uses supercritical fluid of higher temperature and pressure than conventional type, and therefore output per power plant is expected to be increased [2]. In this geothermal development, there is a plan to artificially create geothermal reservoirs when the geothermal fluid enough for the power generation capacity does not exist in the rock. These artificial reservoirs are planned to be created through processes such as cooling rocks by water injection, emergence of brittle region, causing hydraulic fracturing, and then emergence of high permeability region. Here, crack generation and propagation by injecting water and cooling rock have some possibility of inducing earthquakes. Therefore, it is important to elucidate properties of crack generation and propagation in the rock in this situation. However, these properties have not been understood enough. In addition, clarifying the relationship between properties of crack distributions and elastic wave velocities, which is not established so far, may be of useful for investigating the crack distributions at actual geothermal development sites by elastic wave explorations.
In this study, we generate cracks in granite specimens by heating them up to 550℃ then cooling, and we clarified the relationship between the cooling rate and the conditions of crack distributions in the specimens. We also tried to clarify the relation between the crack conditions and physical properties such as (elastic wave velocity, porosity and elastic properties derived from the elastic wave velocities) .
Cylindrical specimens (20 mm in the diameter and 40 mm in the length) of granite from Oshima, Ehime Prefecture (initial porosity: <0.38 %, P and S wave velocity ($V_P$), ($V_S$) under water saturated condition: 5.96±0.14, 3.10±0.10 km/s, respectively) were used for the experiments. After being heated the specimens, were cooled in three ways with different cooling rates for the surface temperature (approximately 3.3 ℃/min, 17.7℃/min, and 516 ℃/sec). Observations of X-ray CT images revealed that microscopic cracks were generated in the specimens after the heating-cooling processes. Cracks were extracted from this CT images and the number of cracks was measured. The number of cracks per image (20 mm×40 mm) $N$ was $600 < N < 2600$, and the faster the cooling rate was, the larger $N$ per unit area was. This is probably because faster cooling rate causes the greater temperature difference between the center and surface of specimens, which causes larger difference in the degree of shrinkage of the minerals constituting the specimens, and then the minerals are easier to be separated from each other. When $N$ is lager, the porosity is larger (0.60 - 0.82%), and $V_P$ and $V_S$ are smaller (4.63 - 4.86 and 1.69 - 2.15 km/s, respectively). Bulk modulus and shear modulus were decreased from 61 - 65 to 45 - 48 GPa and 24 - 26 to 7 - 13 GPa, respectively, through the heating-cooling processes. In the presentation, we will investigate the relationship between $p$, a parameter representing the distribution propability of cracks defined by Hestir & Long [3], and physical properties.

# Supercritical Geothermal Resources as a Function of Mass and Energy Transport in Subduction Zone

*Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University

Our research group is conducting fundamental and engineering studies of “Supercritical Geothermal Development”. Fracture networks and their formation mechanisms would be studied by using petrological and fluid inclusion studies in order to understand the geological model of a supercritical geothermal reservoir. The granite-porphyry system provides useful information for understanding supercritical geothermal reservoirs and EGS technology as novel energy system in subduction zone. Hydrothermal experiments under supercritical conditions were performed by using tri-axial machine. Fracture cloud could be formed and permeability was enhanced in supercritical conditions.

# Mineral precipitation/dissolution from water and brine with decreasing temperatures along hydrostatic pressures

*Kenichi Hoshino[1]

1. Department of Earth and Planetary Systems Science, Hiroshima University

Mineral-fluid interactions with decreasing temperatures along hydrostatic pressures, from 15.84 MPa - 500°C to 6.64 MPa - 200°C, have been simulated for 0.01 molal and 1 molal NaCl solutions. The dielectric constants of the former were taken from SUPCRT92 (Johnson et al., 1992), while those of the latter has been proposed from quartz solubility data in brine as:

$$\varepsilon_b / \varepsilon_w = a / (2\pi b)^{0.5} \exp(-(T - c)^2 / (2b)) + d,$$

where, $\varepsilon_b$ is the constant of the 1 molal NaCl solution, $\varepsilon_w$ is that of water derived by SUPCRT92, $\pi$ represents the ratio of the circumference of a circle to its diameter, T is a temperature in Celsius, the parameter a depends on a pressure (P in MPa) as a = -0.9 * P + 420, and b, c and d are the constants as 13000, 300 and 0.8, respectively.

On the other hand, a difference in chemical potentials of a jth solute ($\Delta\mu^\circ_j$) in the solution and water may be expressed as:

$$\Delta\mu^\circ_j = \omega_j (1/\varepsilon_b - 1/\varepsilon_w),$$

where, $\omega_j$ is the Born coefficient of the solute. Since the coefficients of the most charged species as well as $SiO_{2(aq)}$ are positive and $\varepsilon_b$ is larger than $\varepsilon_w$ in the simulated conditions, the chemical potentials of the above solutes in brine are smaller than those in water. This causes great differences between mineral solubilities in water (0.01M NaCl) and in brine (1M NaCl) as below.

Quartz

Since quartz solubility decreases with decreasing temperatures in water and brine, quartz precipitates from the both solvents with decreasing temperatures. However, because a decreasing rate of solubility in brine is smaller at higher temperatures and larger at lower temperatures, the precipitation amount shows a maximum at around 350 - 400°C. On the other hand, the amount decreases monotonically with decreasing temperatures in water.

Feldspar

Aluminum is dissolved mostly as $AlO_2^-$ (= $Al(OH)_4^-$) in the both solvents. Equilibrium constants of dissolution reactions of K-feldspar, albite and anorthite with the above Al species decrease with decreasing temperatures. Therefore, the precipitation amounts of those feldspar from water solvent decrease monotonically with decreasing temperatures. On the other hand, it is quite interesting that they dissolve in brine at higher temperatures, while precipitate at lower.

Pyroxene and Al-free amphibole

Most pyroxene and amphibole show similar tendencies as feldspar. They gradually precipitate or dissolve small amounts with decreasing temperatures in water, while they dissolve in brine at higher temperatures and precipitate at lower.

One of the conceivable causes of the above temperature dependencies of the silicate precipitation/dissolution in brine is a great difference in activity coefficients of charged species. For

©2019. Japan Geoscience Union. All Right Reserved. 

example, the activity coefficients (Debye-Hückel terms) for a divalent element in 0.01M NaCl solutions at 450°C and 300°C are 0.34 and 0.47, respectively, while they differ largely in 1M solutions as 0.023 and 0.20, respectively.
Carbonate
$CO_{2(aq)}$ is the major dissolved species above 250°C in the both solvents. Since the equilibrium constants of dissolution reactions of calcite, dolomite and magnesite with $CO_{2(aq)}$ decrease with decreasing temperatures, they precipitate from water gradually with decreasing temperatures, while they dissolve in brine at higher temperatures and precipitate at lower as feldspar, pyroxene and amphibole.

It should be emphasized that the temperatures of brine at which the above all silicate and carbonate minerals change their modes from dissolution to precipitation are around 400°C - 300°C.

Precipitation/dissolution of solid solutions of the above minerals and alteration (hydration) of some of the above minerals will also be discussed in the presentation.

Geothermal reservoirs under the supercritical conditions (supercritical geothermal reservoirs) have been taken grater attentions as the potential renewable energy in volcanic areas in the world. The chemical and physical processes of such supercritical regions are of special importance for various geological processes including understanding the formation of hydrothermal ore deposits, hydrological properties around brittle-ductile transitions of the crusts, and metamorphic and metasomatic processes. The thermodynamic data of the aqueous species at elevated temperatures and pressures has been constructed based on the Helgeson-Kirham-Flowers (HKF) model, where molar Gibbs energy is defined as a function of dielectric constant of water and species-specific Born parameter (e.g., Tanger and Helgeson, 1988), and the most common data is available through a software SUPCRT92. However, a large issue for understanding the supercritical water-rock interaction is a lack of thermodynamic data of charged aqueous species (ions and complexes) for the region near critical point of water and low water-density region (<0.35 g/cm3). In contrast to the electrostatic model like HKF model, the empirical density model has been proposed based on the fact that the log of molar Gibbs free energy of aqueous species shows a linear relationship with log of water density. Based on this model, Caciagli and Manning (2003) proposed the extrapolation of SUPCRT log K data to the high pressure regions; however, the effectiveness of this method to the low density region is not clear. In addition, the experiments for dissolution experiments are lacking for the low-density region.

In the present study, we tried the expansion of log K data set of the speciation and mineral dissolution into the vapor-like supercritical region (400, 420 degreeC, 20-35 MPa). We also conducted the new experiments for the mineral solubility measurements. The apparatus consist of 60 ml vessel with Ti inner wall, and pressure was controlled by syringe pump. We conducted the dissolution experiments with albite power and mix powders of albite-K-feldspar-quartz. Then, for evaluating the validity of the extrapolated data, we compared the extrapolated logK of mineral dissolution equilibrium and the ion products (log Q) obtained from the solution chemistry of the experiments and extrapolated log K data set of aqueous species. The deviation of log K from log Q is systematic and less than 2 in log unit, indicating the effectiveness of this method as the first approximation.

# Nitrogen isotope ratios of ammonium in hypersaline hot spring waters distributed along Arima-Takatsuki fault zone.

*Kazuhiro Amita[1], Takashi Nakamura[2], Shinji Ohsawa[3]

1. Faculty of Engineering Science, Akita University, 2. International Research Center for River Basin Environment, University of YAMANASHI, 3. Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

Recently, there has been a lot of research on the relationship between hot springs and deep thermal fluids (Slab dehydrated fluids) which are thought to be released from subducting oceanic plate (eg, Kazahaya et al., 2014; Kusuda et al., 2014). These researches shown that the water of slab dehydrated fluid is a high salinity of Na-Cl type and rich in the CO2, and that the isotope ratios of helium and carbon had the similar values as that of the mantle. On the other hand, although nitrogen (ammonium ion) is a component contained in most deep fluids, it is not clear properties and behaviors. Studies on nitrogen in rocks have been conducted since the 1960's that have been obtained many knowledge on their concentrations and isotope ratios. Haendel (1986) pointed out that the concentration and isotope ratios of ammonia nitrogen in rock, change systematically with the progression of a series of metamorphism from sediment to rock. In this relation, the nitrogen concentration decreased as the degree of metamorphism progressed, and conversely the nitrogen isotopic ratio increased. Similar trends have also been confirmed in subsequent studies (eg, Gray and Marilyn, 1991, Yiefei, 2006). On the other hand, Amita et al. (2014) pointed out the possibility that metamorphism is involved in the made of deep thermal fluids. Therefore, it is expected that we can obtain knowledge about the behavior of nitrogen in deep under the earth's surface by clarifying the relationship between the nitrogen isotope ratios of rocks and deep fluids. Therefore, as a preliminary approach to the measurement of the nitrogen isotope ratios of ammonium ion contained in the hypersaline hot spring, two hot springs distributed along the Arima-Takatsuki fault zone are selected and performed sampling survey and nitrogen isotope ratios of ammonium ion were measured. Two sampling points are part of the hot springs that the authors have performed research in the past (Osawa et al., 2015) and are well-understood hot springs whose chemical and isotopic properties. Therefore, as a preliminary approach to the measurement of the nitrogen isotope ratios of ammonium ion contained in the hypersaline hot spring, two hot springs distributed along the Arima-Takatsuki fault zone are selected and performed sampling survey and nitrogen isotope ratios of ammonium ion were measured. The hot spring water samples collected at the sampling site were immediately cooled and frozen immediately to suppress biological activity and kept until just before the isotope analysis. Pretreatment for measurement of nitrogen stable isotope ratio of ammonium ion was carried out by ammonia gas diffusion method which can suppress measurement inhibition due to decomposition of dissolved organic nitrogen. The water samples were made alkaline in a sealing vial, ammonium ion was scattered as ammonia gas, and catched to a filter paper acidified with diluted sulfuric acid, and the object was analyzed using an isotope ratio mass spectrometer (ANCA-GSL with Hydra 20-20, Sercon Ltd.). As a result of the analysis, we obtained results of +13.3 (‰) and +12.8 (‰) as nitrogen isotope ratios of two hot spring water samples. Since these results are values before data correction, careful consideration is required at the evaluation. Although, it was confirmed that the measurement of nitrogen isotopic ratios can be performed even for hyper saline hot springs where the total dissolved solids exceeds tens of thousands ppm.

# Crustal fluid pressure gradients and permeability estimated from fluid-rock reaction zones

*Masaoki Uno[1], Diana Mindaleva[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University

High pore fluid pressure has been recognized by geophysical observations and is generally considered as triggers of earthquakes and slow–earthquakes (e.g., Audet and Bürgmann, 2014). Although such high pore fluid pressure is recognized as mineral filled fractures in geologic observations, the actual fluid pressure gradients in the crustal rock have not been evaluated quantitatively and remain largely unknown. Here we propose a new methodology estimating the fluid pressure gradients recorded in fluid-rock reaction zones, by utilizing thermodynamic analyses in conjunction with trace element profiles along the reaction zones. With numerical analysis of reactive advection-diffusion transport profiles of Cl and F in the fluid-rock reaction zones, we constrain the duration, fluid velocity and permeability of the fluid-rock reaction zones. We have analyzed amphibolite and granulite hosted fluid–rock reaction zones at Sør Rodane mountains, East Antarctica. The analyses of decimeter scale granitic dyke–crust reaction zone at 0.5 GPa, 700˚C (Uno et al., 2017) show fluid pressure gradients of ~100 MPa/10 cm or ~1 MPa/mm. mm-sized hydration reaction zones around single fracture at ~0.5 GPa, 450˚C (Mindaleva et al., in prep.) also suggest fluid pressure gradients of ~1 MPa/mm. These extremely high fluid pressure gradients represent the low permeability of the intact amphibolite and granulite host rocks without fractures. The estimated permeabilities are ~$10^{-20}$ $m^2$ for the granulite–granitic dyke reaction zones and amphibolite–fluid reaction zones, and are several orders smaller than the widely accepted crustal permeability model (~$10^{-18}$ $m^2$; e.g., Ingebritsen and Manning, 2010). On the other hand, permeability along the fractures are estimated as high as $10^{-14–15}$ $m^2$ for the granulite and amphibolite-hosted fractures, which is analogous to the permeability estimated for the hypocenter migration for the inland earthquake swarms (~$10^{-15}$ $m^2$; e.g., Okada et al., 2014). These results show the importance of low permeability of intact amphibolite/granulite-facies metamorphic rocks in conjunction with episodic high permeability of brittle fractures even at high temperature conditions of 450–700˚C, both of which affect the regional scale permeability in the deep crust.

EGS (Engineered / Enhanced Geothermal System) is expected to generate significant energy and reduce CO2 emission. Although EGS could be effective in Japan where many volcanoes exist, there are still many problems to solve to run the power plant using EGS. The supercritical fluid which can exist below the brittle-ductile transition (BDT) is essential to develop the EGS. However, structures and physical properties around and below BDT are still unclear. Since the development of EGS needs long time before operation and requires high cost, it is important to evaluate the suitable area for EGS. Therefore, estimating the structure in high spatial resolution from surface to around BDT is important to develop EGS and reduce risks.

In recent years, surface-wave analysis has been widely applied to estimate underground structure from ambient noise. In this analysis, surface-wave phase velocity can be estimated from ambient noise, and S-wave velocity structures can be estimated from surface-wave phase velocity because phase velocity strongly depends on S-wave velocity. Surface-wave analysis using ambient noise does not require active sources. Therefore, this is effective to survey steep area where it is difficult to enter such as geothermal area. In addition, this method is also effective to monitor change in subsurface for a long period because we can obtain seismic ambient noise continuously only using seismometers.

We used continuous seismic data recorded by a high-sensitivity seismograph network (Hi-net) for a year. We computed cross spectra of ambient noise data between the station pairs, and extracted phase velocity dispersion curves using the frequency domain method. Since the frequency domain method can overcome the limitation of interstation distance (far-field approximation) occurred in the time domain method, we can extract phase velocity at short-interstation pairs which reflect local structures. We then estimated the 3D S-wave velocity structure by applying a direct surface-wave inversion method. Our results show the low velocity structures beneath active volcanoes such as Mt. Asama, and Mt. Nasu, that could reflect volcanic fluid. If we apply this method to dense seismometers around the geothermal fields or volcanic area, we could obtain S-wave velocity in higher spatial resolution and use the information to identify suitable reservoir for EGS.

# Resistivity-Based Temperature and Permeability Estimation of the Kakkonda Geothermal Field, Japan, Using a Neural Network

*Ugou Tsubasa[1], Kazuya Ishitsuka[2], Toru Mogi[3]

1. Department of Socio-Environmental Engineering Scool of Engineering Hokkaido University, 2. Division of Urban Management, Grduate School of Engineering, Kyoto University, 3. Division of Sustinable Resources Enginieering, Faculty of Engineering, Hokkaido University

Estimation of temperature distribution around a geothermal field is important to understand a geothermal system. Previously, temperature distributions were successfully estimated by a neural network based on temperature logs and magnetotelluric (MT) data (Ishitsuka et al., 2018). This method firstly learns the relationship between three-dimensional locations, resistivities and temperatures by a neural network or neural kriging. Then, the optimized neural network is used to estimate temperature distribution based on a resistivity structure obtained by the MT method. On the other hand, not only temperature but also permeability are important physical parameters to evaluate a geothermal system. In this study, we developed a method to estimate permeability distribution as well as temperature distribution by a neural network and neural kriging. The methodology was applied to the Kakkonda geothermal field, Japan.
Permeability along a well is not generally measured. Therefore, to create a training data of permeability, we estimated permeability along a well based on porosity deduced from resistivity log using Archie’ s law. Temperature-dependence of the resistivity of water was corrected at the processing. In addition, we assumed that the salt concentration at each depth was equal to the salt concentration of the collected fluid inclusion. Subsequently, the porosity was converted into the permeability by the Kozeny-Carman equation.
We then estimated temperature and permeability distribution around the Kakkonda geothermal field. For training data, we used temperature logs and the estimated permeability logs using resistivity profiles at the 7 wells (Hanano and Kajiwara, 1999). To estimate temperature distribution, we used the resistivity structure by Yamaya et al. (2017) using the MT method.
As for the result, the temperature rising was estimated in the deep part, and the point where the high-temperature fluid is considered to be rising from the geothermal reservoir was estimated. The permeability showed a high value, especially in the low resistivity part. The accuracy of the estimated temperature and permeability distribution was evaluated by comparing temperature data measured beneath a depth of 3100 m of WD-1 well. As a result of accuracy verification, neural networks showed the smallest temperature error when the number of the intermediate layers was 2, and the permeability error was the smallest when the number of the intermediate layers was 9. Both the temperature and the permeability of neural kriging were smaller than those of neural networks. Although further development of the methodology to increase the accuracy of the estimation is required, our results demonstrated the effectiveness of our neural network approach to estimate permeability as well as temperature distribution around a geothermal field.
This study is supported by a NEDO project.

Inner part of Sanzugawa caldera, NE Japan, is one of the promising geothermal areas that had been found by many geological and geophysical surveys after 1970’ s. In this area, one geothermal power plant (Uenotai geothermal power plant) is currently in operation, and additional one (Wasabizawa geothermal power plant) is being constructed now.

There are a number of high-temperature hot springs along Akayumatasawa river that flows through the center of Sanzugawa caldera. This study reports the resistivity and geological structures based on MT surveys and field surveys around Akayumatasawa. In addition to these structures, the gravity structure, distribution of hot springs, and hypocenter clusters under Akayumatasawa indicate existence of geothermal fluid that is ascending from deep subsurface.

# Characterization of hydraulic fracturing phenomena in supercritical geothermal environments revealed by elastic wave measurements

*Miura Takahiro[1], Noriaki Watanabe[1], Kiyotoshi Sakaguchi[1], Ryota Goto, Kota Yamane, Takeshi Komai[1], Youqing CHEN[2], Takuya ISHIBASHI[3], Noriyoshi Tsuchiya[1]

Supercritical geothermal resources above the critical temperature of water (374℃) are expected as potential novel geothermal resources [Watanabe et al., 2017, Nat. Geosci.]. Although granitic rocks under temperature and depth conditions where supercritical geothermal resources are present are considered ductile against compression, they may be brittle against tensile, so that it is suggested that the reservoir layer may be formed. In fact, we carried out hydraulic fracturing experiments on cylindrical granite with a borehole in $\sigma_1$ direction placed under 450℃ and confining pressure triaxial stress (greatest principal stress $\sigma_1$:90MPa, intermediate principal stress $\sigma_2$ / least principal stress $\sigma_3$:40 MPa), and then three-dimensional isotropic reticulated fractures are formed with a smaller water pressure than hydraulic fracturing at low temperature, and it is found that the permeability increases by about 1000 times [Watanabe et al., 2017, Geophys. Res. Lett.]. Based on this previous study, we are currently working on clarifying the phenomenon of hydraulic fracturing under supercritical geothermal environments using a hydraulic fracturing experiment system under high stress and true triaxial stress conditions.

We have carried out hydraulic fracturing experiments on cubic granite with vertically downward borehole at 400℃ or 450℃ and true triaxial stress ($\sigma_1$:40 MPa, $\sigma_2$:15 MPa, $\sigma_3$:5 MPa), and AE (Acoustic Emission) measurement during the experiment and P-wave velocity measurement before and after the experiment have been conducted. As a result, irrespective of temperature and stress field, the P wave velocity of the rock after the experiment decreased isotropically, and it was suggested that the formation of reticulated fractures found in the previous study is mainly due to pressurization of existing microcracks which are isotropically distributed in rocks by low viscosity water. Furthermore, as a result of AE measurement during the experiment, the peak of AE occurrence was present not only at the time when the borehole pressure reached the maximum value (breakdown pressure) but also after the breakdown. Considering the deformation behavior of the rock during the experiment and the observation result of the thin sections after the experiment, it is suggested that the first peak is due to the occurrence of hydraulic fracturing but the second peak is due to the occurrence of small scale shear deformation and fracture depending on the stress field of the rock where strength has decreased by hydraulic fracturing. As a result, the possibility that the rock behavior after the breakdown also affects the ultimate fracture pattern and the change of permeability was newly found.

# Experimental measurements of transport pore radius of thermally cracked granite and the relationship of pore structure to permeability

*Sueyoshi Kazumasa[1], Tadashi Yokoyama[2], Ikuo Katayama[1]

1. Department of Earth and Planetary Systems Science, Hiroshima University, 2. Graduate School of Integrated Arts and Sciences, Hiroshima University

Fluid flow in rocks plays a key role in many geological processes such as geothermal reservoirs. Permeability is known to be dependent on porosity and pore radius (Walsh and Brace, 1984), while direct determination of pore radius is usually more difficult than determination of permeability. Water expulsion method (Yokoyama and Takeuchi, 2009) is a way to determine the radius of transport pore from gas pressure at which gas breaks through a water-saturated sample ($\Delta P_{break}$). Although several previous studies investigated the relationship between permeability and $\Delta P_{break}$ of impermeable rock such as mudstone, those of granite have not been reported. In this study, we develop the water expulsion method under confining pressure and aim to evaluate the relationship between permeability and pore characteristics such as porosity and transport pore radius under high pressure up to 30 MPa.

Thermally-cracked Aji granites were prepared to cylindrical shape (20 mm long and 20 mm in diameter). Thermal cracking was introduced by heating up to 600 ℃ and porosity of a heat-treated sample was about 2.4 % . The transport pore radius was determined by a manner similar to those reported in Yokoyama and Takeuchi (2009), which is an experimental method measuring gas pressure $\Delta P_{break}$ (Pa) at which gas breaks through a water-saturated sample. From $\Delta P_{break}$ and interfacial tension $\gamma$ (N m$^{-1}$), transport pore radius $r$ (m) can be estimated as follows: $r = 2\gamma / \Delta P_{break}$. Permeability was determined from the flow rate at a constant pore pressure ($P_p$ = 0.5 - 3 MPa). The flow rate was measured by a flow method using water as a pore fluid and permeability was calculated following Darcy’ s law. Porosity was estimated using the gas porosimeter, where the grain volume and pore volume of a sample were determined by using Boyle’ s law. Experiments were performed under confining pressure ranging 5 to 30 MPa at room temperature.

Transport pore radius and permeability of thermally-cracked Aji granite were 0.74 $\mu$m and 5.5×10$^{-17}$ m$^2$ under confining pressure of 5 MPa. These values decreased with increase in confining pressure and were 0.14 $\mu$m and 2.0×10$^{-18}$ m$^2$ under confining pressure of 30 MPa. Permeability $k$ (m$^2$) of granite can be approximated by pore radius $r$ and porosity $\phi$ according to the relation: $k = 5.32\times10^{-3}\,\phi r^2$. This indicates that permeability is primarily dependent on transport pore radius. These results are consistent with the conventional permeability model (Simpson et al., 2003) and estimation of transport pore radius is important for understanding permeability of granite.

# Geothermal reservoir evaluation by using TL of Quartz and Fluid Flow Simulation Model of the Kakkonda system in Japan

*Alvaro Josue Amaya[1], Nobuo Hirano[1], Noriyoshi Tsuchiya[1]

1. Tohoku University. Graduate School of Environmental Studies

Thermoluminescence (TL) of quartz is used in many geoscientist applications: Radiation measurements, geological dating and recently in geothermal activity prospection. After kinetic understanding, a new geothermal reservoir model has been developed based on the analysis of geological thermoluminescence surface samples and cuttings of borehole quartz samples combined with the system behavior equations. This novel methodology has been designed especially for an early stage of geothermal exploration condition and has been validated in the Kakkonda geothermal field in its initial exploration state. The system was simulated from surface to 5 Km on depth. In order to obtain the geothermal model that uses TL as a heat sensor, the sensitivity of the mineral property to natural heat has been monitored and evaluated through kinetic TL quartz decay experiments using aliquots of a standard sample rooted from same geothermal origin and subjected to different controlled conditions of temperatures taken at different time and deconvoluted by keeping constant 4 peak positions for all database; this has allowed the development of novel TL equations that have been coupled in this proposed reservoir model, which, is based on the description of the system through 3 governing equations for a specific control volume: the geothermal potential system balance, the Fourier equation, and the non-steady state heat conduction equation. Coupled with reservoir model and thermoluminescence model, we can obtain a numerical model of three-dimensional geothermal prospecting temperatures at any position (X, Y, Z) got through geoprocessing GIS tools. Finally, the 3D thermal model was used to parameterize a fluid flow simulation that considers the supercritical condition of the system at 5 Km as a heat source model and by using Hydrotherm software many scenarios of natural system evolution were gotten and a novel sustainable application for operation of the geothermal production operation in the Kakkonda Geothermal Power Plant was proposed.

## [S-CG59] Reducing risks from earthquakes, tsunamis & volcanoes: new applications of realtime geophysical data

convener:Masashi Ogiso(Meteorological Research Institute, Japan Meteorological Agency), Naotaka YAMAMOTO CHIKASADA(National Research Institute for Earth Science and Disaster Resilience), Satoshi Kawamoto(Geospatial Information Authority of Japan), Mitsuyuki Hoshiba(Meteorological Research Institute)

As the number of population centers grows in regions with earthquake, tsunami and volcano hazards, the importance of improving methods for rapid, realtime estimates of activity increases. Realtime monitoring, analysis, and prediction of seismic ground motion, crustal movement and tsunami will be powerful tools to contribute to earthquake and tsunami disaster preparedness/mitigation. Tsunami and Earthquake Early Warning systems exist today in many locations around the world. Now JMA has started to promptly provide Eruption Notices to inform people of impending and beginning volcanic eruptions. Large events like the 2011 Tohoku Earthquake (Mw9.0) have demonstrated some of the shortcomings of existing techniques. In this session, we invite presentations on new ideas, methods and applications of (near) realtime analysis of seismic, geodetic and tsunami data, to the problem of realtime prediction aimed at improving disaster preparedness/mitigation in the fields of earthquake, tsunami and volcano observation. Presentation is encouraged to bring together scientists, engineers, and practitioners from a broad range of backgrounds from around the world, and to promote collaborative communication at the leading edge of the science and technologies.

# Numerical Shake Prediction for earthquake early warning: prediction of distant future using Green function method

*Mitsuyuki Hoshiba[1]

1. Meteorological Research Institute

Although many previous studies of earthquake early warning have focused on rapid estimation of hypocenter and magnitude, recently we proposed a method called “Numerical Shake Prediction” (Hoshiba and Aoki, 2015), in which ground motion is predicted directly from monitored ground motion skipping the process of estimation of hypocenter and magnitude. In the Numerical Shake Prediction, current wavefield is estimated precisely using data assimilation technique, and then future wavefield is predicted using physics of wave propagation. Hoshiba and Aoki (2015) investigated a method to predict envelope of seismic wave focusing on seismic intensity. Furumura et al.(2018) studied an application to long period ground motion. For Tsunami, Maeda et al.(2015) tried the method to tsunami early warning. The researches, estimation of current wavefield and then prediction of future wavefield skipping the process of source information, is now progressed for earthquake and tsunami early warning.

Recently Wang et al.(2017) proposed a method to use Green function method for tsunami early warning, in which Green function is used instead of simulation of wave propagation. Oba et al.(2018) investigated an application of the Green function technique to early warning of long period ground motion. Because future wavefield is estimated from iterative calculation of seismic wave propagation in Hoshiba and Aoki (2015), it requires more computation time for more distant future. Using Green function technique, the computation time is not different between near future prediction and distant future prediction. It is also possible to predict distant future, skipping the prediction of near future.

I will show application of the Green function method for prediction of envelope of seismic wave focusing on seismic intensity. For the physics of wave propagation, radiative transfer theory is applied as the same as Hoshiba and Aoki (2015). This is high-frequency approximation based on ray theoretical approach, and energy propagation is considered instead of wave propagation itself. Energy which arrives at location, (X, Y) at time T later is quantitatively calculated beforehand from unity energy which propagats at (xi, yi) into direction qn. That is, Green function; G(X,Y,T; xi, yi, qn). Energy at location (X, Y) at time T later can be predicted from spatial and directional integrals of multiplication of this Green function and current energy distribution, E(xi, yi, qn), which is evaluated from data assimilation.

Using the Green function, it is possible to predict distant future with less computational time if the target points are not so many. On the other hand, it requires more computational time for prediction of more target points. When the target points are not so many, the Green function is effective method for prediction, including distant future.

# Introduction of forward scattering model into the Numerical Shake Prediction scheme

*Masashi Ogiso[1]

1. Meteorological Research Institute, Japan Meteorological Agency

A real-time ground motion prediction scheme based on a real-time monitoring of current wavefield (e.g., Hoshiba, 2013) is one of the promising approaches for an earthquake early warning (EEW) purpose. Hoshiba and Aoki (2015) implemented the idea and proposed the Numerical Shake Prediction scheme for the EEW. Hoshiba and Aoki (2015) adopted a radiative transfer theory in 2D space based on an isotropic scattering model for the prediction of future ground motion. The isotropic scattering model is suitable for the development of coda waves, however, it cannot represent an envelope broadening effect of the direct waves. The radiative transfer theory with non-isotropic (forward) scattering coefficients can model full seismogram envelopes (e.g., Wegler et al., 2006). In this study, we introduce a forward scattering model into the Numerical Shake Prediction scheme and investigate how the scattering model affects the ground motion prediction.

To introduce the forward scattering effect in the radiative transfer theory, we assume 2D exponential-type random media where the correlation distance is 1 km and the root-mean-square of the fractional random fluctuation is 0.05, then calculate non-isotropic scattering coefficients based on the Born approximation.

We compare the prediction results based on the non-isotropic scattering model with those based on the isotopic scattering model (Ogiso et al., 2018). Although the forward scattering model yields slightly larger residuals in maximum seismic intensity prediction than the isotropic scattering model, the forward scattering model results in smaller prediction residuals in whole seismogram envelope than the isotropic scattering model. The forward scattering model improves the prediction residuals, especially in the coda part. When we adopt momentum transfer scattering coefficient of the 2D random media as the scattering coefficient of isotropic scattering model, envelope prediction of the coda part is similar to that by the forward scattering model, however, residuals of maximum seismic intensity in isotropic scattering model become larger than the forward scattering model. Hence, we conclude that only the forward scattering model has a possibility to predict whole seismogram envelopes in the Numerical Shake Prediction scheme.

# Magnitude estimation by using ocean-bottom pressure gauge data

*Takeshi Nakamura[1], Eiichiro Araki[2], Narumi Takahashi[1], Kensuke Suzuki[2], Shunroku Yamamoto[3], Masahiro Korenaga[3], Shunta Noda[3]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Agency for Marine-Earth Science and Technology, 3. Railway Technical Research Institute

Deployments of ocean-bottom stations such as DONET and S-net could enhance early signal detections and improvements of accuracy for hypocenter analyses of suboceanic earthquakes. However, at some accelerometer stations deployed in ocean-bottom areas, tilt and rotation motions of sensor and/or sensor hysteresis would have occurred during strong motions, which causes anomalous waveforms and analysis errors on seismic motions. At the 2016 moderate-sized suboceanic earthquake (Mjma 6.5) occurring off the Mie prefecture in southwest Japan, significant amplifications of observed amplitude to amplitude calculated from the empirical equation and their considerable spatial variations are found at the DONET stations (Nakamura et al., 2018), which would not be explained by the source radiation pattern and subsurface structures. These undesired amplifications and variations are considered to be caused by acceleration offsets that are associated with the tilt and rotation motions and/or sensor hysteresis and could contribute to the overestimation and instable estimation results of source analyses such as magnitude estimation and finite fault modeling. In this study, we attempt to estimate the amplitude magnitude by using pressure gauge (Paroscientific 8B7000-2) data at DONET stations instead of using accelerometer (Metrozet TSA-100S) data to suppress the undesired features and evaluate the stabilities. We analyzed the waveforms after integrating the observed pressure gauge data and applying a high-pass filter with a corner period of 6 s. In the case of ocean-bottom stations deployed in a water depth of more than 2,200 m, the amplitude of pressure waveforms in this period band is roughly consistent with the vertical amplitude of ocean-bottom velocity (e.g., Matsumoto et al., 2012). The period band of less than 6 s corresponds to that used for estimating the amplitude magnitude of the unified hypocenter catalogue and EEW by JMA. We constructed the empirical equation between the magnitude and the filtered amplitude data and estimated the magnitude for each event data.
Our results show that the magnitude estimated from using pressure gauge data correlates well with that in the JMA list. The deviation (two sigma) is 0.70, which is the same value as that estimated from using three component data of accelerometer. For the event data of the 2016 earthquake (Mjma 6.5), the estimated magnitudes by accelerometer data are 6.64–8.34, while those by pressure gauge data are 6.33–6.81, indicating that the magnitude estimation using the latter data provides less amplification and stable results. The pressure gauge installed at DONET stations may be relatively low sensor hysteresis and less effects of sensor rotation on short-period component of waveforms compared with those of accelerometer.
