This study contrasts midlatitude continental and tropical maritime deep convective cores using polarimetric radar observables and retrievals from selected deep convection episodes during the MC3E and TWPICE field campaigns. The continental convective cores produce stronger radar reflectivities throughout the profiles, while maritime convective cores produce more positive differential reflectivity (Z_{dr}) and larger specific differential phase (K_{dp}) above the melting level. Hydrometeor identification retrievals revealed the presence of large fractions of rimed ice particles (snow aggregates) in the continental (maritime) convective cores, consistent with the Z_{dr} and K_{dp} observations. The regional cloud-resolving model simulations with bulk and size-resolved bin microphysics are conducted for the selected cases, and the simulation outputs are converted into polarimetric radar signals and retrievals identical to the observational composites. Both the bulk and the bin microphysics reproduce realistic land and ocean (L-O) contrasts in reflectivity, polarimetric variables of rain drops, and hydrometeor profiles, but there are still large uncertainties in describing Z_{dr} and K_{dp} of ice crystals associated with the ice particle shapes/orientation assumptions. Sensitivity experiments are conducted by swapping background aerosols between the continental and maritime environments, revealing that background aerosols play a role in shaping the distinct L-O contrasts in radar reflectivity associated with raindrop sizes, in addition to the dominant role of background thermodynamics.

Videosonde and HYVIS cloud particle imaging radiosondes: Carrier frequency migration from 1680 to 400 MHz

*Norio Nagahama[1], Kensaku Shimizu[1], Takuji Sugidachi[1], Kenji Yamaguchi[1], Kenji Suzuki[2], Fujiwara Masatomo[3]

1. meisei electric co.,ltd., 2. Graduate School of Sciences and Technology for Innovation, Yamaguchi University, 3. Faculty of Environmental Earth Science, Hokkaido University

The Videosonde and HYVIS (Hydrometer Videosonde), which are weather-balloon-borne special instruments for observing cloud/precipitation particles, have been developed since the late 1980s to understand cloud microphysics. They are able to downlink images of cloud/precipitation particles to the ground station by using 1680 MHz band radiowaves. The Videosonde captures video images of precipitation particles in the air without contact to those particles. It sends those images to the ground station in real time and can provide information on the size and shape of those particles such as raindrops, snowflakes and graupel. It also has an induction ring to measure the electric charge of the particles. On the other hand, the HYVIS focuses on cloud particles, utilizing a method in which the images of cloud particles deposited on a clear filmstrip are taken with a microscope and sent to the ground station in real time.

The Videosonde and HYVIS have been used as a strong tool for understanding cloud microphysics. In the 2000s, with the progress of remote sensing technology such as cloud radars, and with the progress of cloud-resolving models, these instruments were started to be used also as a reference instrument.

Although the 1680 MHz carrier radiowaves used in the Videosonde and HYVIS systems have been designated as a meteorological band until now, the band is being considered worldwide to be open for other uses in the future. Therefore, the migration of the frequency to 400 MHz also needs to be considered for Videosonde and HYVIS. In the current Vidoesonde and HYVIS, the NTSC video signals of 30 fps outputted from the cameras are connected directly to the transmitter and are downlinked to the ground receiving system with 1680 MHz radiowaves. Because these video signals are analog, the received images become lower in quality as the balloon goes higher and farther. As a result, there is larger uncertainty when analyzing cloud/precipitation particles taken at a longer distance from the ground receiving system. In addition, it is not easy to utilize automatic image processing softwares to analyze the particle images because the quality of the images is unstable. To solve these issues, a digital transmission that does not cause image degradation within the data receivable range needs to be considered.

The bandwidth allowed for the 400 MHz band is 60 KHz. Experiments were conducted with various communication rates, modulation depths, and modulation methods. It was found that baudrate of 56 Kbps, deviation of 14 KHz, and modulation index of 0.5 are the upper limits that conform to the radiowave standard. Assuming that the transmission rate is 50 Kbps, 6 KBytes of data can be sent per second. A black-and-white image of 640 x 480 pixels is 50 to 100 KBytes per image, depending on complexity of the image. Considering the balance between the image quality and the image size, the optimal setting may be to compress the image to 10 KByte or less and to transmit one image every 2 seconds. Unlike analog images, digital images do not deteriorate with the transmission distance. Thus, stable image quality can be expected.

[A-AS10] Land-Atmosphere interactions and precipitation variations over the Asian monsoon region.

convener:Hiroshi G. Takahashi(Department of Geography, Tokyo Metropolitan University), Hirokazu Endo(Meteorological Research Institute, Japan Meteorological Agency), Shiori Sugimoto(JAMSTEC Japan Agency for Marine-Earth Science and Technology), Hatsuki Fujinami(Nagoya University)

This session aims to discuss land-atmosphere interaction over the Asian monsoon region because this interaction is one of the essential components of the Asian monsoon system. Precipitation characteristics and cloud-precipitation processes are closely tied with land-atmosphere interactions, which are also a key target. Over Asia, climate are various, which produces various land-atmosphere-precipitation interactions. Influences of complex topography on precipitation characteristics are also considered. It may be interesting that the interactions can vary with scales in space and in time.
In addition, monsoon precipitation variability is a target of this session, which can be also associated with land surface conditions. We would like to approach the mechanism behind the precipitation/precipitation characteristics variability. In addition, to understand past and future precipitation variability, impacts of land-use changes and/or global warming should be considered. A large variety of observation, numerical modeling and their combined analyses are encouraged.

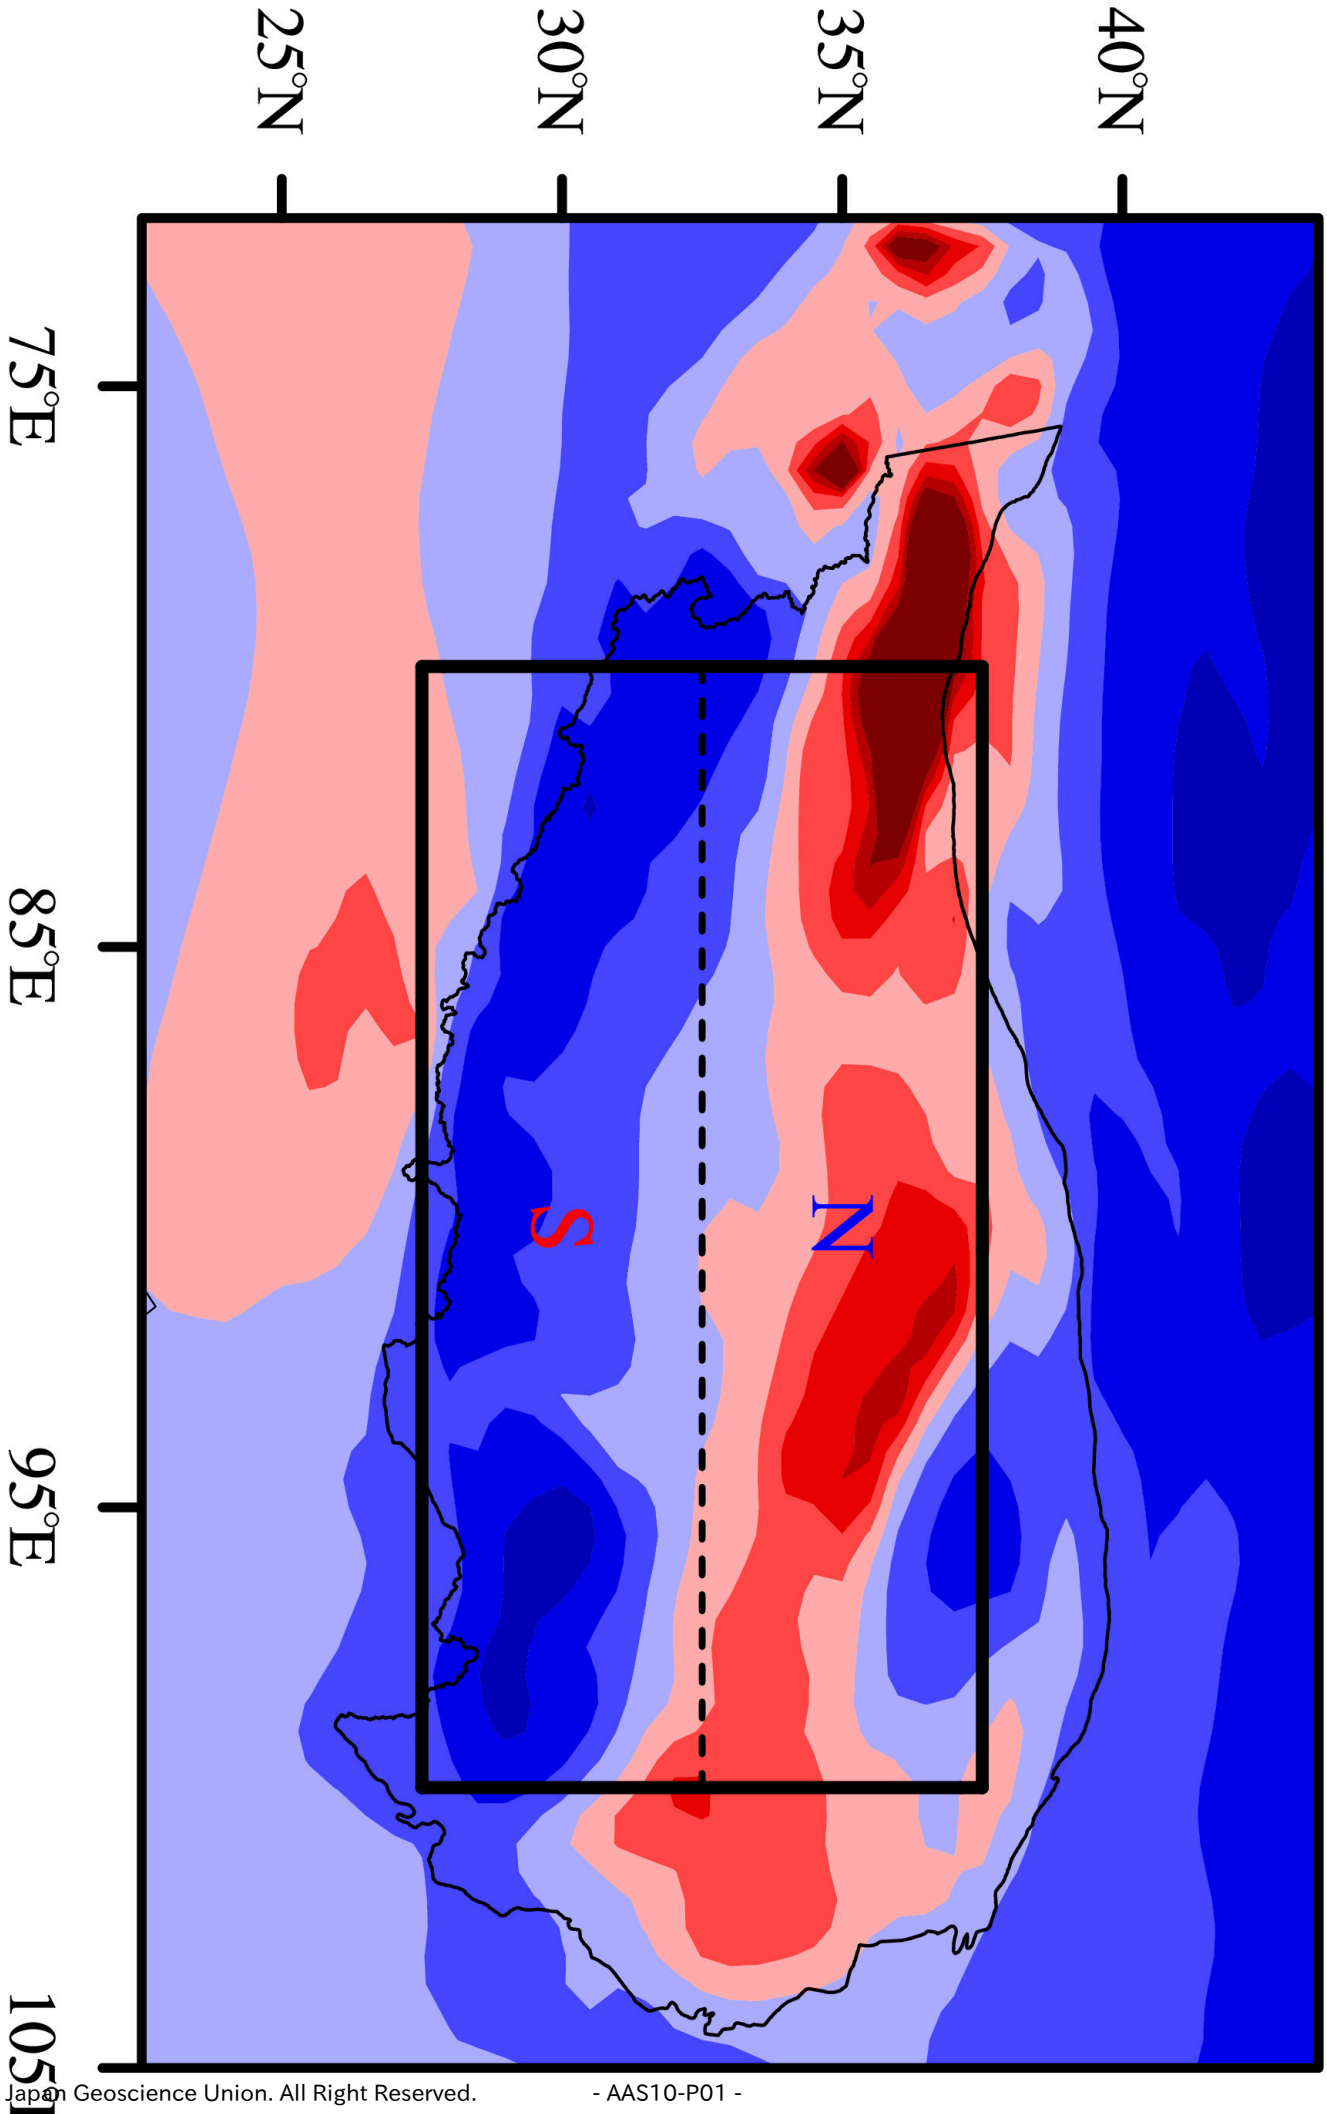
Spatial differences of the Tibetan Plateau monsoon and its application



*Shaobo Zhang[1], Xianyu Yang[1], Yong Zhao[1]

1. Chengdu University of Information Technology

As a unique climate phenomenon forced by the Tibetan Plateau (TP) heat flux, the TP monsoon is closely connected with the global climate, especially the East Asian climate. The TP monsoon index, which reflects the TP monsoon extent, has been treated as a useful tool for studying the TP monsoon. In this work, a new TP monsoon index (PMI_{zhang}) was used to analyze the spatial differences among different parts of the TP, explore the relationship between the TP monsoon index and precipitation, and discuss its prediction value. The following conclusions were obtained: PMI_{zhang} had a reversed correlation coefficient with precipitation between the eastern and western parts of the TP, which reflected the first mode of summer precipitation in the TP and showed high consistency with the TP precipitation in terms of interannual and annual variation. When considering the correlation coefficient between the TP monsoon index and precipitation, the result of PMI_{zhang} was a combination of the results of the monsoon index in the northern part of the TP (PMI_{zhangN}) and the southern part of the TP (PMI_{zhangS}). Compared with the southern part of the TP, the northern part of the TP had a stronger surface sensible heat flux, which made the thermal wind characteristics in the region more apparent. As a result, the variation and intensity of PMI_{zhangN} were more evident than that of PMI_{zhangS}. When the PMI_{zhangN} in May positively anomalous, cyclonic circulation anomalies and anticyclonic circulation anomalies could be found in the western part and eastern part of the TP, respectively, leading to positive anomalies and negative anomalies of precipitation in the western part and eastern part of the TP, respectively. Therefore, the interannual variation in the PMI_{zhangN} in May had a proper correlation with the TP summer precipitation, showing its potential application value.

The concurrent effects of the South Asian monsoon and Tibetan plateau monsoon on summer rainfall in Tarim Basin of China

*YONG ZHAO[1], XIAOJING YU[2]

1. Chengdu University of Information Technology, 2. Institute of Desert Meteorology, CMA

Based on the observed rainfall data at 34 stations over the Tarim Basin (TB) and the NCEP–NCAR reanalysis data during 1961–2012, the concurrent effects of the plateau monsoon (PM) over the Tibetan Plateau and the South Asian monsoon (SAM) on summer rainfall over the TB are investigated. Mid-upper tropospheric temperature (500-200 hPa) (MUTT) plays an important role in linking the PM and the SAM with summer rainfall over the TB. The concurrent influential mechanisms of the PM and the SAM on summer rainfall over the TB can be summarized as follows. The strengthened (weakened) PM and the weakened (strengthened) SAM causes mid-upper tropospheric cooling (warming), which tends to result in the migration of the subtropical westerly jet further southward (northward). Then an anomalous southerly (northerly) flow prevails over the TB, and more (less) water vapor is transported into the TB by a two-step process. All above contribute significantly to an increase (decrease) in the occurrence of summer rainfall over the TB. In addition, we also discuss the relative contribution of the PM and the SAM to summer rainfall over the TB. Partial correlations show that the PM and the SAM can both individually influence summer rainfall over the TB. The PM has a direct effect on summer rainfall over the TB, for its considerable relations not only with MUTT but also with atmospheric circulation. But the SAM has an indirect effect, because it can influence only MUTT, which then gives rise to an anomalous circulation related to summer rainfall over the TB.

Numerical simulations of precipitation in high altitude Himalaya mountainous area by using JMA-NHM

*Akihiro Hashimoto[1], Masashi Niwano[1], Hatsuki Fujinami[2], Akiko Sakai[3], Koji Fujita[3]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Institute for Space-Earth Environmental Research, Nagoya University, 3. Graduate School of Environmental studies, Nagoya University

Precipitation over high altitude Himalaya mountain area has a large influence to the mass balance of glaciers and the water discharge of rivers originating from there, which is an important factor not only in the water resource management but also the disaster mitigation for the countries in the watersheds. Although efforts have been made to reveal the temporal and spatial change of precipitation, its hydrological impacts, and related processes, they are not yet fully understood.

The authors have performed simulations to estimate annual precipitation amount in Himalaya's high altitude and the surrounding areas by using Japan Meteorological Agency Non-Hydrostatic Model (JMA-NHM), and additional simulations to examine the sensitivity to a topography smoothing technique, horizontal resolution and turbulence parameterization scheme. At first, we tested to relax the limitation of land surface slope angle to allow it to be up to 30 %, while the original threshold is 10 %, which is one of topography smoothing techniques for numerical stability of simulation. This did not much affect the simulation results. The simulations with the 5 km horizontal resolution tended to displace the major precipitation area toward the mountainside and to underestimate the precipitation on the plane in the summer season, compared with the observed precipitation amount provided by the Global Satellite Mapping of Precipitation (GSMaP), while the simulations with the 1 km horizontal resolution showed better agreement with the observation. Regarding the turbulence parameterization, Deardorff's scheme produced more precipitation on the plane than Mellor-Yamada's scheme in the summer season. In the presentation, we will also show the simulation results on annual and seasonal precipitation amounts in the several glacier catchments.

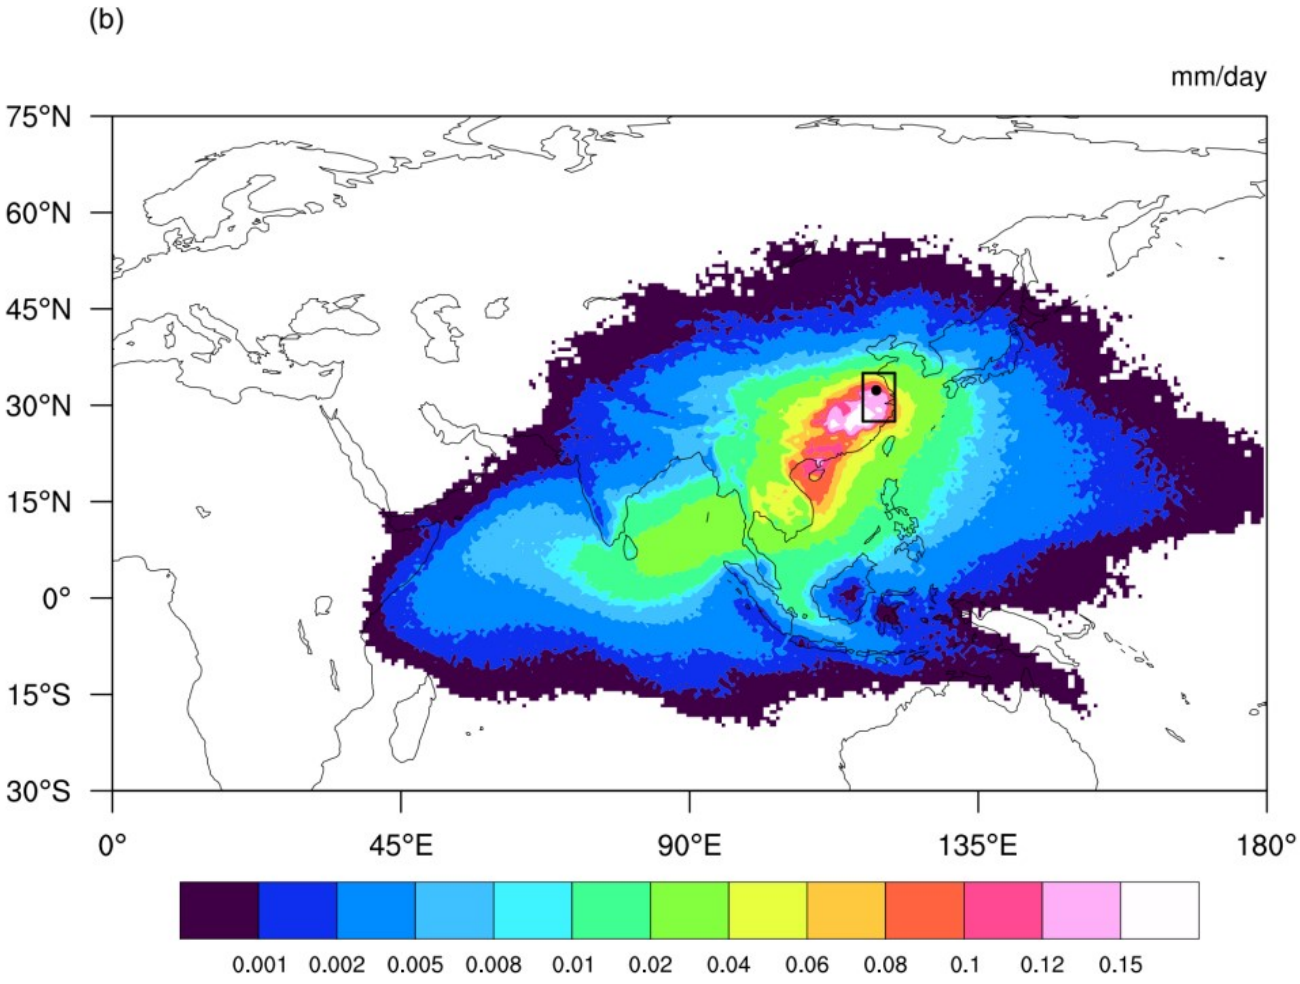
Moisture sources of summer precipitation over eastern China during 1979–2009: A Lagrangian transient simulation



*QIN HU[1]

1. Chengdu University of Information Technology

In this study, moisture sources for summer (June–July–August) precipitation over eastern China are investigated by performing a transient simulation for the period 1979–2009 using the Lagrangian particle dispersion model FLEXPART. The results show that the Indochinese Peninsula plus southern China, the South China Sea, the northwestern Pacific Ocean, the Asian continent, and the Bay of Bengal are major moisture source regions for summer precipitation over eastern China and that the moisture originated from eastern China, the Arabian Sea, and the Indian subcontinent has minor contributions. The contribution of the oceanic sources significantly surpasses that of the continental sources. The contributions of the various moisture source regions exhibited significant interannual variations during 1979–2009, especially the Indochinese Peninsula plus southern China, the South China Sea, the northwestern Pacific Ocean, the Asian continent, and the Bay of Bengal. Moreover, moisture sources have obvious monthly variations and seasonal cycle features, which are responsible for providing moisture for precipitation in the different stages of the monsoon over eastern China. In addition, it is revealed that a great amount of moisture for the slight precipitation over eastern China originates from the local and northwestern continental regions and eastern oceanic regions adjacent to eastern China, while more moisture comes from southwestern oceanic source regions and their adjacent continental regions for heavy precipitation.

Study on the severe weather caused by mesoscale convective system on the Meiyu front in northwestern Taiwan

*LI-ZHEN SU[1], Jou-Ping Hou[1], Ba-Xiu Wei[2]

1. Chung Cheng Institute of Technology National Defense University, 2. Air Force Weather Wing

Along the coast of northwestern Taiwan, when the Meiyu front passed, there were occasional rapids caused by the terrain, and after convergence with the prevailing wind field, it caused severe precipitation. In 1987, some studies conducted by Taiwan mesoscale experiment (TAMEX) found that low-level jet (about 1 km high) under certain conditions, known as barrier jet, strongly affected the heavy rainfall in northern Taiwan. On the morning of June 2, according to the results of the study in the meiyu frontal contact north Taiwan, in just 12 hours later to Keelung and north coast down to the super heavy rain of reason, may be related to frontal subject in northern Taiwan snowy mountains, the enhancement of barrier jets occurring near the surface height is related to the increase in barrier jets during the movement of the frontal body, which leads to cyclonic circulation around the jet zone, accompanied by the instability of temperature gradients and the enhancement of positive vortex anomalies, which indicates the cause of the strong water in this case. Based on the observation data and model simulation results, this study analyzed the main causes and physical mechanisms of the severe precipitation in northwest Taiwan, and then speculated on the dynamic and thermodynamic processes of such weather phenomena over time.

Long-term trends and interannual variability in precipitation over Vietnam during 1984-2016

*Hoa Thi Thanh Pham[1], Hiroshi G. Takahashi[1]

1. Department of Geography, Tokyo Metropolitan University

The precipitation variability in Vietnam is unique because different types of precipitation are dominant during the boreal summer and winter. During the late summer, tropical disturbances are associated with the precipitation variation in Vietnam. On the other hand, cold or northerly surges of the winter Asian monsoon play important role during winter. Thus, long-term variations in precipitation should be investigated with consideration of the seasonal march, including sub-seasonal time-scale. This study investigated the long-term variations in precipitation over Vietnam for the period from 1984 to 2016, which was corresponded to the economical exaggeration era of the country. The results showed that the long-term trends in precipitation over Vietnam greatly differed from region to region on decadal timescale. To understand the long-term changes associated with climatological precipitation characteristics, we analyzed the long-term changes on a monthly basis. Focusing on long-term changes in precipitation of decadal timescale from September to February, in October and February the decreasing trend was witnessed across mostly overall the country while in September, November and December, precipitation generally increased. In term of sub-climatological regions, North Central Area and Highland tended to be less rainy than South Central Area and Southern Vietnam. In addition, we also analyzed wind fields at 850hPa and water vapor fluxes. The decadal changes in atmospheric circulations are basically consistent with that of precipitation. Moreover, we will discussed the cause of the long-term changes in terms of the climatological seasonal march, including sub-seasonal time-scale, in precipitation and atmospheric circulation.

Recent increase of rain-on-snow events and rain proportion in north-eastern Japan

*Alexander Brandt[1,2], Maximo Larry Lopez Caceres[1]

1. Yamagata University, 2. United Graduate School of Agricultural Scienes (UGAS)

Winter precipitation along the Japan Sea depends on cold winter monsoons from Siberia. These winds bring cold air and heavy snowfall to north-eastern Japan and Hokkaido. With more than 1000 mm of precipitation within the winter period deep snow covers are the result. Snow cover is not only important for tourism (Toyama snow corridor, e.g.) but even more important for forest ecosystems and agriculture, since snowmelt is the main supply for plants in the relatively dry spring. However, recently snow cover decreases due to less snowfall and more rainfall during winter. Rain-to-snow proportion changed from 1:2 to almost 1:1 within the last decade in the Shonai plains in Yamagata prefecture. As consequence, snow cover (in a mild winter 2019/2020) was in January 80% smaller than in the years before. Results of the last decade show that the total amount of precipitation, especially between December and March does not significantly change. In contrast, because of significantly more rain, Snow Water Equivalent (SWE) will decrease.

Comparing different meteorological stations and the shifting snow-to-rain transition more recurrent mild and rainy winters can be expected for future. Those winters may result in water shortage in April and May, because snowmelt finishes early and precipitation is low in these months. Simultaneously forest plants start transpiration and agricultural lands are prepared, a significant decrease in snow due to climate change could therefore have negative impact on forest and agriculture. Climate change models already predicted weakening of Siberian winter monsoons, which will result in warmer winters with less snow. In order to characterize changes along the Japan sea we compared precipitation data of different meteorological stations and analyzed the change of rain proportion within the last decade.

Regional snowfall and precipitation distributions in a Japan-Sea side of central Japan associated with low-frequency variabilities in the Eurasian and East Asian regions

*Akira Yamazaki[1], Meiji Honda[2], Hiroaki Kawase[3]

1. Application Laboratory, Japan Agency for Marine-Earth Science and Technology, 2. Niigata University, 3. Meteorological Research Institute, Japan Mereorological Agency

This study found that regional snowfall distributions in a Japan-Sea side area of Japan are controlled by intraseasonal jet variability, particularly the 10-day-timescale quasi-stationary Rossby waves across the Eurasian continent and the atmospheric blocking over the East Asian region. Our results revealed that distribution types in which heavy snowfall events occurred over the area were related to the southward shift of the westerly jet over Japan associated with an intensified trough, i.e., cyclonic anomalies, originating from quasi-stationary Rossby waves along westerly jets over Eurasia (Eurasian jets). The cyclonic anomalies were found to be also related to blocking cyclones because the frequency of blocking events considerably increased in the East Siberian region.
Similar data analyses were conducted for regional precipitation distributions in the same area. Climatological features of the precipitation, such as seasonal marches and interannual frequencies were different from those for the snowfall events. However, composite fields for heavy precipitation events rather show similar features near Japan Island, such as the cyclonic anomalies, with those for the snowfall events. Those results imply that underlying mechanisms and/or boundary conditions which connect the global with the local atmospheric circulations can be different between the heavy snowfall and precipitation events.

Quantitative identification of moisture sources over the Tibetan Plateau and the relationship between thermal forcing and moisture transport

*Chen Pan[1,2,3,4], Bin Zhu[3,4], Zhiming Kang[1,2]

1. Jiangsu Meteorological Observatory, Nanjing, China, 2. Key Laboratory of Transportation Meteorology, China Meteorological Administration, Nanjing, China, 3. Key Laboratory for Aerosol-Cloud-Precipitation of China Meteorological Administration, Nanjing University of Information Science & Technology, Nanjing, China, 4. Collaborative Innovation Center on Forecast and Evaluation of Meteorological Disasters, Nanjing University of Information Science & Technology, Nanjing, China

Despite the importance of the Tibetan Plateau (TP) to the surrounding water cycle, the moisture sources of the TP remain uncertain. In this study, the moisture sources of the TP are quantitatively identified based on a 33-year simulation with a horizontal resolution of 1.9°×2.5° using the Community Atmosphere Model version 5.1 (CAM5.1), in which atmospheric water tracer technology is incorporated. Results demonstrate that the major moisture sources differ over the southern TP (STP) and northern TP (NTP). During the winter, Africa, the TP, and India are the dominant source regions, contributing nearly half of the water vapour over the STP. During the summer, the tropical Indian Ocean (TIO) supplies 28.5±3.6 % of the water vapour over the STP and becomes the dominant source region. The dominant moisture source regions of the water vapour over the NTP are Africa (19.0±2.8 %) during the winter and the TP (25.8±2.4 %) during the summer. The overall relative contribution of each source region to the precipitation is similar to the contribution to the water vapour over the TP. Like most models, CAM5.1 generally overestimates the precipitation over the TP, yielding uncertainty in the absolute contributions to the precipitation. Composite analyses exhibit significant variations in the TIO-supplied moisture transport and precipitation over the STP during the summer alongside anomalous TP heating. This relationship between moisture transport from the TIO and the TP heating primarily involves the dynamic change in the TIO-supplied moisture flux, which further controls the variation in the TIO-contributed precipitation over the STP.

Multi-scale convection system simulation during Meiyu season in Taiwan

*Yi Hao Liao[1], Jou-Ping Hou[1], Yu-De Wu[2]

1. Department of Environmental Information and Engineering, CCIT, National Defense University, 2. Air Force Weather Wing

The first front of Mei-yu rainy season passed through Taiwan area on May 1, 2019. Although the front did not reach rainfall intensity of the typical Mei-yu front, but the multi-scale convective system triggered by it revealed important clues that caused the Meiyu front to produce severe precipitation. Diagnostic analysis of this case, we found that the position of overseas development of convective clouds were closed to the 700hPa convergence zone position. The analysis of 850hPa and 700hPa shows that there are obvious low-level jets that continuously supply vapor, so that 850hPa has a significant vapor flux, which improves the mixing ratio, resulting in low-level convergence and sufficient vapor. It is easy to make convection develop local rainfall. At the same time, during the rapid movement of the frontal system to the southeast, the frontal system was damaged by the terrain. Although this case has a large-scale linear convection system in northern Taiwan, there is no severe precipitation. In the small-scale convection system in central and southern Taiwan,, precipitation is more obvious. In addition, we use WRF V3.9.1.1 version, two nesting domain design to simulate the frontal system on May 1, 2019, where the horizontal spatial resolution of the outer grid and the inner grid is 3 km and 1 km. The simulation experiments found that the number of grid points in the outer grid will affect the radar echo and precipitation intensity simulated by the inner domain. At the same time, the sensitivity of different microphysical parameters and boundary layer parameters will be tested to simulate the intensity of precipitation. Significant differences also occur in the rainfall intensity simulations.

Responses of rainfall characteristics to the land surface conditions over the wet Asian monsoon region

*Hiroshi G. Takahashi[1]

1. Department of Geography, Tokyo Metropolitan University

This study estimated the sensitivity of rainfall characteristics to land-surface conditions over Southeast Asia, which has a wet land surface during the rainy season. To obtain the regional difference in sensitivity and simulate basic cloud-precipitation systems, we used a high-resolution regional climate model. The sensitivity of rainfall amount to an increase in soil moisture was dependent on the location. This implies that the response of rainfall characteristics to soil moisture is not simple, suggesting that changes in rainfall characteristics are not solely determined by evapotranspiration. In addition, the sensitivity of rainfall characteristics displayed remarkable regional characteristics. The coupling of an increase in water vapor in the planetary boundary layer and a decrease of sensible heat flux can explain the response. The increase in water vapor in the planetary boundary layer was associated with a reduction of the development of deep convections and an increase of boundary layer clouds.

Analysis of Characteristics and Causes of Meiyu over the Yangtze–Huai River Basin in 2019

*Ruoyun Niu[1]

1. National Meteorological Center, China Meteorological Administration

Using the daily NCEP reanalysis dataset and the observations data of precipitation in China the characteristics of Meiyu over the Yangtze–Huai River Basin and its atmosphere circulation causes in 2019 are analyzed. The results show that: (1) In 2019, the onset date of Meiyu (June 16th) over the Yangtze–Huai River Basin was later than nomal, the outset date (July 17th) was close to normal, and the duration was shorter. The Meiyu precipitation (intensity) was more (stronger) than normal in the south of the Yangtze river and less (weaker) than normal in the north of the Yangtze river. (2) Between June 8 to 15 the cold air activities were intensified. In correspondingly, the Northwest Pacific Subtropical High (NWPSH) was phased southward, the fore boundary of East Asia summer monsoon (EASM) lied south of normal with the northward march delated. The above caused the onset date later. (3) During the Meiyu season (especially in July 1 to 15),the coast trough of East Asia was deeper and the western ridge of NWPSH was further south and the water vapor transport and its convergence at low level was is more southward. Meanwhile the eastern ridge of the South Asia High and upper-level westerly jet was southward, the upper-level divergence was also southward. The above all caused the Meiyu intensity with the southern stronger and the northern weaker.

Similarities and differences of summer persistent heavy rainfall and atmospheric circulation characteristics in the middle and lower reaches of the Yangtze River between 2016 and 1998

*Xiaolin ZHAO[1]

1. National Meteorological Centre, China Meteorological Administration

During the summer of 2016 and 1998 in the context of the decaying phase of the super El Niño event, the three persistent heavy rainfall events occurred in the middle and lower reaches of the Yangtze River from June 19 to July 7 in 2016 (hereinafter referred to as during the period of 2016), from June 12 to 27 (hereinafter referred to as during the period I of 1998) in 1998, and from July 17 to August 2 (hereinafter referred to as during the period II of 1998) in 1998, which brought great challenges to the national flood control business. Based on daily precipitation at 2407 meteorological observation stations in mainland China, daily reanalysis atmospheric data from NCEP/NCAR and other data, we have conducted a comparative analysis of the similarities and differences of summer persistent heavy rainfall and associated atmospheric circulation characteristics in the middle and lower reaches of the Yangtze River between 2016 and 1998. Results are as follows. (1) The persistent heavy rainfall belt is the northernmost during the period of 2016 and the southernmost during the period I of 1998 among the three events, while the rainfall intensity during the period of 2016 is roughly the same as that during the period I of 1998, and it for both periods is stronger than that for the period II of 1998. (2) There are many similarities in the atmospheric circulation characteristics during the three periods of persistent heavy rainfall. For example, there exist low troughs near the eastern coast of China, the Northwest Pacific Subtropical High (NWPSH) and South Asia High (SAH) are larger in range and stronger in intensity than normal, and the intensity of the upper westerly jet (UWJ) and low southwest jet and the easterly water vapor transport along the south side of the NWPSH are also stronger than normal. (3) The significant differences in the atmospheric circulation during the three periods of persistent heavy rainfall events are that the low trough near the coastal of eastern China during the persistent heavy rainfall of 2006 (1998) is shallow (deep). When upper-level divergence zone between the north sides of NWPSH and SAH ridge lines and the south sides of westerly jet belt, low-level jet belt and shear line with convergence, and Australian High in the southern hemisphere are northerly (southerly) in position, the persistent heavy rainfall zones are also northerly (southerly). NWPSH, SAH, and upper-level westerly jet during the period of 2016 and the period I of 1998 are significantly stronger than those during the period II of 1998. The rainfall intensity in the former two periods is also greater than that in the later period.

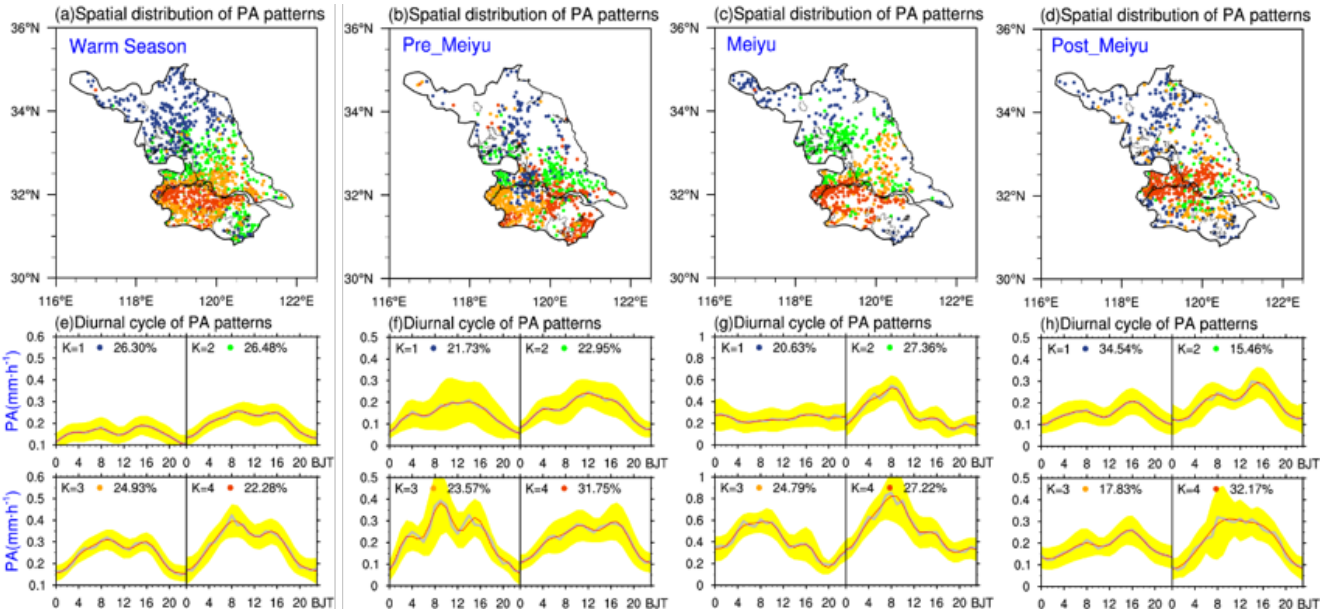
Characteristics of the Precipitation Diurnal Variation over Jiangsu, Eastern China during Warm Season



*Xiyu Mu[1], Qi Xu[2], Yang Wu[3], Anning Huang[3]

1. Key Laboratory of Transportation Meteorology of CMA; Jiangsu Institute of Meteorological Sciences; Nanjing Joint Institute for Atmospheric Sciences, 2. Jiangsu Air Traffic Management Branch Bureau of CAAC, 3. School of Atmospheric Sciences, Nanjing University

Based on the hourly precipitation data observed from ~1800 gauge stations during 2013-2017, the characteristics of precipitation diurnal variation over Jiangsu Province in Eastern China during warm season (May to September) have been revealed in this study. Results show that the precipitation amount (PA), frequency (PF) and intensity (PI) are zonally distributed over Jiangsu. The large PA center is located over the south side of the west end of Jiangsu Section of Yangtze River (JSYR). The PA shows distinct diurnal cycles. From midnight to noon, the PA center expands westwards and northwards from east JSYR to west JSYR with the PA increased. Hereafter the PA center shrinks eastwards and southwards with the PA decreased from noon to midnight. The strongest diurnal Peak of PA (PPA) is located over the south side of the west end of JSYR and the diurnal PPA gradually decreases northwards and eastwards from morning to midnight. The PA is larger in the daytime than in the nighttime over most Jiangsu. The PA shows two diurnal peaks with one in the early morning and the other in the afternoon contributed by the long duration rainfall and the short duration rainfall, respectively. The total rainfall is largely contributed by the long duration rainfall, which is determined by the summer monsoon circulation. The short duration rainfall is mainly affected by the local thermal conditions resulted from the underlying surface. The contribution of the rainfall with long (short) duration to the total rainfall over most areas shows very distinct sub-seasonal variations with a clear decreasing (increasing) trend from pre-Meiyu through Meiyu to post Meiyu. Among the three sub-periods, the PA and diurnal cycle of the total rainfall are mostly contributed by those during Meiyu period. The results of the cluster analysis show that the representative patterns of precipitation diurnal variation and their spatial distributions are closely connected with the underlying surface, such as the Yangtze River, big cities, Lake Taihu, Lake Hongze and coastal. The diurnal variation of the rainfall influenced by different underlying surface shows respective features.

Frequency of noon/afternoon convective precipitation dominates on wet surface conditions over Indian summer monsoon region

*Rakesh Teja Konduru[1], Hiroshi G. Takahashi[1]

1. Department of Geography, Tokyo Metropolitan University

Soil moisture can play an important role for determining precipitation characteristics over the tropical Asian region. In this study with the help of convection-permitting regional climate model (RCM), impacts of soil moisture on precipitation characteristics are investigated on different temporal scales over the Indian monsoon region. A set of wet and dry soil moisture surface conditions were forced to the Weather Research and Forecasting model WRFv3.9.1.1 as the RCM during the summer monsoon season. The contrasting soil moisture conditions found to affect the timing, frequency, intensity, and duration of precipitation during the peak monsoon over central India, along the mountains of foothills of Himalayas and over the Bay of Bengal. To understand diurnal contribution to daily accumulated rainfall, we also analyzed diurnal variations of precipitation characteristics. The changes in precipitation characteristics due to the surface conditions are basically regional characteristics. During noon/afternoon, a greater frequency of convective precipitation over the Indian land region, along the mountains of western Ghats and foothills of Himalayas was simulated under the wet surface condition, compared with the dry surface condition. Weakening of convective precipitation was found associated with the wetter surface conditions over the Indian land region. The frequency of short duration (3-6 hours) rainfall events were found to increase over Indian land region under the wet surface conditions than dry. In addition, the frequency of mesoscale convective systems propagating from land to the offshore Bay of Bengal found to decrease during the early morning over the wet land surface condition, compared with the dry condition. Moreover, we will discuss the mechanisms why these changes are simulated.

Modification of near-surface temperature over East Asia associated with local-scale paddy irrigation

*Shiori Sugimoto[1], Hiroshi G. Takahashi[2], Sekiyama Hirosato[2,3]

1. JAMSTEC Japan Agency for Marine-Earth Science and Technology, 2. Tokyo Metropolitan University, 3. Japan Meteorological Agency

The Sichuan Basin is a major region for paddy irrigation in China. We conducted two kinds of numerical experiment using the Weather Research and Forecasting (WRF) model to assess the impact of paddy irrigation in the Sichuan Basin on the regional climate over East Asia. In the control experiment (CTL run), which was used to calculate soil moisture using the unmodified Noah land-surface scheme, near surface temperature was higher than in the observation. The sensitivity experiment (SEN run), which incorporated an increase in soil moisture over the basin at the beginning of the rice-growing season, improved the simulated near surface temperature because of the change in the Bowen ratio associated with the increase in soil moisture. The modification of the land surface wetness in the Sichuan Basin also decreased the near surface temperature over northeastern China and increased it over southern China comparing with the CTL run, which are caused by the changes in the cloud convection and the solar & net radiation at the surface as well as the partitioning into the sensible and latent heat fluxes. The greenhouse effect associated with an increase in precipitable water in the SEN run also influences near-surface warming over southeastern China and the ocean north of southwestern Japan, where the impacts of radiation processes and surface heat fluxes on the near-surface temperature are small. The local-scale modifications to soil moisture in the Sichuan Basin results in changes in the larger-scale spatial distribution of near surface temperature over East Asia.

The freeze-thaw cycle and key parameters in a Tibetan Plateau lake using LAKE2.0 model and field observation

*Zhaoguo Li[1], Shihua Lyu[2], Lijuan Wen[1], Lin Zhao[1], Xianhong Meng[1], Yinhuan Ao[1]

1. Northwest Institute of Eco-Environment and Resources, Chinese Academy of Sciences, 2. School of Atmospheric Sciences, Chengdu University of Information Technology

Few studies have paid attention to the freeze-thaw process of Tibetan Plateau (TP) lakes and key control parameters. By combining 216 simulation experiments using a LAKE2.0 model with the observation, we evaluated the effects of ice and snow albedo, ice and water extinction coefficients on the lake ice phenology, water temperature, sensible and latent heat fluxes in Ngoring Lake. The increase of ice albedo, snow albedo and the ice extinction coefficient (K_{di}) induce significant decrease in water temperature. Compared with the latent heat, the sensible heat flux is more sensitive to these three parameters. With the decrease in high K_{di}, the ice thickness, water temperature and frozen days present an extensive increase. If K_{di} less than 2.5 m^{-1}, the increase of ice thickness is no longer obvious. In the frozen period with little snow, the K_{di} exhibit little influence on frozen days. The frozen days is significantly affected by the snow albedo and changes fastest in the snow albedo from 0.5 to 0.75.

Numerical simulation of the climate effect of high-altitude lakes on the Tibetan Plateau

*Yinhuan Ao[1], Shihua Lyu[2], Zhaoguo Li[1]

1. Northwest Institute of Eco-Environment and Resources, Chinese Academy of Sciences, 2. School of Atmospheric Sciences, Chengdu University of Information Technology

In this study, the Weather Research and Forecasting Model (WRF v. 3.6.1) is employed to conduct three numerical experiments in the Ngoring Lake Basin (the original experiment, an experiment with a tuned model, and a no-lake experiment) to investigate the influences of parameter optimization on the lake simulation and of the high-altitude lake on the regional climate. After the lake depth, the roughness lengths, and initial surface temperature are corrected in the model, the simulation of the air temperature is distinctly improved. In the experiment using a tuned model, the simulated sensible-heat flux (H) is clearly improved, especially during periods of ice melting (from late spring to early summer) and freezing (late fall). The improvement of latent-heat flux (LE) is mainly manifested by the sharp increase in the correlation coefficient between simulation and observation, whereas the improvement in the average value is small.After the lakes are removed, the air temperature increases significantly from June to September over the area corresponding to the two lakes, and an abnormal convergence field appears; at the same time, the precipitation clearly increases over the two lakes and surrounding areas.

Impacts of four land-use products on the simulation of land surface temperature in East China

*Yongjie Pan[1]

1. Northwest Institute of Eco-Environment and Resources, Chinese Academy of Sciences

Land surface temperature (LST) plays a crucial role in earth system for its uneven spatial distributions could trigger local circulations through land surface –atmosphere interactions. However, the accuracy of modelled LST depends on land surface characteristics, such as land use/cover types. In this study, the Community Land Model (CLM4.5) and four land-use products were employed to investigate the effect of underlying vegetation characters on LST simulation in East China. Moderate Resolution Imaging Spectroradiometer (MODIS) land surface temperature products (MOIDIS_LST) and observations from nine sites were used to evaluate the simulated LST. Compared with ground temperature from site observations, the CLM model could properly simulate ground temperature in urban area. However the differences between the MODIS_LST and simulated LST shown that the model overestimated LST in East China. Over the forest areas, the distributions of LST differences between model and remote sensing from four simulated cases are dissimilar because the different identifications of plant types in four land-use product. We also found a large deviation of leaf area index (LAI) between CLM prescribed value and remote sensing observation. The replacement of LAI in model surface data with MODIS LAI brings the modeled LST closer to MODIS LST. Besides the LAI, other factors contributing to the differences of LST between model and MODIS are also identified, including uncertainties in atmospheric forcing data, MODIS LST product, and land surface plant types identification. These findings could have implications for improving the simulation of land surface energy balance in regional weather models or global climate models.

Topographic and resolution impact on the monsoon rainfall in dynamical downscaling simulation

*Yoshiyuki Kajikawa[1,2], Tsuyoshi Yamaura[1,2]

1. Research Center for Urban Safety and Security, Kobe University, 2. RIKEN Center for Computational Science

It is worthwhile to understand the monsoonal rainfall system comprehensively based on the boundary problem; e.g. surface condition, orographic effect or resolution of the climate model, for the future climate prediction. We first ever conducted the downscaling monsoon experiment for the broad scale computational domain (30E-160E, 20S-45N) by using regional climate model; SCALE-RM (http://r-ccs-climate.riken.jp/scale/index.html) to examine the impact of (1) horizontal resolution (45km and 15km) and (2) topography (steep terrain) on the climatological monsoonal rainfall. We also specifically examined the topographic effect over the monsoonal rainband area (0-20N, 60E-150E). The results show that Increase of horizontal resolution (45km to 15km) provides more rainfall over the Indochina Peninsula and the entire western Pacific (WP). In contrast, the rainfall over the Indian subcontinent and Arabian Sea (AS) is decreased. Increase of acceptable slope of the topography in the model enhances the rainfall along the Himalayan foothill and southwesterly wind toward to Himalayan foothill both in 45km and 15km experiment, while it suppresses the rainfall along the broad monsoonal rain area (0-20N). Topography along the monsoonal rain area (0-20N) clearly confine the monsoonal rainfall area along the steep terrain. We discuss the impact of continuous integration on the reproducibility of the monsoonal rainfall in the model as well in the presentation.

Keywords: monsoon, rainfall, topography

[A-AS11] Aerosol impacts on air quality, climate system, and our society

convener:Teppei J Yasunari(Arctic Research Center, Hokkaido University), Kyu-Myong Kim(NASA Goddard Space Flight Center), Hongbin Yu(NASA Goddard Space Flight Center), Toshihiko Takemura(Research Institute for Applied Mechanics, Kyushu University)

Aerosol particles degrade air quality, modulate the radiation budget, influence the formation and evolution of clouds and precipitation, affect the ecosystems and biogeochemical cycles. These impacts have important implications for global sustainability and societal benefits. This session invites papers reporting latest advances in understanding lifecycles of aerosol and assessing aerosol impacts on air quality, the climate system from regional to global scales using in situ observation, remote sensing, and numerical modeling techniques. We also welcome papers on how the important roles of aerosol in air quality and climate system have influenced our society such as economic and educational activities. The topics of interest include but are not limited to: (1) physical processes on aerosol emission, transport and deposition, (2) trends of regional aerosol and their controls by emissions and meteorology, (3) aerosol influences on radiation through scattering, absorption, as well as albedo changing, (4) aerosol impacts on monsoon hydrological cycle and extreme weather events such as drought, flood, wildfire, typhoon, as well as the influences of the extreme weather events on aerosol emissions and transport, (5) the role of aerosol in global biogeochemical cycles, (6) aerosol impact on our society and economy, (7) new analytical methods for assessment and prediction such as machine learning, and (8) aerosol related education and outreach.

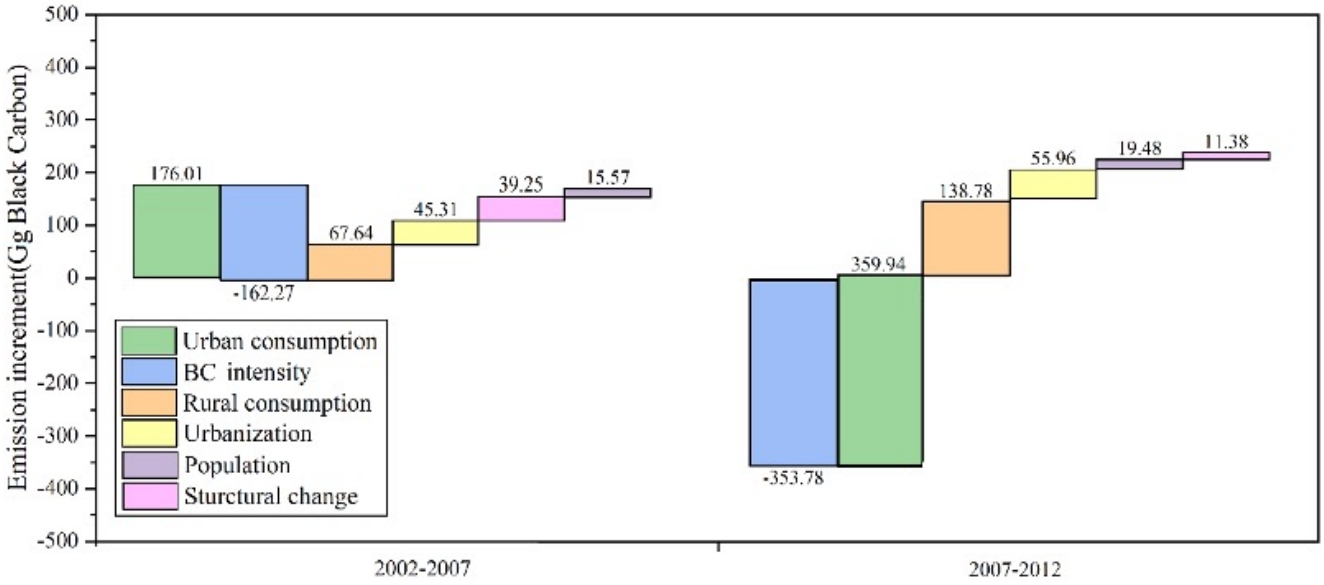
The impact of urbanization and consumption patterns on China's Black Carbon emissions —Based on SDA and IO Analysis



*Zhongci Deng[1], Xiaoling Zhang[1], Ping Kang[1]

1. School of Atmospheric Sciences, Chengdu University of Information Technology, China

With the gradual improvement of China's urbanization level and corresponding household consumption changes, emissions increase with time. However, little is known about black carbon (BC), not to mention their quantitative description of BC emissions. Therefore, we first collect the BC emission factor of various sectors to calculate the consumption-based BC emissions in China, and use the structural decomposition analysis (SDA) and input-output analysis (IOA) to explore the impact of urbanization and changes in consumption patterns on BC emissions from 2002 to 2012, focusing on sectoral BC emissions. The results showed that: the total BC emissions of various sectors in China increased from 1083Gg in 2002 to 1942Gg in 2007, and to 2551Gg in 2012. Meanwhile, with the deepening of urbanization (from 39.1% in 2002 to 45.9% in 2007, and to 52.6% in 2012), household consumption BC emissions increased from 446.2Gg in 2002 to 627.7 Gg in 2007, and to 895.5Gg in 2012. Focused on sectoral emissions, we found that urban consumption and BC intensity were the main contributing factors to the household BC emissions change. From 2002 to 2007, Urban consumption (positively) contributed 176.01 Gg of the incremental in household BC emissions, while 162.27 Gg were offset by BC intensity (negatively). From 2007 to 2012, due to per capita consumption or changes in consumption amount, urban consumption has increased. Consumption resulted in increased household emissions from 176.01 Gg to 359.94 Gg. However, due to the offset by BC intensity, we found that the total BC emissions increment from 2007 to 2012 was lower than that from 2002 to 2007(total BC emissions increment was 6.16Gg and 13.74Gg respectively). During the decade from 2002 to 2012, population-related factors contributed positively to total household BC emissions. The BC emissions increment impacted by urbanization was 45.31 Gg from 2002 to 2007 and 55.96 Gg from 2007 to 2012. Focused on the incremental BC emissions of each sector, transport, farming and residential contributed the most BC emissions. In particular, the transportation sector has the most significant impact on BC emissions. Urbanization affects BC emissions through its complex relationship with various sectors. So, it is necessary to formulate mitigation policies for the transportation sector.

Size-resolved hygroscopic behaviour of submicron aerosols in a megacity of Sichuan Basin

*Liang Yuan[1]

1. Chengdu University of Information Technology

In situ measurements are performed to study the size-resolved hygroscopic behaviour of submicron aerosols during pollution and fireworks episodes in winter from late January to February 2019 in Chengdu, a megacity in Sichuan Basin, using a humidity tandem differential mobility analyser (H-TDMA). The H-TDMA is operated at a relative humidity of 90% with dry aerosol diameters between 40 and 200 nm. Three modes of aerosol particles, including nearly hydrophobic mode (NH), less hygroscopic mode (LH), and more hygroscopic mode (MH), are found in the probability distributions of the growth factor (*GF*-PDF) during the campaign. The *GF*-PDF shows that aerosol particles are usually externally mixed. The average ensemble mean hygroscopicity parameter values (κ_{Mean}) over the entire sampling period are 0.16, 0.19, 0.21, 0.23, and 0.26 for aerosols with diameters of 40, 80, 110, 150, and 200 nm, respectively. These averages are lower than those in Shanghai and Nanjing. κ_{Mean} for aerosols larger than 110 nm, however, are higher than those in Beijing and Guangzhou during winter. Distinct diurnal patterns for all measured sizes are observed for the number fractions of the NH (NF_{NH}) and MH (NF_{MH}) modes as well as κ-PDF and κ_{Mean}. The NF_{NH} values are lower, but κ_{Mean} exhibits peak values during daytime. More aerosols are internally mixed because of photochemical ageing during daytime. The number fraction of LH (NF_{LH}) for the 40-nm diameter aerosols in clean periods (CPs) is larger than that in the pollution episode (PEs) because of the increasing amount of SOA formation. More aerosols of diameters larger than 80 nm are internally mixed during CPs and stage of contaminant accumulation, resulting in higher κ_{Mean} values compared to those in PEs. The aerosol emissions of fireworks that accumulate during the Chinese New Year's Eve contribute to the slow and continuous increasing trend in κ_{Mean} with average values of 0.19, 0.19, 0.21,0.23, and 0.27 for the 40, 80, 110, 150, and 200-nm diameter aerosols, respectively. These values are higher than those during the pre- and post-fireworks days. The hygroscopic properties of submicron aerosols in Chengdu are essential for understanding the formation and evolution of severe haze events in Sichuan Basin.

Comparison of absorption coefficient and black carbon concentration at Byeongcheon, South Korea using Tricolor absorption photometer (TAP) and Multiangle absorption photometer (MAAP)

*Jeonghoon Lee[1]

1. KOREATECH

We evaluate the tricolor absorption photometer (TAP) and the multiangle absorption photometer (MAAP) with respect to their response to black carbon concentration ranging 0-7 mg/m^3 at KOREATECH located in Byeongcheon, South Korea. While the MAAP employs basically similar principle to the TAP, that is, light extinction through an aerosol particle-deposited filter, it has a unique scheme to get rid of artifacts originating from the scattering effect of the aerosols deposited on the filter. In addition to comparing the absorption coefficients acquired by TAP at three different wavelengths, we also compare the absorption coefficients to the mass concentration of black carbon measured by the MAAP. We also derived absorption Ångström exponents (AAE) and mass absorption cross sections (MACs) by using the absorption coefficients reported by the TAP and the mass concentration reported by the MAAP without performing correction process. We observed that absorption coefficients showed similar trend to the mass concentration of black carbon. Our study finds that using the constant MAC value recommended by manufacturer at the wavelength used in MAAP results in aerosol light absorption coefficients that are different from those reported by the TAP. We also find that black carbon concentration at KOREATECH is as high as urban area although the campus is located in countryside. A discussion on high concentration, along with the results of an inter-comparison between TAP and MAAP will be presented.

Atmospheric particulate matter of size of 2.5 μm or less are denoted as $PM_{2.5}$. The generation of $PM_{2.5}$ encompasses primary processes on the ground surface and complicated secondary processes in the atmosphere. In the year 2009, an environmental standard value was set for $PM_{2.5}$ because of its health effects. Since then, their negative impacts on health have been reduced through continuous observations and warnings issued by measuring stations around Japan. Although component analysis is effective in identifying $PM_{2.5}$ sources, setup and operating costs for observation facilities are high, and high-frequency observation results cannot be obtained. In addition, there are automatic measuring machines (measuring at hourly intervals), which follow official methods, but the number of installations are low due to cost issues and difficulty in identification of $PM_{2.5}$ sources. On the other hand, in recent years, small particle sensors that are capable of measuring with high temporal resolution have become widespread. These sensors are based on light scattering methods; they can obtain observations at 1-second intervals and can be mounted on drones. Therefore, these sensors are expected to contribute to the diffusion process of $PM_{2.5}$ and identification of the source. However, since the mass concentration value obtained by the light scattering method is indirectly calculated from the particle number concentration, the accuracy of the obtained hourly values is not known. In this study, we compared the two data types by performing simultaneous observations with a sensor based on the laser light scattering method and an atmospheric environment measurement station that uses the official measurement method. We also compared these results with the $PM_{2.5}$ concentration obtained by the small sensor to estimate the accuracy of the obtained data Furthermore, based on the results, we attempted to correct the obtained observation values onboard the drone.The $PM_{2.5}$ concentration was measured using a Pocket $PM_{2.5}$ Sensor manufactured by Yaguchi Denshi Kogyo. To conduct simultaneous observations with the measurement station data, an observation station was constructed independently at the Shogunno General Atmospheric Environment Measurement Station in the East Third Block of Tsuchizaki Station on November 13, 2019, with the permission of Akita City. The height of the observation pole was 3.1 m, and $PM_{2.5}$ concentration data was acquired at 1-second intervals. For comparison with the measurement station, the 1-hour average values and standard deviation of the data were obtained from the small sensors. The 1-hour values, published as preliminary values by the Ministry of the Environment Air Pollutant Wide Area Monitoring System Soramame-kun (http://soramame.taiki.go.jp/Index.php), were used for the data from the measurement station. During the observation period from November 2019 to January 2020, 502 1-hour average values were obtained from sensor observations. The difference between the $PM_{2.5}$ concentrations measured by the sensor and the measurement station data, as well as the correlation coefficient between them are -1.7 ±4.7 μg/m³ and r = 0.48, respectively. A negative observation error of approximately 2 μg/m³ was observed. Based on these observations, corrections were made for the observed data up to an altitude of 500 m while using a drone from June 2018 to February 2019. The results of this study suggest that the $PM_{2.5}$ observations using a drone can be used to determine high and low concentrations, as defined by environmental standards, despite the observed errors. In this

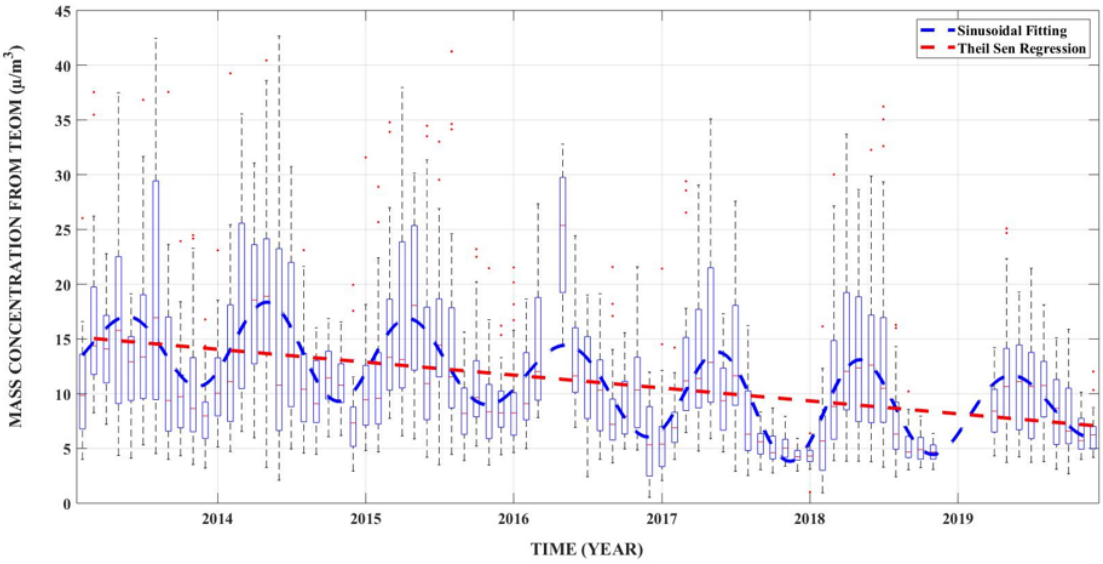
Department of Applied Chemistry, Faculty of Science and Technology, Keio University, 6. Tokyo Metropolitan Research Institute for Environmental Protection

According to Zeng et al. (2019) [1] the concentration of particulate matter (PM) have decreased significantly in China since 2013. Whether this decrease can be detected eastward, remains to be validated. In particular, the 2013-2017 summary report of the Long-range Transboundary Air Pollutants project [2] has estimated that China's contributions to PM2.5 concentration affecting Japan is 24.6 percent, while South Korea's contributions are 8.2 percent, based on source-receptor relationship simulations. Then, it is expected that a decrease of Long-range Transboundary Air Pollutants (LTP) will have a positive feedback in the air quality of many cities of Japan. To validate these assumptions and improve our understanding on LTP, it is necessary to perform continuous monitoring of air quality, especially in remote sites, scarcely affected by local emissions.

In this study we report a comprehensive survey on the trend of PM2.5 measured from 2013 to 2019 at NOTOGRO (acronym for NOTO Ground-based Research Observatory). Due to its special location, the site (37.45˚N, 137.36˚E) is well suited to assess the influence of transboundary air pollutants with respect to the background. Through the analysis of 7 years' worth of measurement data, we have investigated the seasonal and the long-term trend of the aerosol mass and size distributions.

Figure 1 shows the boxplot of the PM 2.5 mass concentration measured by a tapered element oscillating microbalance (TEOMseries1400). The blue fitting highlights the seasonal trend, while the red fitting traces the long-term trend based on Theil-Sen analysis. Monthly average concentrations are high in spring, and low in late autumn and winter. These variations are largely associated to the occurrence of long–range transport in spring, and increased amount of precipitation characteristically seen along the western coast of Japan in winter. Furthermore, PM2.5 concentrations are higher in summer, than in autumn, due to the influence of secondary formation that are driven by photochemical reactions.

In addition to these seasonal variations, a consistent decrease in the annual mean mass concentration can be observed. Considering that the analyzed period overlaps the ‘Chinese Action Plan on Prevention and Control of Air Pollution’, we suggest that LTP arriving in NOTOGRO are changing, as response to the decrease scenario of the Asian continent emissions. To further understand these modifications, our analysis has considered also the number and size distribution of the dried atmospheric aerosols for the same period 2013-2019.



The analysis of the aerosol number concentration, for Dp>0.3 μm, measured by an optical particle counter (OPC from RION model KC-01E) shows a decrease of the total number concentration below 2 μ

©2020. Japan Geoscience Union. All Right Reserved.

m and mainly in the accumulation particles mode. The analysis of the particle size distributions measured in the range 0.01-0.3 μm, by a scanning mobility particle sizer (SMPS, from TSI DMA model 3081+CPC model 3776) is also considered. From the peak analysis of SMPS data, we observe that there was no significant change in the median seasonal distributions. However, the size segregated total aerosol number concentration indicates distinct behaviors in the long-term trends of different particles modes. Furthermore, SMPS data confirms a decrease only for the range 0.2-0.3 μm.

These findings support that a preferential particle size range (0.2-2 μm) is responding mostly to the decreases of LTP, and the decreased emissions doesn't affect equally all particle sizes. Our results are worthwhile for the validation of emission inventory and simulation models.

Recurrent Neural Network (RNN), Long short-term memory (LSTM) for Aerosol Optical Depth (AOD) using NASA's MERRA-2 Reanalysis

*Mohammed Ezzat Magooda[1], Muhammed Eltahan[2], Karim Moharm[3]

1. Aerospace Engineering Dept, Cairo Univ., Cairo, Egypt, 2. Institute of Bio-Geosciences (IBG-3, Agrosphere), Forschungszentrum Jülich, Jülich, Germany, 3. Electrical Engineering Dept., Alexandria University, Alexandria, Egypt

Predication of temporal trends of aerosol optical depth (AOD) within the numerical climate models with enabled chemistry module is very challenging and computationally expensive. In this work, new predication model is introduced based on artificial neural networks (ANN) in order to estimate average AOD over Egypt. Long short-term memory (LSTM) algorithm which is artificial recurrent neural network (RNN) architecture, is selected to construct the predication model. Seven input datasets for LSTM algorithm are from NASA's Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA-2) reanalysis within period (1980-2017). The seven variables are pressure (PR), temperature (T), wind speed (W), dust surface particulate matter (PM2.5), surface (SO2) and (SO4) concentrations and (CO) concentration. AOD is the output of the trained and validated model. Effects of changing the number of both hidden layers and number of neurons per layers were evaluated.

The results of increasing the number of neurons per one hidden layer revealed that increasing the number of neurons leads to three main finding (a) leads to faster convergence of loss function. (b) Produces more realistic AOD estimation (c) RMSE is reduced by increasing number of neurons. It was also found that, the model with one hidden layer and 50 neurons is the best model setup with RMSE (0.06).

However, our studies showed also that increasing the number of hidden layers has no dominant effect on model RNN performance. The proposed LSTM model showed a very high level of accuracy with percentage 99.94 %. Future work can include more variables that has direct effect on AOD calculations. Both ensemble algorithms and different datasets can have more positive impact on the current proposed model.

Development of SCALE-Chem and its application for regional simulation targeting on urban area and mountain area of Japan

*Makiko Nakata[1], Mizuo Kajino[2], Yousuke Sato[3,4], Hisashi Yashiro[5,4], Itaru Sano[1], Sonoyo Mukai[6]

1. Kindai University, 2. Meteorological Research Institute, 3. Faculty of Science, Department of Earth and Planetary Sciences, Hokkaido University, 4. RIKEN Center for Computational Science, 5. National Center for Environmental Studies, 6. The Kyoto College of Graduate Studies for Informatics

A chemical transport model (CTM) (Kajino et al., 2019) was implemented into a meteorological model; Scalable Computing for Advanced Library and Environment (SCALE; Nishizawa et al., 2015; Sato et al., 2015) for investigating the local scale transport of aerosol. The CTM coupled with SCALE (SCALE-Chem) enabled us to conduct numerical simulations with fine grid spacing (O(10 ~ 100 m)) enough to resolve the local scale phenomena contributing to the local scale transport of aerosols and chemical tracer. Using SCALE-Chem, we conducted the numerical simulation targeting on urban area of Osaka, Japan, and the validity of the SCALE-Chem was confirmed through the comparison between the aerosol optical thickness (AOT) and particulate matter measured by the observation campaign of Distributed Regional Aerosol Gridded Observation Networks (DRAGON) Osaka (Holben et al., 2018; Sano et al., 2016) and those simulated by SCALE-Chem. Figure 1 shows the DRAGON-Osaka site distribution. Our analyses indicated that SCALE-Chem successfully simulated the observed aerosol properties. As well as the simulation for the urban area of Osaka, we will conduct numerical simulations targeting on mountain area of Nagano Prefecture, Japan to investigate the contribution of the local aerosol and aerosols transported from continent to aerosols measured by the observational campaign of Joint work to the Aerosol Properties and process Simulations (J-ALPS).

Figure 1. These black circles indicate AERONET (Aerosol Robotic Network) station and these open circles indicate sites that sun photometers are put into place during a period of DRAGON field campaign. The extended figure shows DRAGON-Osaka site distribution. Osaka, Kobe, Kyoto, and Nara are located in very close each other.

Regional trends of combustion aerosol and dust in recent decades: a satellite-model integrated analysis

*Hongbin Yu[1], Yang Yang[2], Hailong Wang[1], Qian Tan[3,4], Mian Chin[1], Robert Levy[1], Lorraine Remer[5], Steven Smith[2], Tianle Yuan[1,5], Yingxi Shi[1,5], Zhibo Zhang[5], Qianqian Song[5], Paul Ginoux[6]

Emissions and long-range transport of mineral dust and combustion-related aerosol from burning fossil fuels and biomass vary from year to year, driven by the evolution of the economy and changes in meteorological conditions and environmental regulations. This study offers both satellite and model perspectives of interannual variability and possible trends of combustion aerosol and dust in major continental outflow regions over the past 15 years (2003-2017). The decade-long record of aerosol optical depth (AOD, denoted as t), separately for combustion aerosol (t_c) and dust (t_d), is derived from the aerosol products of the Moderate Resolution Imaging Spectroradiometer (MODIS) onboard both Terra and Aqua. The MODIS datasets, complemented by aerosol source-tagged simulations using the Community Atmospheric Model Version 5 (CAM5), are then analyzed to understand the interannual variability and potential trend of t_c and t_d in the major continental outflows. Both MODIS and CAM5 consistently yield a similar decreasing trend of -0.017 to -0.020 per decade for t_c over the North Atlantic Ocean and the Mediterranean Sea that is attributable to reduced emissions from North America and Europe, respectively. On the contrary, both MODIS and CAM5 display an increasing trend of +0.017 to +0.036 per decade for t_c over the tropical Indian Ocean, the Bay of Bengal, and the Arabian Sea, which reflects the influence of increased anthropogenic emissions from South Asia and the Middle East in the last 2 decades. Over the northwestern Pacific Ocean that is often affected by East Asian emissions of pollution and dust, the MODIS retrievals show non-monotonic but overall decreasing trend of -0.021 per decade for t_c and -0.012 per decade for t_d, which is however not reproduced by the CAM5 model. In other outflow regions strongly influenced by biomass burning smoke or dust, both MODIS retrievals and CAM5 simulations show no statistically significant trends; and the MODIS observed interannual variability is usually larger than that of the CAM5 simulation. Seasonal variations of regional trends will also be discussed.

Development of a regime-dependent autoconversion parameterization using satellite observations

*Tomoki Hirata[1], Takuro Michibata[2], Toshihiko Takemura[2]

1. Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, 2. RIAM Research Institute for Applied Mechanics

Aerosol-cloud interactions (ACI) are major sources of uncertainty in climate modeling due to their complex dependences on cloud regimes, which are less understood. Most of the climate models tend to overestimate the magnitude of ACI compared with satellite observations partly because of an autoconversion parameterization in which the magnitude of warm rain modulation depending on aerosol perturbations is prescribed regardless of cloud regimes. Here we develop a new autoconversion parameterization which includes the regime-dependence of ACI inferred from satellite observations. The new scheme represents the magnitude of ACI as a function of the precipitation efficiency characterized by the ratio of rainwater to total liquid water. The proposed scheme is designed to reproduce a lower cloud susceptibility to aerosols in a more efficient precipitating regime according to the satellite-derived relationship, which allows to simulate nonmonotonic cloud responses to aerosol perturbations with spatial dependence in terms of cloud regimes. This is supported by the satellite statistics that show an inverse correlation between the cloud susceptibility and precipitation efficiency, and is also in good agreement with a steady-state model in a past study. Our results that are expected to fix the magnitude of ACI and hence ignore the regime dependence are more realistic than previous autoconversion schemes. The new scheme will reconcile some of the common biases in particular the excessive ACI in current global climate models. We show an impact of the new scheme on the simulated precipitation characteristics and aerosol effective radiative forcing using a single-column model and a global aerosol-climate model.

Aerosol data assimilation experiment using GCOM-C SGLI aerosol product

*Taichu Y Tanaka[1], Keiya Yumimoto[3,1], Mayumi Yoshida[2], Hiroshi Murakami[2], Takashi M. Nagao[4], Megumi Okata[2]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Earth Observation Research Center, Japan Aerospace Exploration Agency, 3. Research Institute for Applied Mechanics, Kyushu University, 4. Atmosphere and Ocean Research Institute, The University of Tokyo

The Global Change Observation Mission - Climate (GCOM-C) satellite was launched on 23 December 2017, for long-term environmental monitoring of the Earth. The GCOM-C satellite carries the second-generation global imager (SGLI), which is a multi-wavelength optical radiometer that has 19 observation wavelength bands from near-ultraviolet to thermal infrared and has characteristic functions such as polarization, multi-directional, and near-ultraviolet observation. SGLI observation data contributes to the improvement of the accuracy of the processes in climate models such as clouds, aerosols, sea colors, vegetation, and snow ice, and to be applied in various applications such as predictions of sand and dust storms, fishing ground, and understanding of red tide occurrence. JAXA Earth Observation Research Center (EORC) retrieves and provides quantitative information on atmospheric aerosols from SGLI data. The SGLI standard non-polarized aerosol product includes aerosol optical thickness (AOT), Angstrom exponent, and single scattered albedo on land are derived. JAXA EORC, Meteorological Research Institute of Japan Meteorological Agency (MRI/JMA), and Research Institute for Applied Mechanics (RIAM) of Kyushu University have been carrying joint research to utilize the geostationary and low-orbit satellites to monitor and predict the atmospheric aerosols, and to create an integrated aerosol product. MRI/JMA is currently developing a global aerosol prediction system that assimilates SGLI aerosol products using the global aerosol model MASINGAR. We will show the initial results of data assimilation experiments using two-dimensional variation (2D-Var) for the global aerosol model, and discuss the data verification, quality control, and the effects of the data assimilation.

A study on the effects of sulfate aerosols on ocean circulation and the consequent atmospheric feedback

*Yuki Kusakabe[1], Toshihiko Takemura[2]

1. Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, 2. Research Institute for Applied Mechanics, Kyushu University

Sulfate aerosols are generally known to have negative radiative forcing and then cool the earth. The effects on the atmosphere are not uniform globally, and regional variations have been simulated by atmosphere-ocean coupled global climate models. Although Collier et al. (2013) showed that anthropogenic aerosols can alter the ocean circulation, on the other hand, there are no detailed analysis of it due to specific anthropogenic aerosol components in past studies. Then, in this study, using sensitivity experiment data from MIROC-SPRINTARS it is examined how sulfate aerosols affect ocean circulation and atmospheric feedback. In the sensitivity experiment, the anthropogenic emissions of SO_2, a precursor of sulfate aerosol, are perturbed to be 0, 0.3, 0.5, 0.8, 1.5, 2, 5 and 10 times from the current emissions. The calculations were performed for 100 years in the equilibrium experiments, and the data in the last 50 years were used for analysis. The results show that spatial distributions of changes in sea surface temperature (SST) are similar to those of surface air temperature. A peculiar perturbation of SST is shown in the mid-latitude of the North Atlantic, which the SST increases (decreases) due to an increase (decrease) in SO_2 emission. Analysis of ocean currents and wind fields suggests that strengthening or weakening of westerly winds by sulfate aerosols perturbation may change a flow path of the Gulf Stream, causing the characteristic change in SST.

Surface air temperature response to large-scale volcanic eruptions and its relationship with ENSO

*Sho Kitabayashi[1], Hiroshi G. Takahashi[1]

1. Tokyo Metropolitan University

A volcanic eruption injects sulfate aerosols into the atmosphere, which decrease the surface air temperature (SAT). When the aerosols expand in the stratosphere, a decrease in SAT can be maintained globally during a few years, although it is generally difficult to estimate the effects of a volcanic eruption because of the existence of internal variations in the climate system. This study estimated the SAT change after large low-latitude volcanic eruptions focusing on the phase of El Niño-Southern Oscillation (ENSO) by analyzing CMIP5 historical experiments. Volcanic eruptions, as an external forcing of climate system, are prescribed based on the observational datasets. However, internal variabilities like ENSO are different in each ensemble. Thus, it is possible to analyze SAT changes in the same eruption that are different in the phase of ENSO. Results showed that global SAT changes after volcanic eruptions contain a difference in the phase of ENSO. In addition, the “combined” effect of ENSO and volcanic eruptions still was found after the eruptions globally. The contribution of the ENSO to SAT was estimated approximately 1/10 to 1/5 of the whole decrease in SAT. Furthermore, the SAT changes were different in the both hemispheres. In the northern (southern) hemisphere, the decrease in SAT was larger (smaller), and the SAT changes continued shorter (longer) periods.

[A-AS12] Weather and climate extremes in East Asian monsoon system: mechanism, predictability, and projection

convener:JinHo Yoon(GIST Gwangju Institute of Science and Technology), Shih-Yu (Simon) Wang(Utah State University), Hyungjun Kim(The Univ. of Tokyo)

Weather and climate extremes have happened in sequence with similar characteristics, such as long-lasting drought and severe forest fire. Recently, the succession of two extreme yet opposite characteristics occurring in close proximity, such as the 2018 Japan severe flood followed by record-breaking heat wave, calls for a closer look at the synoptic-climate, which is largely linked to the East Asian Summer Monsoon system. From Europe to Asia, heat waves and severe thunderstorms can happen in rapid succession as well, modulated by a quick phase change of the meandering yet semi-stationary short waves. The changing climate may or may not affect all those circulation ingredients, making extreme-event attribution analysis difficult. However, in-depth understanding of the mechanism and its lifecycle is critically important to disaster mitigation and water security in warming climate. This session calls for recent advancement in combining the mesoscale, synoptic-scale, and large-scale diagnostics and modeling towards understanding mechanism, prediction and its future with a focus on weather and climate extremes particularly in East Asian monsoon system.

The study on the dynamic influence factors of the interdecadal variability of the subtropical high in the Western Pacific Ocean based on the information flow method

*Mei Hong[1], Ren Zhang[1], Kefeng Liu[1], Liang Zhao[1], Jingjing Ge[2]

1. National University of Defence Technology, 2. The 31110 troop of PLA

The subtropical high in the Western Pacific (WPSH)is one of the most important weather systems. It is the most important large-scale circulation system in low latitude. Its location and intensity directly affect the weather system in East Asia. Its abnormal activities often lead to disastrous weather in East Asia. Our paper deals with the complexity and uncertainty of the decadal variations of WPSH based on the information flow method. The eastern equatorial Pacific SST, the equatorial western Pacific SST, the equatorial Indian Ocean SST, eastern qinghai-tibet plateau geothermal flux of qinghai-tibet plateau, the main body of regional geothermal flux, geothermal flux in southern qinghai-tibet plateau region, the qinghai-tibet plateau in the western region of geothermal flux can be chosen as influence factors.By using the information flow method, the causal relationship between each factor and the interdecadal variability of the index of WPSH is calculated. On this basis, more important factors are screened out, and the interaction facts and mechanism between them and the interdecadal variability of WPSH are analyzed.

Keywords: western Pacific subtropical high, dynamic influence factors, information flow, SST near the equator

Characteristics and Formation of a Synoptic Situation Causing Sudden Turning of Mesoscale Convective Systems over South China

*Zhaoming Liang[1], Ying Liu[1], Jinfang Yin[1]

1. Chinese Academy of Meteorological Sciences

The rainfall of the pre-flood rainy season (April–June) contributes more than 40% of the annual rainfall for South China, and warm-sector mesoscale convective systems (MCSs) have been indicated as the principal systems causing heavy or extreme rainstorms in this rainy season [1–4]. Compared to frontal rainfall systems, warm-sector MCSs are harder to predict [5], owing to difficulties in accurately capturing their initiation, development and motion. In contrast to the initiation and development, the motion of MCSs over South China has seldom been investigated, especially for those with complex motion.
In the present study, the characteristics and formation of a synoptic situation that causes a sudden turning motion of warm-sector mesoscale convective systems (MCSs) over South China are described, based on the collection and investigation of associated cases during April–June 2011–2017 using high-resolution observational data and ERA (ECMWF Re-Analysis)-Interim data. The results show that the blocking of a marked low-level high over eastern China (eastern high) on a strengthening low-level trough over southwestern China (southwestern trough) results in significant enhancement of southerly winds ahead of the trough, which produces a strong southeastward vertical wind shear at low levels near western Guangdong province. This low-level vertical wind shear results in sudden southeastward turning motion for the warm-sector MCSs entering into Guangdong province from Guangxi province. The formation of the eastern high is mainly attributable to the strong cyclonic wind anomaly over the northwestern Pacific Ocean, which continuously brings cold air from higher latitudes to eastern China, where high synoptic-scale transient anomaly of geopotential height (SSTA-GH) forms. This cyclonic wind anomaly is induced by a low SSTA-GH, which travels from the north and south sides of the Tibetan Plateau to the northwestern Pacific Ocean and develops significantly as a result of a strong upper-level low SSTA-GH coupling with it or approaching it. On the other hand, the high SSTA-GH over eastern China blocks the eastward extension of the low SSTA-GH originating from the Tibetan Plateau. Consequently, this low SSTA-GH turns to extend or move southeastward/southward to southwestern China, leading to intensification of the southwestern trough.

Large-Scale Circulation Anomalies Associated with Extreme Heat in South Korea and Southern–Central Japan

*Ke Xu[1]

1. Institute of Atmospheric Physics, Chinese Academy of Sciences

The large-scale circulation anomalies associated with extreme heat (EH) in South Korea and southern–central Japan are examined using data during the time period 1979–2016. Statistical analysis indicates that EH days in these two regions are concentrated in July and August and tend to occur simultaneously. These EH days are therefore combined to explore the physical mechanisms leading to their occurrence. The composite results indicate that the anomalous atmospheric warming during EH days is dominantly caused by a significant subsidence anomaly, which is associated with a deep anomalous anticyclone over East Asia. Further investigation of the evolution of circulation anomalies suggests that the anomalous anticyclone over East Asia related to EH is primarily initiated by wave trains originating from upstream regions, which propagate eastward along the Asian westerly jet in the upper troposphere. These wave trains can be categorized into two types that are characterized by the precursor anticyclonic and cyclonic anomalies, respectively, over central Asia. The distinction between these two types of wave train can be explained by the wavenumbers of the Rossby waves, which are modulated by both the intensity and the shape of the Asian westerly jet as the background basic flow.

A Synoptic Assessment of Climate Models' Representation of Summer Precipitation Extremes over East China

*Yi Deng[1], Yang Hu[2], Zhimin Zhou[2]

1. Georgia Institute of Technology, Atlanta, Georgia, United States, 2. Institute of Heavy Rain, China Meteorological Administration, Wuhan, China

The large-scale circulation anomalies associated with extreme precipitation events over the middle reaches of Yangtze River (MRYR) in early summer (June and July) are classified into three canonical synoptic patterns via hierarchical clustering. All clusters indicate a distinct connection between the MRYR extreme precipitation and anomalous moisture convergence driven by 1) low-level anomalous southwesterlies associated with the expansion of the Western Pacific Subtropical High, and 2) the anomalous northerlies tied to three distinct extratropical circulation anomalies ranging from zonally-elongated barotropic to developing baroclinic disturbances. The reproduction of these canonical patterns and their ties to extreme precipitation are found only in a subset CMIP5 models, where underestimates of the occurrence frequency of these patterns are largely responsible for underestimates of the occurrence frequency of extreme precipitation over East China in boreal summer. Our analysis also reveals that a few CMIP5 models simulate a reasonable rain rate spectrum in this region through a series of synoptic patterns that are not seen in observations. The differences in the potential responses among various synoptic patterns to greenhouse-gas forcing suggest the need of validating and better constraining climate model simulations of extreme events from a synoptic and weather perspective in order to achieve a more realistic projection of the near term changes in these events of tremendous societal impacts.

Comparison of the East Asian Summer Monsoon Activities Represented by Clouds and Precipitation

*Yunying Li[1], Yun Jia[1]

1. College of Meteorology and Oceanography, National University of Defense Technology, China

Based on the pentad average ISCCP (International Satellite Cloud Climatology Project) D1 cloud data and a merged station and satellite precipitation data from 1998 to 2007, two types of cloud index and precipitation index are defined, which respectively reflect changes in clouds and precipitation locations and precipitation intensity associated with the East Asian summer monsoon (EASM) activities. The cloud and precipitation indices are used to study the advancing process of the EASM in mainland China. It is found that both indices can well represent the quasi-stationary stage and the north jump of the EASM, and they are consistent spatially and temporally. Based on changes in the cloud indices, active, transitional and interruptive monsoon periods in three regions of South China, East China and North China are defined. Differences in the cloud indices as well as differences in the circulation and water vapor fields at 500 hPa between the active and interruptive periods are examined, and the reasonability of the cloud indices is proved. Comparison of monsoon activity periods defined by the cloud indices and precipitation index shows that the monsoon active (interruptive) days are basically the same. However, the difference between the cloud and precipitation indices is that the precipitation index emphasizes the change in precipitation, while the cloud indices emphasize the change in cloudiness. The difference between monsoon active (interruptive) days respectively defined by cloud and precipitation indices could also reflect differences in the feature and type of precipitation.

Impact of the recant warming of the surrounding ocean on the heavy rain event of July 2018 in Japan

*ATSUYOSHI MANDA[1], Satoshi Iizuka[2], Hisashi Nakamura[3], Takafumi Miyasaka[4,5,3]

1. Mie University, 2. National Research Institute for Earth Science and Disaster Resilience, 3. The University of Tokyo, 4. Japan Meteorological Business Support Center, 5. Meteorological Research Institute

The western North Pacific and the Asian marginal seas exhibit a rapid warming trend compared to the global average during the past century, and this trend is projected to continue toward the end of this century. Some recent studies suggest that the warming marginal seas in mid-latitudes plays a vital role in torrential rainfall events during a warm season, but the impact of the maritime warming is still debatable and thus under active research. A torrential rainfall that occurred from 28 June to 8 July 2018 caused widespread and devastating floods, landslides, and mudflows and they led to severe damages over wide areas in Japan, especially in its western part. We examine the impact of the recent warming of the surrounding ocean, including the marginal seas, on the torrential rainfall event, through the numerical simulations with a high-resolution regional atmospheric model. A fractional change of 3-day accumulated rainfall over land from 5 to 8 July, during which the most intensive rainfall was observed, is approximately 10%/K, which is consistent with a previous modelling study. This change cannot be explained quantitatively by the well-known theoretical argument based on the Clausius-Clapeyron relationship, i.e., change in precipitable water solely due to the atmospheric warming. Rather, our experiment suggests that the change in sea surface temperature can account for the rainfall change via the modification of convectively unstable air from the tropics. The specific mechanisms for the rainfall changes will be discussed in this presentation.

The effects of boundary layer processes on snowfall in Yanqing Zone of 2022 Winter Olympic Games

*BO YU[1], Jia DU[1], Ruixin LIU[1], Yujue LIU[2], Ziming LI[3], Luyang XU[1]

1. Beijing Municipal Weather Forecast Center, 2. Institute of Urban Meteorology, China Meteorology Administration, 3. Environmental Meteorology Forecast Center of Beijing-Tianjin-Hebei

Yanqing Zone of Beijing, as the venues for alpine skiing, sleigh and sled in 2022 Winter Olympic Games, the characteristics of snowfall have attracted much attention. According to the difficulty of snowfall forecast, the snowfall processes in Yanqing Zone during 2008 to 2018 was divided into two categories, synoptic scale system dominance and boundary layer process dominance (without obvious influence of synoptic scale system). In view of the snowfall dominated by the boundary layer processes, which was relatively difficult to predict, the analysis showed that one day of snowfall per year was caused by boundary layer processes. The snowfall dominated by boundary layer processes was divided into two types, northerly flow and westerly flow, and on the ground, it was usually a weak pressure field or an easterly flow. The northerly flow pattern accounted for a higher proportion of boundary layer process dominance, when the ground was easterly wind, if the saturated air and the terrain were forced to rise together, it could produce snowfall; when the lower layer was northerly wind, and it would produce local snowfall in high altitude area. The westerly flow pattern usually caused snowfall with large range and long duration, when the wind direction in boundary layer changed from easterly to southeasterly and the wind speed increased, it corresponded to the strongest period of precipitation; when the easterly wind speed decreased, the snowfall intensity also decreased.

MJO Effects on the Formation and Subseasonal Predictability of Record-breaking Northeast Asian Heatwave in the Summer of 2018

*Pang-Chi Hsu[1], Yitian Qian[1], Hiroyuki Murakami[2]

1. Nanjing University of Information Science & Technology, 2. NOAA/GFDL

In the summer of 2018, Northeast Asia experienced a heatwave event that broke the existing high-temperature records in several locations in Japan, the Korean Peninsula and northeastern China. At the same time, an unusually strong Madden–Julian Oscillation (MJO) was observed to stay over the western Pacific warm pool. Based on reanalysis diagnosis, numerical experiments and assessments of real-time forecast data from two subseasonal-to-seasonal (S2S) models, we discovered the importance of the western Pacific MJO in the generation of this heatwave event, as well as its predictability at the subseasonal timescale.

During the prolonged heat extreme period (11 July to 14 August), a high pressure anomaly with variability at the intraseasonal (30–90 days) timescale appeared over Northeast Asia, causing persistent adiabatic heating and clear skies in this region. As shown in the composites of MJO-related convection and circulation anomalies, the occurrence of this 30–90-day high anomaly over Northeast Asia was linked with an anomalous wave train induced by tropical heating associated with the western tropical Pacific MJO. The impact of the MJO on the heatwave was further confirmed by sensitivity experiments with a coupled GCM. As the western Pacific MJO-related components were removed by nudging prognostic variables over the tropics towards their annual cycle and longer timescales (>90 days) in the coupled GCM, the anomalous wave train along the East Asian coast disappeared and the surface air temperature in Northeast Asia reduced. The MJO over the western Pacific warm pool also influenced the predictability of the extratropical heatwave. Our assessments of two S2S models' real-time forecasts suggest that the extremity of this Northeast Asian heatwave can be better predicted 1–4 weeks in advance if the enhancement of MJO convections over the western Pacific warm pool is predicted well.

Causes of Inter-decadal Increase in Intraseasonal Rainfall Variability over Southern China around Early 1990s

*Lu Wang[1], Tim Li[2,1], Yifeng Cheng[1]

1. Nanjing University of Information Science and Technology, Nanjing, 210044, China, 2. University of Hawaii, Honolulu, HI 96822, USA

The summer intraseasonal rainfall variability in Southern China (SC) shows a significant increase around 1992/1993, which coincides with the inter-decadal increase in summer mean rainfall. This study explores the causes of the inter-decadal change of 10-30-day rainfall variability over SC from 1979-1993 (P1) to 1994-2008 (P2). The SC intraseasonal rainfall events during 1979-2008 are objectively decomposed into three groups using K-means cluster analysis: southward propagating (SP) type, northwestward propagating (NWP) type and northward propagating (NP) type. A further analysis shows that it is the increase in the occurrence frequency of NP type that results in the enhancement of intraseasonal rainfall variability from P1 to P2, while the intensity of each type doesn't change significantly. Vorticity budget analysis suggests that the northward propagation results from the advection of intraseasonal vorticity anomaly by summer mean southerly wind in the middle-to-lower troposphere. A marked increase in the summer mean southerly wind in P2 relative to P1 causes more frequent occurrence of NP type and thus stronger intraseasonal rainfall variability over SC. No significant inter-decadal increase is found in the atmospheric instability over the south China Sea, suggesting that this factor doesn't contribute to more frequent NP type of rainfall in P2 than P1.

Consecutive extreme flooding and heat wave in Japan: Are they becoming a norm?

*JinHo Yoon[1], Shih-Yu (Simon) Wang[2], Hyungjun Kim[3], Jeehoon Jeong[1]

1. GIST Gwangju Institute of Science and Technology, 2. Utah State University, 3. University of Tokyo

In July 2018, Japan experienced two contrasting, yet consecutive, extreme events: a devastating flood in early July followed by unprecedented heat waves a week later. Death tolls from these two extreme events combined exceeded 300, accompanying tremendous economic losses (BBC: July 24, 2018; AP: July 30, 2018). Meteorological analysis on these 2018 events quickly emerged (JMA-TCC, 2018; Kotsuki et al., 2019; Tsuguti et al., 2019), highlighting several compound factors: a strengthened subtropical anticyclone, a deepened synoptic trough, and Typhoon Prapiroon that collectively enhanced the Baiu rainband (the Japanese summer monsoon), fostering heavy precipitation. The comprehensive study of these events, conducted within a month and released by the Japan Meteorological Agency (JMA) (JMA-TCC, 2018), reflected decades of knowledge of the Baiu rainband and new understanding of recent heat waves in southern Japan and Korea (Xu et al., 2019). Regardless, an extended forecast of this record-breaking precipitation remains challenging, with a skillful prediction of no more than 3 days (Kotsuki et al., 2019). Given the impending Baiu season of 2019, it is prudent to reflect upon these successive 2018 events by parsing out the critical components while discussing the potential of future compound extremes.

Consecutive compound extremes of flood and heatwave within East Asia Summer Monsoon Lifecycle

*Hyungjun Kim[1], Gavin Madakumbura[2], Shih-Yu (Simon) Wang[3], JinHo Yoon[4]

1. The Univ. of Tokyo, 2. University of California, Los Angeles, 3. Utah State University, 4. Gwangju Institute of Science and Technology

In recent years, East Asian countries have faced to wet and dry extremes frequently. For example, Japan experienced a catastrophic flood, and it was followed by a record-breaking heatwave in July 2018. The flood caused about 10 billion USD of economic damage which was a record breaking. The casualties by flood and drought exceeded 200 and 1000, respectively. In this study, we suggest that the timing of the consecutive flood and drought would not be coincident, but they are tightly connected with the active, break and revival phases of East Asia Summer Monsoon Lifecycle. Also, we examine the extend to which these back-to-back extreme events changes under the global warming and to which the human-induced warming is attributed to the intensification of the wet and dry swing. Multi-model large-ensemble simulations based on historical (naturalized and all-forcing) and future (+1.5 and +2.0 degree warming above preindustrial period) were adopted from Half a degree Additional warming, Prognosis and Projected Impacts project.

[A-AS13] New particle formation and its impacts on atmospheric chemistry

convener:Jun Zheng(Nanjing University of Information Science and Technology), Lin Wang(Fudan University)

Despite of the fact that new particle formation (NPF) contributes about half of the aerosol population globally, the underlying mechanisms governing the NPF remain poorly understood. Current NPF models often lead to conflicting results with respect to real-time in-situ observations. Consequently, NPF process is seldomly incorporated into atmospheric models, causing great hindrance to accurately assess aerosol atmospheric impacts on air pollution formation and climate change on both regional and global scales. Although H2SO4, basic gases, and HOMs have been proposed to be responsible for NPF, searching for potential NPF precursors are still an active subject of research. Many recent studies strongly indicate that NPF mechanism may differ from place to place and the newly formed particles may also possess distinct properties (e.g., CCN activity). Nevertheless, there is a great demand to reconcile the conflicting results and to improve our understanding of the mechanisms for NPF. This session solicits contributions that describe research progresses on any aspects of NPF, including laboratory studies, theoretical calculation and modeling, and field measurements.

Formation of sulfuric acid clusters governed by a combined effect of dimethylamine and condensation sink in polluted northern China

Yiqun Lu[1], Gan Yang[1], Yiliang Liu[1], Yuwei Wang[1], *Lin Wang[1]

1. Fudan University

Formation of sulfuric acid (H_2SO_4, SA) clusters is considered to be responsible for atmospheric sulfuric acid - dimethylamine (C_2H_7N, DMA) nucleation in atmospheric new particle formation (NPF) processes, where the critical roles of both amines and condensation sink (CS) have been demonstrated. However, their combined effect is still not quantitively discussed in ambient observation. In this study, a comprehensive field campaign of NPF was carried out in Wangdu, Hebei province, which represents a typical polluted site in northern China. A number of key precursors and atmospheric parameters were recorded concurrently including the concentrations of sulfuric acid monomers and dimers, DMA, and aerosol particle number size distributions. H_2SO_4-DMA-H_2O ternary nucleation mechanism was responsible for the observed NPF events through the correlation analysis of sulfuric acid monomers, sulfuric acid dimers, CSs, and nucleation rates, and the comparisons with the results from atmospheric cluster dynamics code (ACDC) and CLOUD experiments. The CS and [DMA] varied significantly on NPF event days: CS ranged from 0.01 to 0.04 whereas the 25-75% percentiles of [DMA] covered 1.1-8.2 pptv (part per trillion by volume), which indicates that the formation of clusters should be govern by the two factors. Based on the well-accepted formation pathway of sulfuric acid dimers in the literature, we quantitatively described the combined effect of [DMA] and CS in the formation of sulfuric acid dimers. The ratio of sulfuric acid dimer to the square of sulfuric monomer, a parameter that describes the likelihood of NPF events, could be written as a function of [DMA] and CS. Our ambient observation in four strong NPF events validates this combined effect.

Role of water molecule in aerosol nucleation and air-water interface reaction: quantum chemical and molecular dynamic simulation

*Fei Xu[1]

1. Shandong University

Recently, quantum chemical calculation and molecular dynamic simulation methods have important theoretical significance and practical application value to study the formation and degradation of atmospheric pollutants, especially the micro-mechanism of atmospheric photodegradation, aerosol nucleation and heterogeneous reaction, and to identify structural information and energy information of the intermediates and products in the reaction process.
Water is the third most abundant species in the atmosphere after N2 and O2, corresponding to 50% of relative humidity at 298 K. Water plays an important role in several gas-phase chemical processes occurring in the atmosphere. For example, we carried out quantum calculation to study the interactions between benzoic acid (BA) and sulfuric acid (SA)/ammonia (NH3)/dimethylamine (DMA) with hydration by 1 to 6 water molecules, and found water molecules have different effect on BA-SA/NH3/DMA nucleation (Figure 1). For BA-DMA-(0-6)H2O, increasing water molecules can inhibit nucleation. For BA-NH3-(0-6)H2O, the most negative Gibbs free energy occur when NH3 are hydrated with 2/6 water molecules and BA is unhydrated. For BA-SA-(0-6)H2O, the most negative Gibbs free energy occur when SA is unhydrated and BA are hydrated with 6 water molecules. Moreover, the Born-Oppenheimer molecular dynamics (BOMD) was used to simulate ammonium bisulfate formation from a series of amines, SO3, and H2O molecules at the air-water interface. The results show that reactions between amines and SO3 involve multiple water molecules at the air-water interface. The reaction center’ s ring structure (amine-SO3-nH2O) promotes the transfer of protons in the water molecules (Figure 2). The formed ammonium cation (-RNH3+) and the bisulfate anion (HSO4-) are present and stable by means of hydrogen bond interaction.

The Cloud Condensation Nuclei (CCN) activity during the New Particle Formation (NPF) events in the mountain region of China inland

*Mingfu Cai[1,2], Baoling Liang[1], Qibin Sun[1], Bin Yuan[2], Min Shao[2], Haobo Tan[3], Lihong Ren[4], Jun Zhao[1,5]

1. Institue for Environmental and Climate Research, Jinan University, 2. School of Atmospheric Sciences, Sun Yat-sen University, 3. Institute of Tropical and Marine Meteorology/Guangdong Provincial Key Laboratory of Regional Numerical Weather Prediction, CMA, 4. Atmospheric Chemistry and Aerosol Research Division, Chinese Research Academy of Environmental Science, 5. Southern Laboratory of Ocean Science and Engineering (Guangdong, Zhuhai), Zhuhai

A one-month field measurement was conducted at a mountain site (32˚23′ N, 111˚02′ E, with an attitude of 862 m) on the Wudang Mountain, Hubei Province, China from 22nd May to 29th June 2018. The particle size number distribution (PNSD, with a size range of 3-400 nm), size-resolved cloud condensation nuclei (CCN, SS=0.2%, 0.4%, 0.6% and 0.8%) and non-refectory PM1 (NR-PM1) chemical composition was measured by a home-made Regular & Nano Scanning Mobility Particle Sizer System (R & N-SMPS), a Cloud Condensation Nuclei Counter (CCNc) and a Time-of-Flight Aerosol Chemical Speciation Monitor (ToF-ACSM). The new particle formation (NPF) events were observed on 4th, 7th and 11th June during the measurement. These events generally started at around 9:00-10:00 Local Time (LT) with a significant distribution mode of particles with a size range of 3-10 nm. During the events, the wind direction was south west or west and the wind speed was about 3-4 m s-1, which might be favor to the occurrence of NPF event, while the mechanism was unclear. The nucleated particles grew to about 40-50 nm at different time, owing to different growth rate (2.963, 7.573 and 11.383 nm h-1 on 4th, 7th and 11th June, respectively). Probably owing to different atmospheric environment, such as gaseous precursors, oxidant and particle concentration, the formation rate (J3) was different during three events varied from 0.59 to 5.05 cm-3 s-1. The contribution of newly formed particles to the CCN number (NCCN) was mainly depend on their final grown size and the time when they affect the NCCN was decided by the GR. Two types of NPF event enhanced by sulfuric acid or organic vapors was found out during the measurement. Therefore, the hygroscopicity of newly formed particles could varied from a large range (0.25-0.8) and exert a large uncertainty on the NCCN prediction. It found out that the deviation of the NCCN prediction at 0.8% SS could vary from -10% to 38%.

Nucleation events within an industrial zone in the YRD region of China

*Jun Zheng[1], Yan Ma[1], Dongsen Yang[1]

1. Nanjing University of Information Science and Technology

Nucleation processes contribute substantial secondary aerosols in the atmosphere, which often lead to severe air pollution episodes in China, especially in heavily populated urban area. In this work, we conducted field observations of nucleation events in Nanjing, China. The field observations were conducted during the Fall of 2015. Both gaseous sulfuric acid (H_2SO_4) and sub-3 nm particles were simultaneously detected. H_2SO_4 and sub-3 nm aerosols showed excellent correlations during the nucleation events. Multivariate analysis indicated that two or three molecules of H_2SO_4 might be present in the critical nuclei. Several nocturnal nucleation events with concurring H_2SO_4 peaks were also observed while the site was within the industrial plumes. High level of alkenes and relative high concentration of O_3 (~30 ppbv) indicated that alkene ozonolysis might be responsible for the nighttime production of H_2SO_4. The impacts of the nocturnal nucleation processes on the local air quality need to be further investigated.

Effects of SO2 on secondary organic aerosol generated from photooxidation of toluene

*Weigang Wang[1]

1. Institute of Chemistry,Chinese Academy of Sciences

Atmospheric aerosol plays an important role in air quality and climate change, in which secondary organic aerosol (SOA) is one of the most important aerosol species. Size distribution, chemical composition, and optical property of secondary organic aerosol (SOA) derived under various atmospheric conditions differ greatly. In this study, we investigated the effect of SO2 under different humidity on optical properties of toluene-derived SOA under four conditions with cavity ring-down spectrometer and photoacoustic extinctiometer at 532 and 375 nm, respectively. Our results showed that SO2 under different humidity can change the refractive complex index (RI, m = n + ki) of toluene SOA by influencing the multiphase processes and altering the aerosol chemical compositions. High relative humidity caused the scattering and absorption properties of SOAs increased greatly, similar to m-xylene and 1,3,5-trimethylbenzene, as previous studies proved. Adding SO2 under dry condition would reduce the refractory index of RI (n) but increase the imaginary index of RI (k), which might be a result of the partitioning of low oxidation state products and enhancement of charge transfer complexes. The extinction properties of condition high humidity with SO2 were 30% higher than condition dry, and mass cross section was about 0.2131 g/m2. Our study demonstrated that different atmospheric conditions could affect the properties of toluene SOA, as well as air quality and the global radiative balance.

[A-AS14] Extreme Events: Observations and Modeling

convener:Sridhara Nayak(Disaster Prevention Research Institute, Kyoto University), JAGABANDHU PANDA(National Institute of Technology Rourkela)

The frequencies and intensities of extreme events such as heavy rainfall, flash floods, droughts, heat waves, tropical cyclones etc. have increased in many regions across the globe and are of serious concern due to their socio-economic and climate change connections. Thus, understanding of the patterns of such events and particularly their characteristics have been the focus of many recent studies. This session invites abstracts on observational and numerical modeling studies to enhance the understanding of the spatial and temporal characteristics and predictability of the extreme events. In particular, abstracts are encouraged on regional analysis of the extreme events in past years and in near or far future (30-100 years), which would assist the policy makers to build potentially more resilient societies to face the extreme event related disasters. This session also welcomes the submissions on model simulations and evaluations to advance the understanding of the physics and dynamics associated with the extreme events.

Heat Wave Identification Using an Operational Weather Model and Analog Ensemble

*Alon Sidel[1], Weiming Hu[1], Martina Calovi[1], Guido Cervone[1,2]

1. The Pennsylvania State University, 2. National Center for Atmospheric Research

Heat waves are notoriously difficult to forecast due to their highly localized variables, yet remain one of the world's deadliest natural disasters. This project uses the Analog Ensemble technique (AnEn), which generates probability information from a deterministic predictive model, to identify heat waves across the continental United States with further accuracy. Heat index was calculated to assess the intensity of heat waves and forecast ensembles for heat index were generated using weather analogs. AnEn was shown to outperform the baseline weather prediction model when a quantile was used to summarize the ensemble.

Assimilation radar reflectivity to improve the simulation of a squall line case

*Linlin Zheng[1,2], Xuexing Qiu[1]

1. Anhui Meteorological Observatory, 2. Anhui Institute of Meteorological Sciences

Based on assimilation of radar radial wind, radar retrieval wind and GPS water vapor data using Ensemble Kalman Filtering (EnKF) method, the initial water vapor field of a squall line occurred on July 30, 2014 in of East Central Anhui was adjusted according to radar reflectivity data. Compared with the simulation results of EnKF, this method has improved the intensity, location, duration, precipitation and surface wind of the squall line. Simulation performance of ground convergence zone near front the squall line is improved after adjusting humidity field, leading to better simulation results of the intensity and location of the squall line. In addition, the squall line maintained for a short time without humidity adjustment. This can be explained by that mid-level dry air entrainment is weak at the rear of the squall line, and the cold pool is quickly propagate away from the squall line, which is unfavorable for maintenance of squall line. In contrast, when the humidity field is adjusted, dry air entrainment at the rear of the squall line is strong, and the resultant downdraft generate the cold pool, which is located in the rear of the squall line, favorable for the squall line maintenance. The possible reason of dry air entrainment strengthening is: atmospheric instability is increased as the moisturizing of middle-low level (600 - 900 hPa) after the humidity field adjustment, and result in the enhancement of the convection and the meso-low system. The westerly in the south of meso-low intensifies, and strengths the rear dry cold air entrainment. This experiment reveals that the adjustment of the humidity leads to the adjustment of the dynamic field, and play an important role in the development and organization of the convection system.

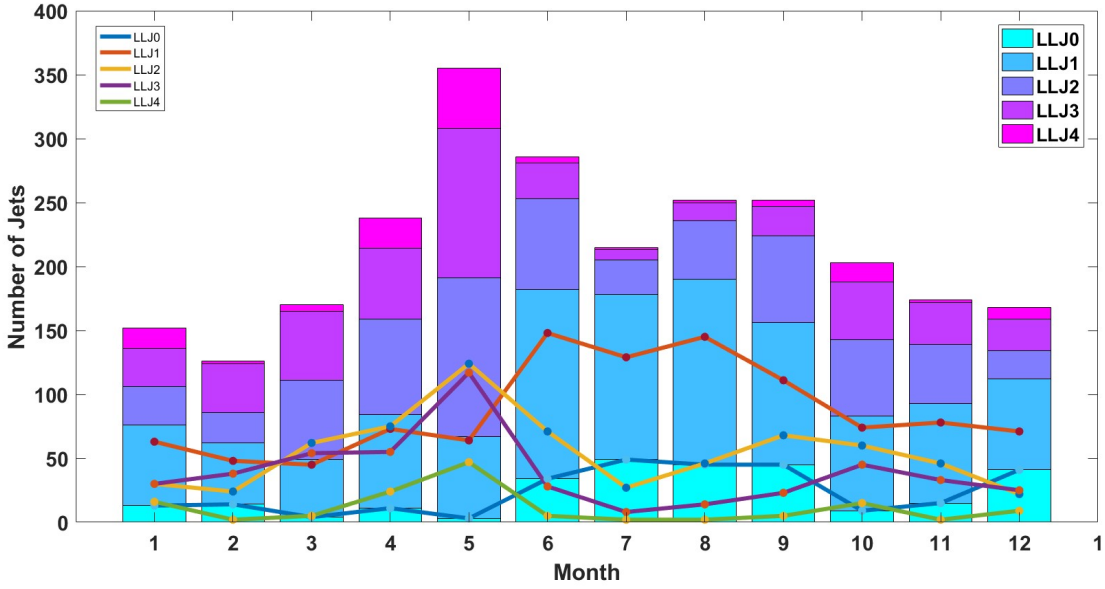
Characteristics of **Low-level Jets** in *Tianjin* with a Wind Profile Radar during 2015-2016



*Bingui Wu[1,2], Zongfei Li[1,2], Tingting Ju[3]

1. Tianjin Key Labarotory of Marine Meteorology, China, 2. Tianjin Meteorological Bureau, China, 3. Institute of Navigation College, Dalian Maritime University, China

Low-level jets (LLJ) are important mesoscale weather system. In this study, the characteristics of the LLJs are studied. The data are collected at a standard weather station Xiqing (54527) operated by the China Meteorological Administration from 2015 to 2016. Based on previous criteria for LLJs given by Bonner (1968) and Wei et al. (2013), a new set of criteria suitable for LLJs over NCP is defined in this study. LLJs were classified into five categories based on two criteria of the Vmax threshold value and difference value (ΔV) from Vmax upward to the adjacent Vmin. The definition are as follows. The criteria of LLJ0 are 6 m/s > Vmax ≧ 4 m/s and ΔV ≧ 2 m/s , and those of LLJ1, LLJ2, LLJ3, and LLJ4 are 10 m/s > Vmax ≧ 6 m/s and ΔV ≧ 3 m/s, 14 m/s > Vmax ≧ 10 m/s and ΔV ≧ 5 m/s, 20 m/s > Vmax ≧ 14 m/s and ΔV ≧ 7 m/s, and Vmax ≧ 20 m/s and ΔV ≧ 10 m/s , respectively. Based on the above criteria, LLJs observed at Xiqing were identified, and the number of 1-h LLJ periods was counted regardless of whether they were continuous or intermittent in the time series. Statistics showed that the most frequently directions of LLJs are 180˚–270˚, which accounted for nearly 47 %. The results of four seasons also verify the same conclusion, except the distribution of occurrence direction in winter. Moreover, compared with the relatively uniform distributions of wind directions of weak LLJs (LL0, LL1, and LL2), the distributions of wind directions of strong LLJs (LL3 and LL4) concentrate in a narrow range between 210˚ and 250˚, which suggests that southwesterly winds contribute to the formation of strong LLJs. The wind speeds of most of LLJs are less than 14 m/s, and the occurrence proportion of LLJ4 is only 5.1 %, which indicates that the super-strong LLJs is rare. The occurrence height distribution of LLJs that most LLJs occur below 2000 m, and the height distribution of LLJs is relatively uniform except the peak at lower levels (500-600 m), which can also be observed in different seasons. Moreover, compared with strong LLJs (LL3 and LL4), LL0 tended to occur at a higher level, however, the height distribution of different strength LLJs are different in four seasons. The result of monthly distribution of the frequency of LLJ occurrence shows that LLJs occur more frequently during warm season than cold season, which maybe because of the increasing amplitude of inertial oscillations in the boundary layer during the warm seasons. In addition, distribution of the frequency of LLJ occurrence display a unimodal distribution, with strong LLJs occur more frequently in spring (March to May), and the occurrence of weak LLJs concentrated in summer (June to August). In addition, it is worthwhile that moderate LLJs (LLJ1 and LLJ2) are contributories to the total LLJs through the whole year. The occurrence number of LLJs has an obvious diurnal variation, with the peak of occurrence number around midnight (2300–1400 CST). Unimodal curves are commonly observed for all categories of LLJs except the super-strong LLJ4, whose distribution can be separated into two parts, a relatively high occurrence number from 1400 CST to 2200 CST and extremely low occurrence number from 0000 CST to 1300 CST. The duration of the LLJs events is usually less than 6h and the most frequent duration is 1–2h (47 %) which suggests that the LLJs are gusty events. However, it is worthwhile the duration of weak LLJs is smaller that of relatively strong LLJs, which indicates that the stronger of the strength of LLJ, the longer duration it will last.

Climate change impacts on extreme rainfall and their differences between weather patterns

*Masamichi Ohba[1], Soichiro Sugimoto[1]

1. Central Research Institute of Electric Power Industry

The impacts of global warming/climate change on extreme rainfall events during the Baiu period in Japan and their dependency on weather patterns (WPs) were examined using the self-organizing map (SOM) method. To investigate the differences in climate change impacts on daily rainfall among the WPs, a SOM was applied to surface atmospheric circulation data from the Database for Policy Decision Making for Future Climate Change (d4PDF) to determine the dominant heavy rainfall WPs. The obtained SOM shows that different WPs are associated with regional variations in extreme rainfall events. Projected future changes in the occurrence of heavy rainfall displayed a non-uniform spatial distribution. To understand the spatial heterogeneous rainfall changes, the sensitivity of heavy rainfall WPs to climate forcing was evaluated. Results of the SOM analysis suggest that this regional variation in the future changes in extreme rainfall events could be attributed to sensitivity differences between WPs to the climate changes. These sensitivity differences can be attributed to the non-uniform spatial changes in the large-scale climatological background state in East Asia via modulations in the moist air intrusion into Japan.

Spatial and Temporal Variation of Thermodynamic Indices in Relation to Pre-Monsoon Thunderstorms over Tripura, India

*Rajesh Kumar Sahu[1], Bhishma Tyagi[1]

1. National Institute of Technology Rourkela, Odisha, India

Thunderstorms are frequent in Eastern and Northeastern Indian region and are the primary source of precipitation and extreme events during Pre-monsoon season. The intensity and frequency of these storms are higher, which leads to impact the climate over these regions. Thermodynamic indices variations are globally accepted to see the variation of a thunderstorm (TD) and non-thunderstorm days (NTD) spatially and temporally, and are helpful in nowcasting of thunderstorm event. In this study, we have analysed both spatial and temporal variation of thermodynamic indices for a northeastern state Tripura, India, to study the prevalence of thunderstorm. Radiosonde observation data are used for the thirty years (1987-2016) to understand the temporal vaiation of thermodynamic indices over Agartala. The thermodynamic indices analysis has been divided in equal interval of five years to see the trend variation of the thermodynamic indices. For spatial variation of thermodynamic indices, we utilities ERA-5 reanalysis dataset with 0.25˚ X 0.25˚ (31 km) resolution over Tripura throughout TD and NTD days. The information of thunderstorm occurrence is obtained from the India Meteorological Department (IMD) for Agartala and over several other locations over Tripura. The results shows a shift in threshold values of some index which mark the impact of climate change by temporal variation of these indices. At the same time, some other indices are unable to show any change in the pattern over this area. For the spatial pattern, some indices (convective and potential) shows better results for categorising the thunderstorm days over Tripura and in contrast conditional instability indices unable to distinguish thunderstorm days spatially. We correlated the changes in the threshold value of the thermodynamic indices by using Man-Kendall trend test to analyse the spatial variation of thermodynamic indices.

Probabilistic Forecast of Extreme High Temperature in Extended Period with the Bayesian Model Averaging

*Wei Zhang[1], Jianyun Gao[1], Qiaozhen Lai[2], Yanzhen Chi[3], Tonghua Su[4]

1. Fujian Institute of Meteorological Sciences, Fuzhou, China, 2. Longyan Meteorological Bureau, Longyan, China, 3. Xiamen Meteorological Bureau, Xiamen, China, 4. Fujian Climate Center, Fuzhou, China

The method of the Bayesian model averaging (BMA) is employed to improve extended probabilistic forecast of extreme high temperature based on the ensemble prediction system (EPS) outputs of ECMWF, NCEP, and UKMO from the sub-seasonal to seasonal (S2S) prediction project database in this study. The outcomes of BMA, single-model EPS and multi-model EPSs are verified with mean absolute error (MAE), correlation coefficient (ACC), brier score (BS), and continuous ranked probability score (CRPS). On the basis of comparison between the verifications, it is suggested that the BMA performs better than single-model EPS and multi-model EPS in all leading times for all verification method. Although the BMA has improved the raw probabilistic forecast substantially, the lead time can only reach up to 9 days in terms of positive skill of BMA Bier skill score for extreme high temperature (≧ 35˚C). To extend valid lead time, the raw outputs of single-model EPS are preprocessed with the running mean method for training before BMA. It turns out that the running-mean BMA is able to extend the lead time of positive skill to 11 days.

Introduction of CLoud Analysis and Ingestion System(CLAIS)

*Ruixia Liu[1], Bingyun Yang[1], Wen Hui[1]

1. China Meteorological Administration

1.Introduction of CLoud Analysis and Ingestion System(CLAIS)

In recent years, there is a growing demand for high spatial-temporal resolution, high-precision and three-dimensional cloud elements in the fields of numerical prediction, weather analysis, aviation meteorology, etc. Although there are more and more ways of meteorological observation and detection, such as surface observations, radar observations and satellite detection, etc. But any single observation of them still can not meet this demand. How to integrate multiple sources of ground, satellite, radar and other kinds of observation data to obtain spatiotemporal continuous, high efficiency, high-resolution cloud products has become one of the trends of technology development.

Through many years of study, National Satellite Meteorological Center of CMA has established the three-dimensional Cloud Analysis and Ingestion system (CLAIS) which can combine FY series meteorological satellite data with ground, sounding, radar and other observations to get 3D cloud parameters.The prototype of the three-dimensional Cloud Analysis and Ingestion system (CLAIS) comes from NOAA LAPS/ STMAS. It is a three-dimensional fusion analysis system that integrates the advantages of a variety of observation data. The accuracy of three-dimensional cloud construction was improved greatly after a series of algorithm updates and improvements including cloud top construction, cloud base constraints, multi-source data collaborative fusion algorithm etc. At present, it can integrate background field of numerical prediction (GRAPES of CMA, NCEP, ECMWF), conventional observation and sounding (MICAPS, CIMISS interface), satellite data (FY-2 VISSR, FY-4 AGRI, FY-4 LMI,FY3 MWHS,H8), radar (Reflectivity), GPS and other data. These observation data is comprehensively analyzed and fused to obtain three-dimensional cloud structure information, three-dimensional Microphysical parameters, and other atmospheric and surface parameters.Study shows that the distributions of the analyzed cloud structure is consistent with the CloudSat observations.Post-processing software was developed to display three-dimensional cloud structure and draw two-dimensional cross section of cloud, and has overlay display function, providing user a convenient tool for accomplishment display and scientific research.

2.The application of CLAIS system

First of all, cloud is one of the important uncertainties of the numerical prediction model. The lack of cloud information in the initial field of the model will lead to the phenomenon of significant delay in the development of cloud and precipitation at the early stage of a model forecast, that is, the problem of spin-up model. Therefore, how to obtain the accurate three-dimensional and space-time continue cloud field and provide the initial field of the model has always been the way of data assimilation efforts. Using 3D cloud analysis data of CLAIS as initial fields of GRAPES and WRF forecasting model, and through case and batch tests, the prediction performance is evaluated. The research shows that the application of CLAIS 3D cloud analysis system can improve the cloud process of NWP model and has a positive effect on the precipitation area and intensity forecast.The system has a very important application potential in convection analysis, artificial weather, aviation meteorology, military application and other fields.

Verification of multiple-Doppler-radar derived vertical velocity using profiler data

*Yi-An CHEN[1,2]

1. Yu-Chieng LIOU , 2. Jou-Ping Hou

The retrieval of vertical velocity using Doppler radar data always contains large uncertainty. In this study the quality of the vertical velocity retrieved by a 3DVar-based multiple-Doppler wind analysis system named WISSDOM (WInd Synthesis System using DOppler Measurement) is investigated. Data from one S-band (RCWF) radar and two C-band radars (RCTP and NCU) in northern Taiwan are utilized.

The accuracy of the vertical velocity from WISSDOM is examined using two profilers (L-band and UHF) observations. The inter-comparison shows that WISSDOM-derived vertical velocity agrees reasonably well with the profiler data. The highest correlation and the smallest RMSD (Root-Mean-Square Deviation) take place when comparing against the L-band profiler data obtained under vertical beam scanning mode. The WISSDOM-derived results are generally better than those reported in a previous study using ARM scanning radar network in Oklahoma.

The winds from the L-band profiler are also merged into WISSDOM, resulting in an overall improvement of the three-dimension wind field at low levels. UHF and RCTP are applied to verify the accuracy of the method. It is shown that WISSDOM assimilating the L-band can reduce RMSD and enhance correlation with UHF and RCTP. The result suggests that the method can get better three-dimension wind field.

Characteristics of the diurnal variations flood period precipitation in Anhui during the last 30 years

*chun liu[1]

1. ANHUI METEOROLOGY SERVICE

The characteristics of flood season daily precipitation were analyzed in the term of rainfall amount, frequency and intensity using the hourly data in Anhui during 1981-2010. The main results are as follows. (1) The daily rainfall amount and frequency have two diurnal peak, one in the early morning and the other in the late afternoon, while the rainfall intensity does not reflect an obvious peak. The peaks of light and moderate rain days lie in afternoon, and there are two peaks in heavy rain days. However, the peak of torrential rain days lies in morning. These differences are due to the different lasting rainfall events. (2) The spatial distributions of rainfall have large diurnal variation with considerable regional features. As amount of daily rainfall increasing, the spatial distribution of peak time performs less consistent. (3) In the 30 years, the annual change of afternoon-peak in rain amount and intensity is almost the same, reflecting an increase between 1993 and 2010. There are more stations of morning peak time in weak monsoon years than strong monsoon years.

Keywords: rainfall diurnal variation, feature of rainfall peak, monsoon

Understanding the impact of soil moisture variations on temperature extremes over the Indian region

*Naresh Govind Ganeshi[1,2], Milind Mujumdar[1], R Krishnan[1], Mangesh Goswami[1,3], Yuhei Takaya[4], Toru Terao[5]

1. Centre for Climate Change Research, Indian Institute of Tropical Meteorology, Pune, India, 2. Department of Atmospheric and Space Sciences, Savitribai Phule Pune University, Pune, India, 3. Kavayitri Bahinabai Chaudhari North Maharashtra University, Pune, India, 4. Meteorological Research Institute, Climate Research Department, Ibaraki, Japan, 5. Faculty of Education, Kagawa University, Kagawa, Japan

Soil moisture (SM) and its long-term memory are known to be linked to near-surface temperature variations through land-atmosphere interactions. While previous studies have reported the association between temperature extremes over India and large-scale atmospheric circulation, the role of land-atmosphere coupling on temperature extremes over the monsoon-dominated Indian region is not well understood. In the present study, we have analysed multiple hydro-meteorological datasets and climate model outputs to understand the impact of SM variations on the occurrence of temperature extremes in a changing climate. Long-term climate observations reveal that the surface temperature over India increased by 0.7^{o}C during 1901-2018, whereas the regional summer monsoon rains have decreased by about 7% since 1950. Our analysis shows that the decrease of SM over north-central India (NCI), in association with the declining monsoon precipitation, has altered the characteristics of temperature extremes in the region through strong land-atmosphere coupling. It is found that the frequency, duration and variability of temperature extremes over NCI have significantly risen during the post-1980, in association with the depletion of soil moisture in the region. Our analysis indicates that the drying trend of SM over the NCI in the recent decades has favoured a significant increase in the occurrence of temperature extremes through enhancement of sensible heat flux and reduction of latent heat flux. In addition, it is noted that the loss of soil moisture memory has led to an increase in the variability of temperature extremes over the region.

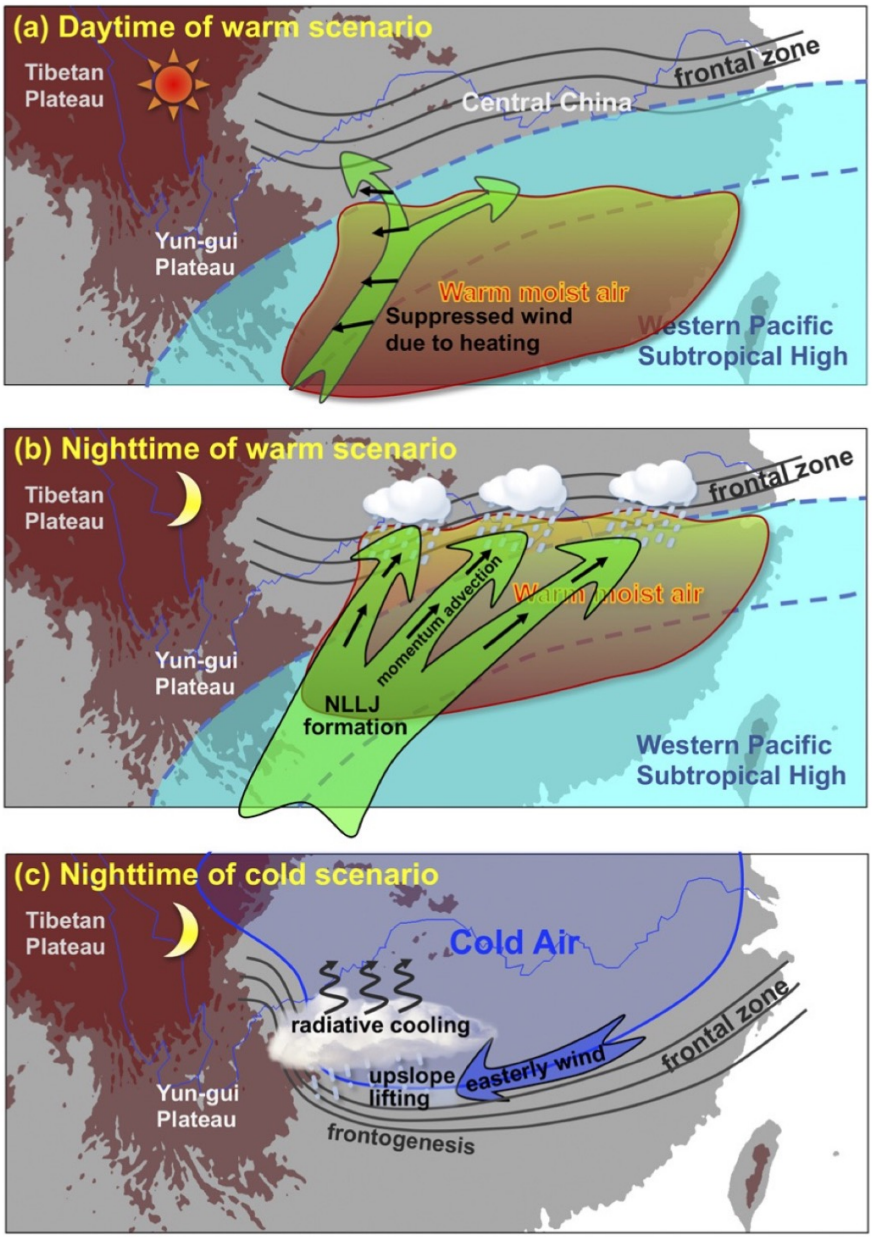
Diurnal Variations of Low-Level Winds and Precipitation Response to Large-Scale Circulations during a Heavy Rainfall Event



*Wenxin Zeng[1], Guixing Chen[1], Yu Du[1], Zhiping Wen[2]

1. School of Atmospheric Sciences, Sun Yat-sen University, 2. Department of Atmospheric and Oceanic Sciences, and Institute of Atmospheric Sciences, Fudan University

A succession of MCSs developed during the last week of October 2016 and produced extreme heavy rainfall in central China. The event underwent an evident shift from a mei-yu-like warm scenario to an autumn cold scenario. Diurnal cycles of rainfall and low-level winds may be modulated by the shifting of large-scale at- mospheric conditions. We conducted observational analyses and numerical experiments to examine how large-scale circulations influenced rainfall systems through diurnally varying processes. The results show that, in the first half (warm) period of the event, intense rainfall mostly occurred in eastern-central China with an early morning peak. It was closely related to a nocturnal southwesterly low-level jet (NLLJ) on the flank of the western Pacific subtropical high. The NLLJ formed near midnight in southern China where ageostrophic wind rotated clockwise due to Blackadar’ s inertial oscillation. The NLLJ extended downstream to central China during the predawn hours due to the horizontal advection of momentum. Both the formation and extension of the NLLJ were supported by an enhanced subtropical high that provided relatively warm conditions with surface heating for boundary layer inertial oscillation and strong background southwesterly winds for mo- mentum transport. The NLLJ induced MCSs at its northern terminus where the low-level ascent, moisture flux convergence, and convective instability were enhanced during the predawn hours. In the second half period with an intrusion of cold air, the diurnal amplitude of low-level winds became small under relatively cold and cloudy conditions. Moderate rainfall tended to occur in western-central China with a peak after midnight, most likely due to frontogenetic processes, upslope lifting, and nighttime cloud-top cooling.

Extreme weather in the context of solar wind coupling to the magnetosphere-ionosphere-atmosphere system

*Paul Prikryl[1,2], Vojto Rušin[3], Pavel Šťastný[4], Maroš Turňa[4], Martina Zeleňáková[5]

1. Physics Department University of New Brunswick, Canada, 2. Geomagnetic Laboratory Natural Resources Canada, 3. Astronomical Institute, Slovak Academy of Sciences, Slovakia, 4. Slovak Hydrometeorological Institute, Slovakia, 5. Technical University of Košice, Slovakia

Tropical and extratropical cyclones can intensify into the most destructive weather systems that have significant societal and economic impacts. Rapid intensification of such weather systems has been examined in the context of solar wind coupling to the magnetosphere-ionosphere-atmosphere (MIA) system. It has been shown [1,2] that explosive extratropical cyclones and rapid intensification of tropical cyclones tend to follow arrivals of high-speed solar wind when the MIA coupling is strongest. The coupling generates atmospheric gravity waves (AGWs) that propagate from the high-latitude lower thermosphere both upward and downward [3,4]. In the upper atmosphere, AGWs are observed as traveling ionospheric disturbances. In the lower atmosphere, they can reach the troposphere and be ducted [4] to low latitudes. Despite significantly reduced wave amplitude, but subject to amplification upon over-reflection in the upper troposphere, these AGWs can trigger/release moist instabilities leading to convection and latent heat release, which is the energy driving the storms. The release of conditional symmetric instability is known to initiate slantwise convection producing rain/snow bands in extratropical cyclones. Severe weather, including severe winter storms, heavy snowfall and rainfall events, have been examined in the context of MIA coupling [5]. The results indicate a tendency of significant weather events, particularly if caused by low pressure systems in winter, to follow arrivals of solar wind high-speed streams from coronal holes. In the present paper we review the published results and provide further evidence to support them. This includes the occurrence of heavy rainfall events and flash floods, as well as the rapid intensification of recent hurricanes and typhoons, with the goal to identify sources of AGWs at high latitudes that may play a role in triggering convective bursts potentially leading to such events.

The threat of stronger typhoons is getting bigger in the Northwest Pacific (NWP) ocean basin as the average number of Super-Typhoons (STYs) reached its maximum of 6 per year during the recent five years (2013-2017) in the recorded history. This study analyzes the favorable seasonal environmental factors for the STYs during the recent years by incorporating the remote sensing imagery and wind vector images created using U and V wind component data. The study successfully detects a crucial role of southwest air flow and northwest cold air mass in partially strengthening the STYs of the summer and winter seasons, respectively. In addition, it finds that most of winter STYs are also partially assisted by southwest air flows and, thus, exhibit higher intensities than summer STYs. The season-wise track angle analysis reveals that winter STYs' genesis positions lie more south in latitude, causing bigger genesis and turning angles, than summer STYs. The study uncovers that all summer STYs merely take recurvature once they finish their individual maximum intensity stage. The regions in the NWP basin, supporting the conversion of typical typhoons' evolution into STYs and consequent recurvature, are also detected. The findings of the current study are important for mitigating the risk related to increasing strength of typhoons in the NWP region by identifying their favorable seasonal environmental factors.

High space resolution atmospheric simulation of severe regional precipitation and vehicle strain mode

*Jou Ping Hou[1], Zan-Han Huang[1], Qun-Yu Fan[1]

1. Chung Cheng Institute of Technology

Under the weakly synoptic scale weather conditions, local thunder showers often occur in the afternoon in Taiwan during summer. Due to the characteristics of small range and heavy rainfall intensity (often exceeding 130 mm hr-1) during precipitation, flooding disasters are often caused and severe precipitation will make vehicles unable to drive on the roads normally, and traffic will be greatly affected. This study uses the WRF 3.9.1 model to simulate a severe precipitation potential area under the design of a two nesting domain with a horizontal spatial resolution of 1 km. We hope that by knowing the possible areas of precipitation, we will study the feasibility of reminding drivers of the degree of flooding after installing water level sensors and buzzers on cars from the perspective of disaster reduction. Airbags are added to the chassis of the vehicle to allow the vehicle to float on the water and reach the car body balance by itself. In addition, the paddles that can be automatically ejected on the wheels are used to enable the driver to control the direction of the water and allow the driver to safely cross the flooded area. This research is not only used for ordinary people's livelihood, it gives ordinary people more chances of survival and prolongs rescue time. In addition, it can also be applied to national defense technology.

Variations of Daily Precipitation Extremes over Xinjiang Province, China

*MINGGANG LI[1], YONG ZHAO[1]

1. Chengdu University of Information Technology

Based on observational daily rainfall data from China meteorological data service center from 1963 to 2017, the temporal and spatial variations of daily precipitation extremes (DPE) over Xinjiang province (the west part of northwest arid zone of China) were investigated. In this work, the statistical characteristics, the concentration degree (CD) and concentration period (CP), along with the persistence and regionality of DPE were discussed for understanding the change features of DPE from different aspects. During recent 55 years, the precipitation in Xinjiang province is becoming more extreme, which is reflected in the significant decrease of low-intensity rainfall but the significant increase of DPE. Both the frequency and intensity of DPE show positive trends at most sites in Xinjiang province, and the increase in DPE frequency is more significant than the increase in DPE intensity. The characteristics of DPE CD and CP in different regions of Xinjiang province vary a lot. The annual DPE CD values of stations over Southern Xinjiang is very large because of the annual occurrences of DPE is very few, which in most years the DPE occurs less than 2 days, therefore the DPE concentration in these stations is high. While the conditions differ in stations over Northern Xinjiang, the average annual DPE of these sites usually more than 3 days, and the annual DPE CD values is relatively low, indicate the occurrence time of DPE is more dispersed in Northern Xinjiang. The annual DPE CP values reflect that DPE occurs most intensively in boreal summer, both in Northern Xinjiang and Southern Xinjiang, but in stations over Northern Xinjiang, there exists a certain number of years that DPE occurs more frequently in spring or autumn, indicate a relatively long season of DPE occurrence. Results of trend analysis show that accompanying with the notable increasing of DPE frequency, this relatively dispersed occurrence time and longer occurrence season over Northern Xinjiang is intensified in the past few decades. Few indices are also calculated for investigate the persistence and regionality of DPE at each station in Xinjiang province, although there are some disparities in different regions, the DPE duration and regionality in Xinjiang stations is generally poor. These results are help for our better understanding the features and changes of climate extremes over arid region under a warming background.

Relevance of Background Error Statistics for Variational Radar Assimilation System

*THIRUVENGADAM PADMANABHAN[1], INDU J[1,2], SUBIMAL GHOSH[1,2]

1. Department of Civil Engineering, Indian Institute of Technology Bombay, Mumbai 400076, India., 2. Interdisciplinary Centre for Climate Studies, Indian Institute of Technology Bombay, Mumbai 400076, India.

Skillful prediction of extreme convective weather events remains a challenge in regional Numerical Weather Prediction (NWP) models. Reduced forecast skill in regional NWP models is often attributed to improper representation of convective storm structure in the initial condition. Assimilation of high-resolution Doppler Weather Radar (DWR) observations through variational systems provide critical information about the pattern and evolution of convective systems in the initial conditions. However, the quality of variational radar assimilation hinges on the Background Error statistics (BES) which is a statistical measure of the error in model forecasts. The BES is generally modeled using control variables through either the National Meteorological Centre (NMC) or the ensemble method. Hence the choice of control variable and modeling method have a significant influence on the skill of analysis from the variational systems [Thiruvengadam et al., 2019]. In this study, we investigate the control variable (CV) properties of both NMC and ensemble-based BES and their impact on the skill of the three-dimensional variational radar assimilation system. Results demonstrate that the use of zonal and meridional momentum CV in both the NMC and ensemble method improves the moisture and dynamics forecast state variables when compared to the use of stream function and velocity potential CV. Best precipitation forecast results are obtained when ensemble-based BES modeled using zonal and meridional momentum CV are used for assimilating DWR observations.

Analysis of Hydroclimatic Extremes over Narmada Basin under Climate Change

*SABYASACHI SWAIN[1], SURENDRA KUMAR MISHRA[1], ASHISH PANDEY[1]

1. Indian Institute of Technology Roorkee

A robust characterization and risk assessment of hydroclimatic extremes is essential considering their pervasiveness and consequences; however, their precise physical quantification is a difficult geophysical endeavor. This is becoming a serious issue for India, having 18% of the world’ s population and 4% of global freshwater, out of which 83% is used in agriculture. In this study, a detailed spatiotemporal assessment of the meteorological droughts (using Standardized Precipitation Index) and extreme rainfall events is carried out over the Narmada Basin for 1951- 2016, using the high-resolution (0.25˚ x 0.25˚, daily) gridded rainfall data. The non-parametric Mann-Kendall (MK) test is applied to investigate the trend of droughts and the 1-day maximum rainfall series. The entire duration is divided into two epochs i.e. 1951-1981 and 1982-2012, for a comparative assessment of hydrological extreme characteristics. Further, the frequency of these extremes are determined for 2020-2050 under RCP 4.5 and RCP 8.5 scenarios to assess the impacts of climate change. The results reveal that the Narmada basin is prone to droughts with a frequency of once in 3 to 6 years. The frequency and severity of droughts have significantly increased in 1982-2012 as compared to 1951-1981. The MK test results indicate a significant increase in the trend of droughts and 1-day maximum rainfall over most parts of the basin. The frequency, severity, persistence and areal extent of droughts are found to be increasing for both the RCP scenarios. The heavy rainfall events are also showing widespread prominence over the basin with a remarkable increase in frequency and intensity. This study suggests that appropriate measures must be taken for better management of the water resources in the basin, and also for mitigation of floods and droughts, considering the increased risk of the high-intensity storms as well as the severe drought occurrences under climate change.

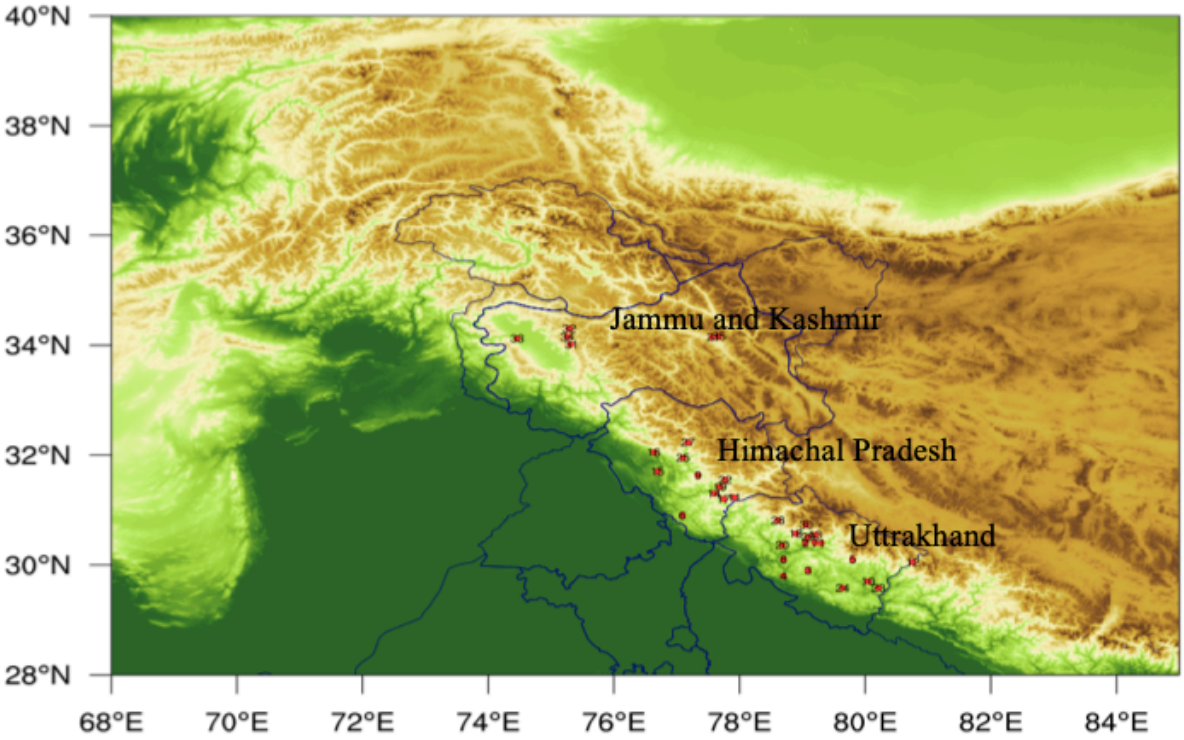
Flashfloods and landslides along the foothills of the Himalayas: their precursors, dynamics and thermodynamics



*Anu Gupta[1], Jun Matsumoto[1]

1. Tokyo Metropolitan University, Tokyo

In the past three decades, the total number of extreme precipitation events during summer monsoon season over north India has increased, which majorly caused flooding and landslides over the Himalayan foothills and north Indian region. Among those extreme precipitation events, some are reported as cloudburst events. In this article, those extreme precipitation events over north India are studied by employing satellite and gauge merged high-resolution precipitation CHIRPS (Climate Hazards Group InfraRed Precipitation with Station data) dataset for the period 1981-2015. Using ERA-Interim reanalysis dataset, cloudburst (CB) events are classified into five major classes C1, C2, C3, C4 and C5 based on the large-scale weather systems observed in the lower, middle and upper troposphere. Analysis shows that cloudburst events of classes C1, C2, and C3 occurs during active monsoon season, whereas, class C4 and C5 cloudburst events develop in the monsoon hiatus/break period. Classes C1, C2 and C3 cloudburst events associated with lower atmosphere cyclonic circulation over the head Bay of Bengal, cyclonic circulation centered over Central India, and East-West oriented low-pressure conveyor system over central India respectively. Further, thermodynamic analysis of each class revealed that class C1, C2, and C3 cloudbursts are associated with the moist instability of the local atmosphere during the cloudburst events, where orographic forcing created potential instability and made them intense and overwhelming. A detailed schematic of each class is presented to understand the overall processes during the cloudburst. This kind of careful knowledge about schematics of extreme precipitation events is very useful in comparing process-based model simulations and monitoring.

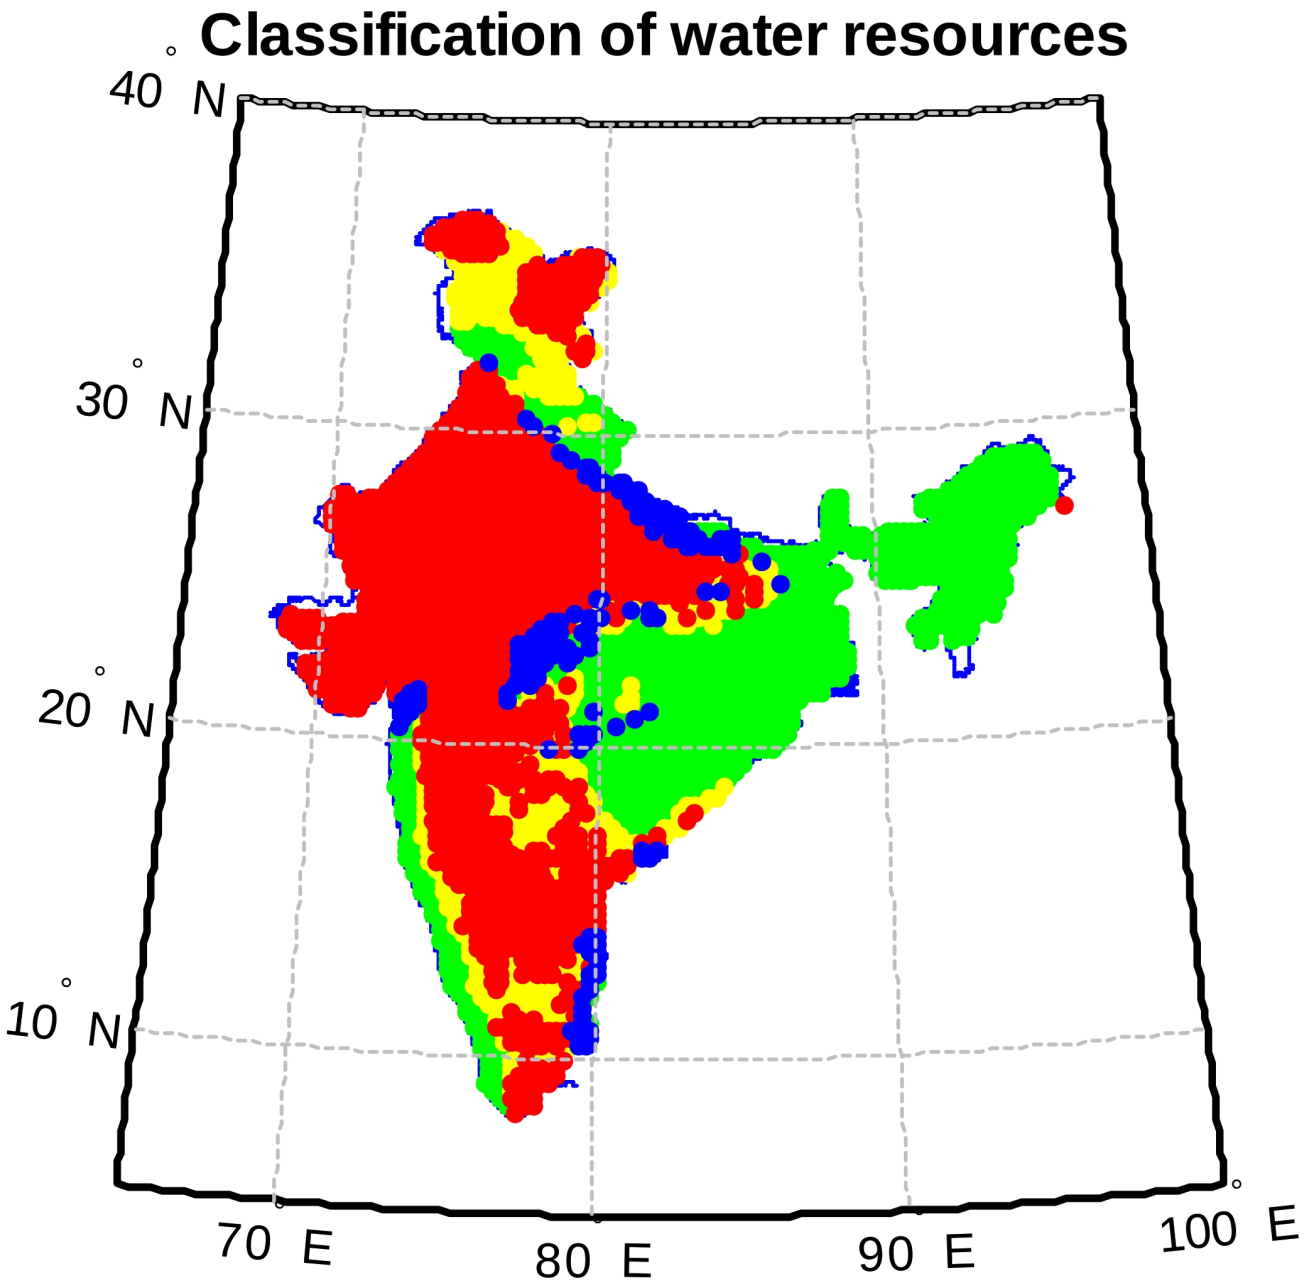
Standardized Variability Index (SVI) : A multiscale index to assess the variability of precipitation



*Ravi kumar Guntu[1], Ankit Agarwal[1]

1. Department of Hydrology, Indian Institute of Technology Roorkee, 247667, India

Quantifying the spatiotemporal variability of precipitation is the principal component for the assessment of the impact of climate change on the hydrological cycle. A better understanding of the quantification of variability and its trend is vital for water resources planning and management. Therefore, a multitude of studies has been dedicated to quantify the precipitation variability over the years. Despite their importance for modeling precipitation variability, the studies mainly focused on the amount of precipitation and its spatial patterns. The studies investigating the spatial and temporal variability of precipitation across the Indian subcontinent, in general, and at multiscale, in particular, are limited. In this study, we introduce a novel measure, Standardized Variability Index (SVI), based on information entropy to investigate the spatiotemporal variability of precipitation. The proposed measure is independent of the temporal scale, the length of the data and can compare the precipitation variability at multiple timescales. Distinct spatial patterns were observed for information entropies at the monthly and seasonal scale. Stations with statistically significant trends were observed and vary from monthly to seasonal scale. There is an increase in the variability of precipitation amount across Central India. Trend analysis revealed there is changing behavior in the precipitation amount as well as rainy days, showing an increase in the probability of occurrence of extreme events in the near future.In addition, coupling the mean annual rainfall with SVI enables a relative assessment of the water resources availability.

[A-OS16] Ocean renewable energy: resource, impacts and technologies

convener:Bahareh Kamranzad(The Hakubi Center for Advanced Research/Graduate School of Advanced Integrated Studies in Human Survivability, Kyoto University), Simon P Neill(Bangor University), Zhaoqing Yang(Pacific Northwest National Laboratory)

The development of renewable energy technologies is a vital part of mitigating the negative impacts related to the combustion of fossil fuels, such as global warming and climate change. More than 70% of the surface of the Earth is covered by water, and the oceans hold more than 96% of all water on the Earth. In addition, two-thirds of the population of the world live within 100 km of the coast. Hence, ocean renewable energies (such as wave, tidal, current and offshore wind) present a sustainable solution to address current and future demand for electricity, particularly in areas that are adjacent to coastal zones. However, the ocean renewable energy resource is not only affected by intra-annual variability, but also longer-term variability due to changes in the climate. Accordingly, as well as quantifying the available resources, it is also important to assess variability over various time scales such as inter- and intra-annual, decadal, etc. Moreover, development of advanced wave and current energy converters that operate efficiently under various ocean conditions and minimizing the potential environmental impacts is crucial to the success of harvesting ocean renewable energy. The levelized cost of energy (LCOE) of ocean renewable energy has been gradually decreasing due to technology advancement. However, much more effort is required to reduce it more compared to other renewable energy resources. In this session, we welcome presentations across a wide-range of themes related to ocean renewable energy, including resource, impacts and technologies.

On the coastal ocean modelling assessment of tidal stream and range energy resources

*Athanasios Angeloudis[1], Lucas Mackie[2], Daniel Stephen Coles[2], Anastasia Fragkou[1], Stephan C Kramer[2], Matthew D Piggott[2]

1. School of Engineering, Institute for Infrastructure and the Environment, University of Edinburgh, 2. Department of Earth Science and Engineering, Imperial College London

Tidal energy can be practically exploited from sites with either high velocity currents or high elevation range. This is accomplished through the deployment of technologies that harness the available kinetic (i.e. tidal stream turbine arrays) or potential (i.e. tidal barrages or lagoons) energy respectively. In particular, the UK features several amplifying coastal characteristics that present viable opportunities for both forms of energy. Even though the rationale for harnessing the energy is fundamentally different, progress has been made on the assessment of prospective schemes using coastal ocean modelling and optimisation methods. As part of the methods developed, we discuss the representation of each of these technologies in the coastal ocean model *Thetis* for several UK-based applications. *Thetis* is an unstructured-mesh, finite-element model that solves both the depth-averaged, as well as the three-dimensional equations with primary applications aimed at the coastal and estuarine zones. It is based on *Firedrake* which is a finite element framework, that automatically derives highly optimised code from a high-level-abstraction description of the finite element equations. Through several UK-based case studies, we present the insight and limitations of the coastal ocean modelling approaches, and highlight specific considerations of the hydrodynamics developed at tidal stream and range sites respectively.

Feedbacks between tidal energy extraction and physical processes

*Simon P Neill[1], Peter Robins[1], Matthew Lewis[1]

1. Bangor Univ.

It is agreed that exploitation of the tidal (stream) energy resource, particularly at significant scales of electricity generation, will impact the marine environment. Although significant levels of extraction will alter the resource itself, particularly in narrow channels, there is one physical process that can indirectly impact the tidal energy resource: sediment dynamics and associated morphodynamics. Here I review the physical mechanisms of how tidal energy conversion influences sediment dynamics, both at device and array scale. I review local and regional impacts, and examine methods of simulating and validating the impact, based on idealized numerical experiments, and case studies including the Alderney Race and the Pentland Firth.

Climate Change Impact on Offshore Wind Energy Resources in Japan

*Masamichi Ohba[1]

1. Central Research Institute of Electric Power Industry

This study investigated the impact of global warming on Japanese wind energy resources and their short-term variations using the large ensemble d4PDF dataset, which consists of dynamically downscaled historical and +4K future climate projections. The capacity factor under the future and present climate was estimated from an idealized power curve based on hourly near-surface wind speeds. The +4K warming future climate projections showed significant changes in wind energy resources that varied both regionally and seasonally. The wind energy potential was projected to slightly increase (decrease) from winter to spring over northern (southern) Japan and decrease from summer to autumn over most of Japan. The projected annual production decreased by about ~5% over Japan in response to climate change. The frequency of wind ramp events also decreased in the latter seasons. The relationship to synoptic weather was investigated using self-organizing maps, whereby weather patterns (WPs) over the region in the present and future +4K climate were classified for a two-dimensional lattice. Future probabilistic projections of WPs under the global warming scenario showed both increases and decreases in the frequency of dierent WPs, with corresponding advantages and disadvantages for wind power generation with regard to future changes in capacity factors in Japan. The importance of these frequency changes on the total change was further assessed by separating the dynamical and thermodynamic contributions.

Sustainability of wave energy potential in Japan

*Bahareh Kamranzad[1]

1. The Hakubi Center for Advanced Research/Graduate School of Advanced Integrated Studies in Human Survivability, Kyoto University

Marine renewable energies and especially the wave energy, as an alternative to fossil fuels, are sensitive to changing climate. In addition, considering both short-term variations and long-term changes in the available resources is necessary for sustainable development. Wave energy potential has been less investigated in Northeast Asia and Japan in long-term and the previous works are limited to three decades at the most and mainly in limited locations and based on wave records or satellite measurements [e.g., 1-5]. This study focuses on the estimation of wave energy resources in Japan using five decades of modeled wave characteristics. For this purpose, SWAN Cycle III version 41.31 (by the Delft University of Technology) [6] was utilized in order to model the wave characteristics in Northeast Asia. The input wind was JRA-55 re-analysis developed by the Japan Meteorological Agency (JMA) [7]. The spatial and temporal resolutions of the wind field are 60 km and 6 hrs, respectively and it is available for the period of 1958-2012. The boundary condition for the model was also obtained from a global performance. The model was validated against satellite measurements and the bias was calculated on a monthly scale showing the similarity between the monthly mean values in the domain. The validated model was performed to generate the wave climate for five decades. The decadal change of wave climate was assessed in 10-yearly periods, i.e., 1961-1970, 1971-1980, 1981-1990, 1991-2000, 2001-2010. The analysis was performed for wind and wave characteristics as well as wave power parameter and the relationship between their change was discussed. The results indicate the difference between the changing pattern in various decades. However, in general, wave height and wave power have been decreased in the Pacific side of Japan during the two latter decades, while the parameters did not change considerably in the Sea of Japan. In addition, the share of swells in the whole wave energy potential has been discussed and the results indicate that almost fifty percent of the total wave power is provided by swells in the Pacific side of Japan while this value reaches around 40 percent in the Ryukyu Islands. In the Sea of Japan side of Japan, the percentage of wave power obtained from swells varied between 15 and 25 percent of the total wave power. Further analysis will be discussed regarding the sustainability of wave energy resources in different time scales.

The effect of future climate-related variabilities of tropical monsoons in the Indian Ocean on wave energy resource around Sri Lanka

*Bahareh Kamranzad[1], Pravin Maduwantha[3], Harsha Rathnasooriya[3], Kasun De Silva[3], Harshinie Karunarathna[2]

1. The Hakubi Center for Advanced Research/Graduate School of Advanced Integrated Studies in Human Survivability, Kyoto University, 2. Zienkiewicz Centre for Computational Engineering, College of Engineering, Bay Campus, Swansea University, 3. Department of Civil Engineering, University of Moratuwa

The direct swell wave approach and relatively narrow continental shelf make more favorable conditions for wave energy harvesting in Sri Lankan coastal region. West and south coasts consist of relatively strong waves comparing to the north and east coasts providing the potential for wave energy harvesting. However, the wave climate in the south and west coasts is highly modulated by the tropical monsoon systems in the Indian Ocean. Southwest monsoon season normally occurs from June to September when winds blow from the southwest, the Indian Ocean and the Arabian Sea, and generate energetic waves in the west and south coasts of Sri Lanka. The northeast monsoon, which falls between December and February, generates high sea waves in the north and east coasts. Although, climate change may alter the regular seasonal cycle. Therefore, it is essential to examine the climate change impacts on available wave energy resource in long term aspects.

Present and future ocean wave climate around Sri Lanka was simulated using numerical wave modeling. The waves have been simulated using wind outputs from the super high-resolution Atmospheric Global Climate Model of the Japan Meteorological Agency, MRI-AGCM3.2S. The future climate scenario of Representative Concentration Pathway (RCP 8.5), as defined by representing trajectories of increasing global radiative forcing reaching + 8.5 W m^{-2}, by the year 2100 compared to pre-industrial conditions, was used. These outputs were first used to develop an Indian Ocean wave model (KU_IO) using SWAN spectral wave model and downscaled up to Sri Lankan Regional model (KU_SLK) (5˚-11˚N, 79.5˚-83.5˚E). Based on the generated wave characteristics, the total average wave power distribution under the present climate (total average power from 1979 to 2003) and future climate (total average power from 2075 to 2099) for the Sri Lankan domain were calculated. The results indicate that even though the west and south coasts of Sri Lanka have the highest available wave power, under the future wave climate, 2 to 3 kW/m wave power reduction can be observed in these regions. In addition, no noticeable change can be seen in the north and east coasts. Future reduction in the available wave power around Sri Lanka can be either due to change in swell conditions of the southern Indian Ocean or due to potential changes to the south-west tropical monsoon. However, these changes may be attributed to wave climate variations in southwest monsoon season since it highly modulates the wave conditions in the south and the west coasts. Therefore, the distribution of total average wave power reduction (total average wave power in the future –total average wave power in the present) was separated into two time periods as southwest monsoon and non-south-west monsoon period. Even in the southwest monsoon season, the highest wave power reduction (2-2.5 kW/m) can be observed along the west to the south coast of Sri Lanka. In this region, the wave power reduction in the future during the non-monsoon period is relatively low (0.4 - 0.6 kW/m). The wave power reduction may cause by the variations of either wave height or wave period. However, the results reveal that according to the model simulations, the future reduction of wave power may be attributed to the change in the southwest tropical monsoon generated wave heights as a result of global climate change.

[A-OS17] Climate variability and predictability on subseasonal to decadal timescales

convener:Takashi Mochizuki(Department of Earth and Planetary Sciences, Kyushu University), V Ramaswamy(NOAA GFDL), Yushi Morioka(Japan Agency for Marine-Earth Science and Technology)

Many efforts have been made to understand and predict climate on subseasonal to decadal timescales (e.g. MJO, IOD, ENSO, PDV, AMV), while our knowledge still remains at an insufficient level to fully resolve socioeconomic challenges arising from climate variations and change. Model simulations and predictions usually present large uncertainties, particularly due to lack of understanding of weather and climate interactions across different spatial and temporal timescales (e.g. tropical cyclones and ENSO), as well as due to multiple physical processes underlying climate variations (e.g. troposphere-stratosphere coupling, air-sea-ice interactions; atmosphere-ocean-land interactions). Recently, datasets from Coupled Model Intercomparison Project Phase 6 (CMIP6) have been opened to the public, and understanding and predicting the changing climate together with its impacts on frequency and intensity of abnormal weather (e.g. cold/heat waves, tropical storms, and floods/droughts) should also be a timely topic in the areas of earth science and socioeconomics. This session aims to share current knowledge of subseasonal to decadal climate variability and predictability in order to identify the unresolved issues and aim at a better understanding and accurate prediction. This session invites all abstracts related to the observational, theoretical, process-level and modelling research on subseasonal to decadal variability and predictability of climate.

It is known that there are two flavors of ENSO events in the tropical Pacific Ocean: traditional eastern Pacific (EP) events and central Pacific (CP) events. Several studies indicated that the CP event is more difficult to predict than the EP event. Here, we assessed the difference of the seasonal predictability for two prominent types of El Nino using the coupled atmosphere-ocean general circulation model (AOGCM) MIROC5 co-developed by Atmosphere and Ocean Research Institute (AORI), National Institute for Environmental Studies (NIES), and Japan Agency for Marine-Earth Science and Technology (JAMSTEC). The spatial resolution is a horizontal triangular spectral truncation at total wave number 85 (T85) with 40 vertical layers, and eight ensemble forecast members are generated according to the protocol of the WCRP Climate-system Historical Forecast Project (CHFP). Hindcast products showed high predictability of tropical climate signals with the significant anomaly correlation coefficient skill scores, even though the ocean anomaly data assimilation is applied to the initialization process.
Overall, the predictable months of CP events are shorter than EP events because CP events are sensitive to atmospheric noises. Characteristics of each error growing process were also investigated.
We also developed a statistical downscaling technique using SVD analysis which is effective for rainfall prediction over the Indochina Peninsula and Australian continent.

Parameter sensitivity analysis for predicting two types of El Niño with an intermediate coupled model

*Haibo Chen[1,2,3]

1. CAS Key Laboratory of Ocean Circulation and Waves, Institute of Oceanology, Chinese Academy of Sciences, 2. Pilot National Laboratory for Marine Science and Technology, 3. Center for Ocean Mega-Science, Chinese Academy of Sciences

Sensitivity of El Niño simulation to model parameters is analyzed using the OPSA method, based on four El Niño events (two EP events and two CP events) simulated by an intermediate coupled model. Results show that the coefficient of entraining anomalous subsurface temperature and the ocean-atmosphere coupling coefficient are two important parameters, while the coefficient of anomalous heat flux is another important parameter for CP events. Observation system simulation experiments shows that El Niño predictions of can be effectively improved if the identified sensitive parameters are more accurately estimated, whereas the improvement is very low or even negative if the estimation of only the insensitive parameters is improved, indicating the significance of the sensitivity analysis result for El Niño prediction.

Interannual Salinity Variability Associated with the Central Pacific and Eastern Pacific El Niños in the Tropical Pacific

*Hai Zhi[1]

1. Nanjing University of Information Science and Technology, Nanjing, China

El Niño exhibits diversity and modulation as indicated by the central Pacific (CP) El Niño and the eastern Pacific (EP) El Niño. Previously, sea surface temperature (SST) has been commonly used to characterize the differences in the two types of El Niño. But, physical processes responsible for the occurrence of the two types of El Niño are still not understood well. Here, ocean reanalysis products and observations are used to analyze the relationships between the two types of El Niño and interannual salinity variability; a budget analysis for mixed-layer salinity (MLS) is performed in the tropical Pacific. The center of negative MLS anomalies in winter tend to move further westward with the CP El Niño, compared with the EP El Niño. The oscillation period with the EP El Niño is found to be approximately 10 years, longer than that with the CP El Niño (approximately 6-8 years). Our results reveal that surface advection, surface forcing and subsurface effect are the three main contributors to mixed layer (ML) tendency of interannual salinity variability, which are regionally dependent. In the eastern edge of the warm pool (WP), surface advection makes a larger contribution (about 40-60 %) to the MLS budget, and subsurface effect (about 20%) and surface forcing (about 20-40%) are relatively smaller; in contrast, in the South Pacific Convergence Zone (SPCZ), the latter two processes make a larger contribution (about 60%). The subsurface effects on the MLS tendency tend to compensate for the imbalance induced by surface forcing and advection: a weakened MLS tendency occurs with the CP El Niño, whereas an enhanced MLS tendency occurs with the EP El Niño, respectively. The MLS tendency leads Niño3.4 by 12 months for the EP El Niño, whereas there is no such significant lead/lag relationship for the CP El Niño. It is demonstrated that the relationships between the interannual SST variability and MLS budget terms can be a clear indicator to distinguish the two types of El Niño.

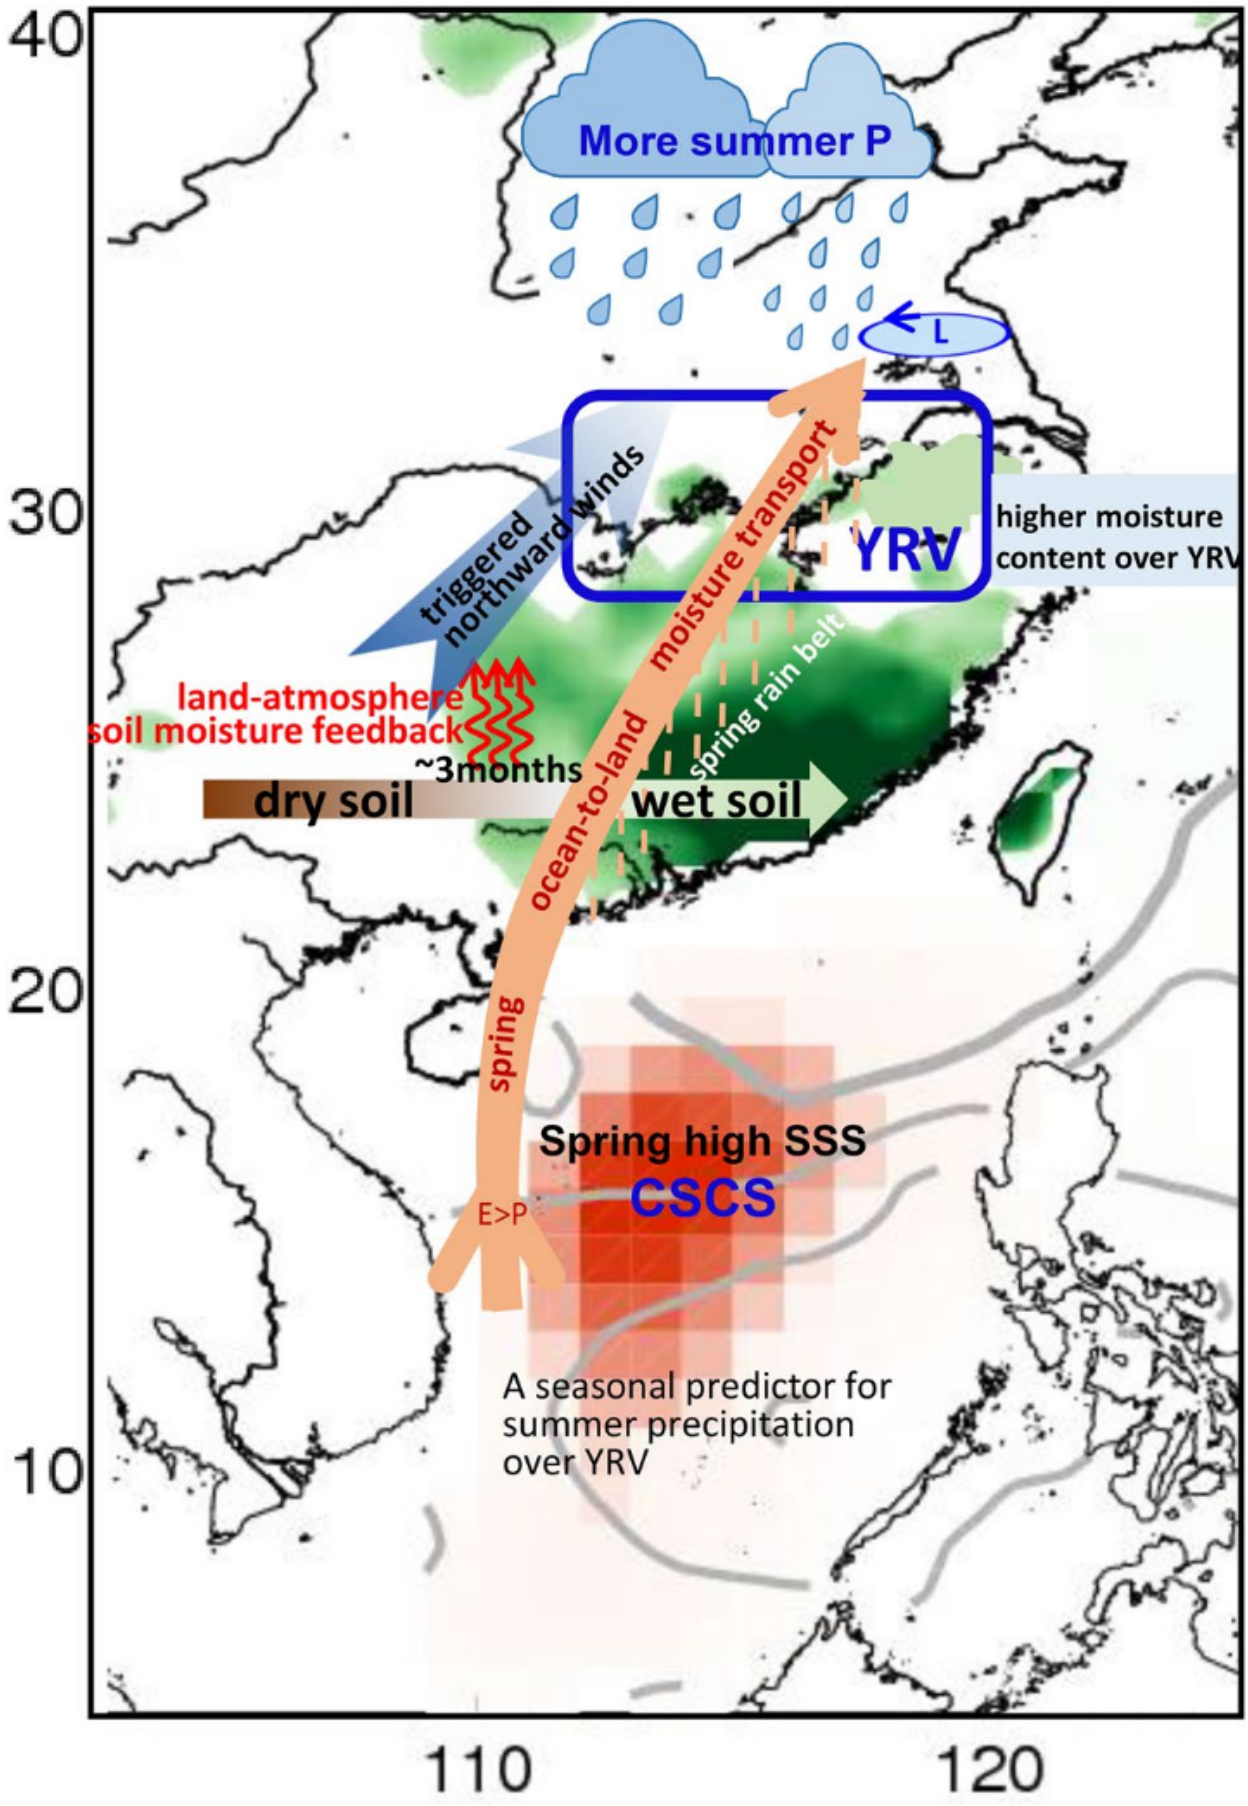
Forecast of summer precipitation in the Yangtze River Valley based on South China Sea springtime sea surface salinity



*LILI ZENG[1], Raymond W. Schmitt[2], Laifang Li[3], Qiang Wang[1]

1. State Key Laboratory of Tropical Oceanography (LTO), South China Sea Institute of Oceanology, Chinese Academy of Sciences, 2. Physical Oceanography Department, Woods Hole Oceanographic Instituti, 3. Earth and Ocean Sciences, Nicholas School of the Environment, Duke University

As a major moisture source, the South China Sea (SCS) has a significant impact on the summer precipitation over China. The ocean-to-land moisture transport generates sea surface salinity (SSS) anomalies that can be used to predict summer precipitation on land. This study illustrates a high correlation between springtime SSS in the central SCS and summer precipitation over the middle and lower Yangtze River Valley (the YRV region). The linkage between spring SSS in the central SCS and summer YRV precipitation is established by ocean-to-land moisture transport by atmospheric processes and land–atmosphere soil moisture feedback. In spring, oceanic moisture evaporated from the sea surface generates high SSS in the central SCS and directly feeds the precipitation over southern China and the YRV region. The resulting soil moisture anomalies last for about 3 months triggering land–atmosphere soil moisture feedback and modulating the tropospheric moisture content and circulation in the subsequent summer. Evaluation of the atmospheric moisture balance suggests both a dynamic contribution (stronger northward meridional winds) and a local thermodynamic contribution (higher tropospheric moisture content) enhance the summer moisture supply over the YRV, generating excessive summer precipitation. Thus, spring SSS in the SCS can be utilized as an indicator of subsequent summer precipitation over the YRV region, providing value for operational climate prediction and disaster early warning systems in China.

Scale-dependent effects on ENSO induced by ocean chlorophyll due to interannual variability and tropical instability waves

*Rong-Hua Zhang[1]

1. Institute of Oceanology, Chinese Academy of Sciences

Large perturbations in chlorophyll (Chl) are observed to coexist at interannual and tropical instability wave (TIW) scales in the tropical Pacific; their combined net effects on ENSO through ocean biology-induced heating (OBH) feedbacks are not known. Here, a new hybrid coupled model for atmosphere and ocean physics-biology (HCM AOPB) is used to quantify ways ENSO can be modulated, individually or collectively, by Chl perturbations at interannual and TIW scales, respectively. HCM-based sensitivity experiments demonstrate a counteracting effect on ENSO: the bio-feedback due to interannual Chl variability tends to damp ENSO via its influence on the stratification and vertical mixing in the upper ocean, whereas that due to TIW-scale Chl perturbations tends to amplify ENSO. A bias source for ENSO simulation is illustrated that is related with Chl effect in the tropical Pacific, adding in a new insight into interactions between the climate system and ocean ecosystem on different scales in the tropical acific. Because ENSO simulations are sensitively dependent on the way Chl effects are represented at different scales, it is necessary to adequately include the related Chl effects in climate modeling. These results reveal a level of complexity of ENSO modulations resulting from TIW-scale Chl effects associated with ocean biogeochemical processes and their interactions with physical processes in the tropical Pacific.

Responses of the subseasonal to seasonal atmospheric variability to the recent Pacific SST anomaly

*Tomoe Nasuno[1], Masuo Nakano[1], Hiroyuki Murakami[2], Kazuyoshi Kikuchi[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. Geophysical Fluid Dynamics Laboratory , 3. International Pacific Research Center

Warm sea surface temperature anomalies (SSTA) is pronounced in the Pacific in recent years. Sensitivity simulations revealed that the warm SST anomaly (SSTA), especially in the subtropics, is responsible for the abnormally active tropical cyclones (TCs) in the Pacific during boreal summer 2018 (Qian et al. 2019). We further examine the SSTA impacts on the TC precursors (e.g., easterly waves) and intraseasonal oscillation (ISO), which are closely related to the TC activity in the western North Pacific (WNP). Simulation dataset using 14-km mesh Nonhydrostatic Icosahedral Atmospheric Model (NICAM) is analyzed. The dataset consists of control experiments (i.e., forced by full SSTA in 2018) and sensitivity experiments without SSTA in a local domain (e.g., tropical Pacific, subtropical Pacific, etc.), and those forced by reginal SSTA in 2018 with other areas restored to the climatological SST. The simulations were forced by the 12 member SST time series for each setup, which were calculated using a coupled general circulation model, the GFDL Low Ocean Resolution (FLOR) model.

The seasonal mean large-scale atmospheric responses and lower tropospheric high-frequency kinetic energy (KE), as a proxy of TC precursor activity, are compared. In the control simulations (with full SSTA in 2018), eastward extension of westerly anomalies in the tropics manifest as the enhanced Asian summer monsoon, which is consistent with the observations. A marked zonal convergence and cross-equatorial flow collocate with high KE anomalies, suggesting the enhancement of the TC precursor activity by accumulation of moisture and large-scale upward motion in the central tropical Pacific. In the WNP, large-scale cyclonic circulation reaches mid-latitude, with positive KE anomalies there. This indicates that the atmospheric response to the SSTA in 2018 provide favorable conditions for the development of TC precursors, leading to the abnormal TC activity in the Pacific (Qian et al. 2019). In the simulations without the SSTA in the subtropics, tropical westerly anomalies in the tropical Pacific and cyclonic circulation in the WNP disappear, with negative KE anomalies over the broad Pacific domain. In the case without the SSTA in the tropics, dominant impacts appear in the WNP with negative KE anomalies and weakening of lower tropospheric westerly anomalies, despite the secondary importance in the central to eastern Pacific. These are closely associated with the different responses of local Hadley and Walker circulations to the regional SSTA, and possibly responsible for complicated responses of ISO in the WNP.

Intraseasonal Variability over the Arabian Sea and Its Impact on the Indian Summer Monsoon Onset

*Jing Cha[1], Yun Qiu[1], Xinyu Lin[1], Fuwen Qiu[1]

1. TIO, MNR

Based on the NCEP/NCAR and ERA-Interim reanalysis data, the processes associated with intraseasonal convection over the Arabian Sea (AS) are investigated during the Indian Summer Monsoon (ISM) onset. Onsets of the years 1980-2016 are sorted into early and late onset categories. Composites reveal that warm SST over the northern AS plays an active role in triggering anomalous convection and the reversal of prevailing winds through regional air-sea interaction before early onset of ISM. Increased latent heat release favors static instability and enhances convergence in lower troposphere which develops into Monsoon onset vortex (MOV). This convergent flow is well coupled with strong divergence pumping in upper troposphere, leading to appreciable growth of intraseasonal convection in early onset years.

On the other hand, the regional air-sea interaction contributes to intraseasonal convection after the late onset of ISM. The static instability plays a small role in the convection development which decays after onset due to anomalous diabatic heating in upper troposphere. Along with the decay of static instability, the de-coupled 3-dimentional circulation also results in the weak convection in late onset years.

Zonal Displacement of the Western North Pacific Subtropical High from Early to Late Summer

*Xiao Dong[1], Chao He[2], Renping Lin[1]

1. Institute of Atmospheric Physics, Chinese Academy of Sciences, 2. Institute for Environmental and Climate Research, Jinan University, Guangzhou, China

The zonal shift in the western North Pacific subtropical high (WNPSH) is closely associated with moisture transport in East Asia and is thus an important factor that determines the amount of summer precipitation in the region. Climatologically, the WNPSH retreats eastward from early to late summer. However, there is high variability in the early to late summer shift in the WNPSH from year to year. Thus, the interannual variability in the intraseasonal zonal displacement of WNPSH from early to late summer was examined in this study. The results showed that the El Niño or La Niña years were not predictive of how the WNPSH would shift zonally from early to late summer. Otherwise, the zonal displacements of the WNPSH were more of mid-latitude origin. In the strongly retreating years (SRY), the mid-latitude wave train was much more significant than that in the weakly retreating years (WRY). The mid-latitude wave train was reminiscent of the Silk Road teleconnection pattern (SRP). In the SRY, the centres of the wave trains had opposite signs in early and late summer, which resulted in the opposite features of the WNPSH between early and late summer. The consistency of the three reanalysis datasets confirmed the robustness of our results.

Impacts of the Indian Ocean Dipole on Sea Level and Gyre Circulation of the Western Tropical Pacific Ocean

*Jing Duan[1,2,3], Yuanlong Li[1,2,3], Lei Zhang[4], Fan Wang[1,2,3]

1. Institute of Oceanology, Chinese Academy of Sciences, 2. Function Laboratory for Ocean Dynamics and Climate, Qingdao National Laboratory for Marine Science and Technology, 3. Center for Ocean Mega-Science, Chinese Academy of Sciences, 4. Department of Atmospheric and Oceanic Sciences, University of Colorado

Interannual variabilities of sea level and upper-ocean gyre circulation of the western tropical Pacific Ocean (WTPO) were predominantly attributed to El Niño-Southern Oscillation (ENSO). Results of the present study put forward important modulation effects by the Indian Ocean Dipole (IOD) mode. The observed sea level in the WTPO shows significant instantaneous and lagged correlations (around -0.60 and 0.40, respectively) with the IOD mode index (DMI). Composite of 14 'independent' IOD events for 1958-2017 shows negative sea level anomalies (SLAs) of 4~7 cm in the WTPO during positive IOD events and positive SLAs of 6~8 cm in the following year that are opposite in sign to the El Niño effect. The IOD impacts are reproduced by large-ensemble simulations of a climate model which generate respectively 430 and 519 positive and negative independent IOD events. A positive IOD induces westerly winds over the western and central tropical Pacific and causes negative SLAs through Ekman upwelling, and it facilitates the establishment of a La Niña condition in the following year that involves enhanced Pacific trade winds and causes positive SLAs in the WTPO. Ocean model experiments confirm that the IOD affects the WTPO sea level mainly through modulating the tropical Pacific winds. Variability of the Indonesian Throughflow (ITF) induced by IOD winds has relatively weak effect on the WTPO. The IOD's impacts on the major upper-ocean currents are also considerable, causing anomalies of 1~4 Sv in the South Equatorial Current (SEC) and North Equatorial Countercurrent (NECC) volume transports.

Predictability study on the seasonal reduction of the upstream Kuroshio transport and related targeted observation application.

*Kun Zhang[1,2]

1. Institute of Oceanology, Chinese Academy of Sciences, 2. Center for Ocean Mega-Science, Chinese Academy of Sciences

With the Regional Ocean Modeling System (ROMS), we realistically simulated the upstream Kuroshio transport (UKT) variations, especially for the transport reduction in autumn. Then the effects of the optimal initial errors estimated by the conditional nonlinear optimal perturbation (CNOP) approach on predicting one seasonal UKT reduction event were investigated. The CNOP-type initial errors are located around (128°E, 17°N) horizontally and in the upper 1000 m vertically. The CNOP greatly affects the UKT by developing into a westward eddy-like structure. Eddy-energetic analysis indicates that the errors obtain energy from the background state through both barotropic and baroclinic instabilities and that the latter plays a more important role. Based on the spatial distribution of the CNOP, the sensitive area for improving the prediction of the UKT reduction event was subsequently identified. Within this sensitive area, we further explored the CNOP-based adaptive observation system design by considering the impacts of two factors: the number of observation sites and observation distance. Observing system simulation experiments (OSSEs) indicate that improving the initial conditions can effectively improve the UKT prediction. Compared to the random or conventional observation system, the CNOP-based observation system always exhibits better performance. Optimal CNOP-based observation networks are established using six or eight observation sites and observation distances of 140 or 165 km, which produce a mean prediction improvement of 43.1%. This preliminary work is expected to provide guidance on future observations in the upstream Kuroshio region and to help realistic UKT predictions.

Remote and local processes controlling decadal sea-ice variability in the Weddell Sea

*Yushi Morioka[1], Swadhin Behera[1]

1. Japan Agency for Marine-Earth Science and Technology

Physical mechanisms underlying decadal sea-ice variability over the Weddell Sea are investigated using a state-of-the-art coupled general circulation model (CGCM). Observational analysis during the satellite period (1982-2018) shows that decadal increase in sea-ice concentration (SIC) over the Weddell Sea is preceded by easterly wind anomalies. A 300-yr simulation of the CGCM confirms the observed relationship and demonstrates that the easterly wind anomalies act to weaken upwelling of warm water from the subsurface ocean and the associated ocean mixing/diffusion, and lower the near-surface ocean temperature thereby inducing the SIC increase. The zonal wind variability exhibits a close link to atmospheric intrinsic variability in the mid-high latitudes, called the Southern Annular Mode. Another sensitivity experiment with 300-yr simulation, in which interannual sea-surface temperature (SST) variations are suppressed outside the South Atlantic and the Weddell Sea, reveals that anomalous cooling of near-surface ocean temperature is induced by anomalous northward outflow of warm water from the northern Weddell Sea linked with the zonal wind variability and anomalous westward inflow of cold water from the eastern Weddell Sea accompanied by strengthening of the Weddell Gyre. The strengthening of the Weddell Gyre is associated with an increase in ocean density, which is mostly due to an increase in salinity induced by enhanced surface evaporation during the transition period of low to high sea-ice. These results indicate that remote atmospheric forcing together with the local ice-ocean interaction is greatly important for generation of decadal sea-ice variability over the Weddell Sea.

Can tropical Pacific winds enhance the footprint of the Interdecadal Pacific Oscillation on the upper-ocean heat content in the South China Sea?

*Fuan Xiao[1], Dongxiao Wang[2]

1. Guangzhou Univ., 2. Sun Yat-sen Univ.

In this study, an enhanced footprint of the Interdecadal Pacific Oscillation (IPO) on the upper-ocean heat content (OHC) in the South China Sea (SCS) since the 1990s was revealed. The negative OHC-IPO correlation is significant (r = -0.71) during 1990-2010 (P2), while it is statistically insignificant during 1960-1980 (P1). Analyses show that the scope of the equatorial Pacific wind anomalies is wider during P2 compared with that during P1 due to a larger east-west SST gradient and enhanced tropical warming in the Indian Ocean. When the IPO is negative during P2, a wider scope of the wind stress anomalies associated with the IPO could lead to 1) the southward migration of the North Equatorial Current bifurcation latitude (NECBL) by affecting the wind stress curl over the key region where it is near the climatological NECBL; 2) the interbasin pressure gradient (Sea Surface Height difference) between the western Pacific and the SCS increase; these two processes strengthen the Kuroshio Current and weaken the Luzon Strait transport (LST) or SCS throughflow into the SCS; and 3) the width of equatorial Pacific wind anomalies are wide enough to directly weaken the LST in the SCS through the Island Rule. These three pathways finally change the oceanic gyre in the SCS and increase the OHC. Our results suggest that the scope of the tropical wind stress is the crucial factor when we consider the relationship between the upper ocean thermal conditions in the SCS and the Pacific variability.

The Atlantic SST influences on the Pacific subdecadal variability

*Takashi Mochizuki[1,2], Masahiro Watanabe[3], Masahide Kimoto[3]

1. Department of Earth and Planetary Sciences, Kyushu University, 2. Japan Agency for Marine-Earth Science and Technology, 3. Atmosphere and Ocean Research Institute, The University of Tokyo

By performing two sets of partial data assimilation experiments using global climate model, we have demonstrated that sea surface temperature (SST) anomalies in the tropical and subtropical Atlantic Ocean contribute to forming high ocean temperature anomalies of the tropical Pacific in the early-2000s. Low SST over the tropical Atlantic changes the Walker circulation and the associated weakening of the Pacific trade wind raises the equatorial SST on the subdecadal timescales. At the same time, high SST anomaly is generated also in the off-equatorial North Pacific through deepening of the upper ocean thermocline due to an accompanying anti-cyclonic surface wind anomaly aloft. While the subtropical north Atlantic SST may help the subdecadal SST rising in the equatorial Pacific, the resultant SST anomalies show 1-year delay in phase transition and are hardly accompanied by the ocean thermocline deepening.

An evaluation of the Decadal Climate Prediction Experiments by the BCC_CSM Model

*Yongjie Fang[1], Tongwen Wu[1], Xiaoge Xin[1]

1. National Climate Center, Chinese Meteorological Administration

Retrospective decadal hindcasts were undertaken using the Beijing Climate System Model (BCC_CSM) as part of Coupled Model Intercomparison Project 6. The hindcasts were anomaly initialized by nudging the oceanic temperature and salinity from the monthly Simple Ocean Data Assimilation (SODA). Each forecast consists of an 8-member ensemble integrated over a 10-year period. Ensemble forecasts were evaluated using observations, and compared to an ensemble of uninitialized simulations (NoINT) which are subject to identical twentieth century historical radiative forcings. The results show that the warming trend of global mean SST simulated by the Decadal forecast is closer to the observation than that in the NoINT runs. The Decadal forecasts show high SST prediction skills over broad regions of Atlantic, western tropical Pacific and tropical Indian Oceans. The initialization increases the skill in forecasting the Pacific Decadal Oscillation (PDO) index for almost a decade compared to the NoINT runs, while reduces the skill in predicting the Atlantic Multidecadal Oscillation (AMO) index. Some features of the ocean state estimates used for initialization and their impact on the forecasts are discussed.

[A-OS19] Marine ecosystems and biogeochemical cycles: theory, observation and modeling

convener:Takafumi Hirata(Arctic Research Center, Hokkaido University), Shin-ichi Ito(Atmosphere and Ocean Research Institute, The University of Tokyo), Enrique N Curchitser(Rutgers University New Brunswick), Eileen E Hofmann(Old Dominion University)

The ocean accounts for about 50% of global net primary production. This production is significant for carbon cycling and ecosystem functioning, and is related directly or indirectly to a variety of climatic and ecological phenomena. The responses to natural and anthropogenic environmental stressors that influence marine production and diversity can cause perturbations to marine ecosystems that alter trophic dependencies and interactions among organisms at a range of space and time scales. Quantification of the principal mechanisms driving spatio-temporal variability of marine ecosystem remains to be done, especially in terms of evaluation of uncertainty in responses. As a result, evaluating vulnerability of marine ecosystems to environmental change requires systematic and holistic approaches that integrate physics to ecology and are based in observations and modelling. In addition, expectations to deliver these science to public society is raising. This session aims to provide a venue for not only discussing recent advances in understanding marine biogeochemical cycles, ecosystems and their interactions, but also networking with a variety of people to seed new ideas in marine ecological research. Observational, modeling and conceptual studies, including technological development and operational applications, that consider linkages among biogeochemical and ecosystem processes, biodiversity, and the effects of multiple stressors from molecular to planetary scales are encouraged.

A modeling study of early diagenesis using an ocean sediment model

*Hidetaka Kobayashi[1], Akira Oka[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

In the ocean upper sediments, the concentration of dissolved materials in pore water changes due to the decomposition or dissolution of biogenic solid particles that have settled down the water column. Because the condition of ocean sediments affects the long-term global ocean biogeochemical cycle through the interaction of dissolved materials at the sediment-water interface, it is necessary to properly simulate the early diagenesis. It is confirmed that the sediment model, which is created based on the formulation presented in previous studies, reproduces the burial and the distribution of biogenic solid particles by giving boundary conditions based on observational data at the sediment-water interface (the sedimentation flux of solid particles and the concentration of dissolved materials) and appropriate parameter settings. We quantitatively evaluate the impacts of the sedimentation flux of biogenic solid particles reaching the seafloor, dust deposition, the coefficient of dissolution rate, and the concentration of dissolved materials above the seafloor on the distribution of solid particles.

A simulation on seasonal variation of bottom oxygen in the Bohai Sea

*Haiyan Zhang[1], Hao Wei[1], Liang Zhao[2]

1. Tianjing University, 2. Tianjin University of Science & Technology

In recent forty years, bottom low dissolved oxygen (DO) conditions (< 3 mg/L) in summer have indicated an intensifying trend in the Bohai Sea (BS). Recent observations reveal that oxygen deficit is a seasonal phenomenon occurring in the bottom water in the depressions northwest and southwest of the Liaodong Bank. In addition, low DO conditions in the BS are accompanied by low pH, suggesting a close coupling between oxygen deficit and acidification, which imposes great stress on marine ecosystems and implies the need for effective management to improve eco-environments. To explore oxygen dynamics and low-oxygen formation mechanisms, a coupled physical-biological model (ROMS-CoSiNE) covering the BS and the Yellow Sea (YS) is established. The model reproduces seasonal evolution of low-oxygen conditions in the BS, and capture the two observed low DO centers, near Qinhuangdao (QHD) and the Yellow River estuary (YRE) respectively. DO becomes unsaturated in June, and reaches a minimum in August. Relatively strong remineralization but weak stratification result in relatively higher DO near YRE compared to QHD. Low DO off QHD could extend northeastward to the northern depression where the DO is relatively high due to weak remineralization. Oxygen budget is evaluated to quantify the contribution of physical and biological processes. Oxygen diffusion across the thermocline is prohibited which favors oxygen deficit in the bottom waters. Water column respiration (WR) is a major oxygen sink for simulated low DO conditions, while more observations are required to figure out the relative importance of WR and sediment oxygen consumption (SOC) and improve models.

Particulate organic carbon fluxes of the upper ocean response to typhoons in the northern South China Sea

*CHUNG-YU CHIANG[1], Yun Hsuan Lu[1], Yung-Yen Shih[1]

1. R.O.C NAVAL ACADEMY Dept. of Applied Science

Remote sensing of chlorophyll *a* (Chl) has revealed evidence of phytoplankton blooms evoked by typhoons in the tropical and subtropical ocean but it is difficult to assess if the particulate organic carbon (POC) fixed by marine phytoplankton can be downward exported into deep waters. Recent sea-going observations have shown increment in primary production, Chl and POC flux associated with the post-typhoons over the shallow waters (< 200 m) of the continental shelf. However, it is still unclear whether typhoons, which originate beyond the continental margin, can transfer the newly fixed carbon to deeper waters. Here we report POC fluxes and other biogeochemical data in the northern South China Sea (NSCS) before and shortly after the passage of typhoons, between September 2012 and June 2014. POC fluxes after the passage of typhoons *Tembin* and *Soulik* were 78 ±12 and 115 ±16 mg-C m^{-2} d^{-1} (average ±1 standard deviation), i.e. 1.6 and 2.4 times higher than those obtained before the typhoon (42~73 mg-C m^{-2} d^{-1}). In addition, variations in both surface and depth-integrated Chl were decoupled from POC fluxes. This decoupling may be resulted from a change in the plankton community composition due to water column instability or to lateral inputs of particulate matter released from shelf or slope sediments. Overall, our analysis of this two-year dataset highlights the spatial and temporal variability of the factors controlling POC exports to the deep NSCS.

Mid-latitude Winter Carbon Export Is Missed Using Prescribed BCG-Argo Sampling ProtocolsAbstract

*Xiaogang Xing[1], Mark Wells[2], Shuangling Chen[1], Yunwei Yan[1], Fei Chai[1,2]

1. Second Institute of Oceanography, MNR, China, 2. University of Maine, US

The mixed-layer pump (MLP) significantly augments the global carbon transport from the surface mixed layer to deeper waters when ephemeral springtime surface blooms are repeatedly mixed to depth by storms. Exploiting an unusual 8-month BGC-Argo dataset of daily profiles in the mid-latitude (31° N) northwestern Pacific, here we show repetitive mid-winter MLP episodes that generated a seasonally-averaged particulate organic carbon (POC) export of ~130 mg C m^{-2} day^{-1}; roughly 25% of the export from the North Atlantic spring bloom. But subsampling this dataset on a 5 or 10-day cycle, as planned in the BGC-Argo program, generated an order of magnitude less export (5-day & 10-day), or even totally missed all MLP events (10-day). These findings demonstrate that more frequent profiling data are needed in at least mid-latitude regions, but such daily cycling would shorten float lifetimes and thereby threaten BGC-Argo program sustainability. We propose that a small number of targeted floats be tasked with daily profiling, and that machine learning strategies be used to link these data with satellite-derived physical and biological parameters to estimate POC export; an approach that did show promise here with our limited dataset. The unexpected large magnitude of the mid-winter POC export suggests that this or other new strategies are essential if the BGC-Argo program is to adequately estimate global carbon export from MLP processes.

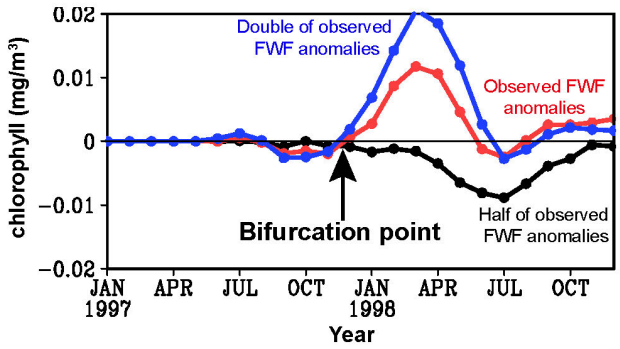
Effects on ocean biology induced by El Niño-accompanied positive freshwater flux anomalies in the tropical Pacific

*Feng Tian[1,2,3,4], Rong-Hua Zhang[1,2,3,4], Xiujun Wang[5]



1. Institute of Oceanology, Chinese Academy of Sciences, 2. Pilot National Laboratory for Marine Science and Technology, Qingdao, 3. Center for Ocean Mega-Science, Chinese Academy of Sciences, 4. University of Chinese Academy of Sciences, Beijing , 5. College of Global Change and Earth System Science, Beijing Normal University, and Joint Center for Global Change Studies, Beijing

The El Niño and Southern Oscillation (ENSO) can induce large perturbations in freshwater flux (FWF, defined as precipitation minus evaporation) and ocean ecosystem in the tropical Pacific. However, how El Niño-induced FWF can affect the tropical Pacific ecosystem (e.g., chlorophyll) is still unknown. Here, a series of ocean-only experiments are performed using a coupled ocean-physical biogeochemistry model forced by prescribed climatological wind stress. Interannual FWF anomalies observed during the 1997-1998 El Niño event are imposed onto the ocean model and the related positive FWF anomalies are specified to be varying in the tropical Pacific, and the corresponding sensitivity experiments are performed to examine the ocean ecosystem response. In general, chlorophyll increases with the intensities of the El Niño-induced positive FWF anomalies at a certain strength, but decreases when the positive FWF forcing is under-represented (e.g., specified to be its half intensity). Additionally, chlorophyll in the eastern tropical Pacific keeps almost steady during the increasing stage of the El Niño-induced interannual FWF forcing, and then rapidly increases after the peak stage of the FWF forcing. The phytoplankton budget and diagnostic analyses are conducted to understand the behavior of chlorophyll in response to varying intensities of FWF forcing. Chlorophyll response to varying intensities of FWF forcing depends on the iron concentration in the mixed layer, suggesting that the ocean ecosystem response may be shifted from one regime to another when FWF forcing reaches a certain intensity. These results offer insights into biophysical interactions and chlorophyll-induced feedback effects on ENSO.

Spatial and temporal variability of biological carbon pump in the northern South China Sea

*Jia-Jang Hung[1], Zong-Ying Lin, Ching-Han Tung, Shao-Hung Peng, Yen-Hui Lin

1. Department of Oceanography, National Sun Yat Sen University, Kaohsiung, Taiwan

The marine biological carbon pump (BCP) consists mainly of active and passive fluxes, which transfers organic carbon produced in the euphotic zone to the deep ocean, may be critical in controlling the air-sea flux of atmospheric CO_2. Here we report the spatial and temporal variability of BCP in the northern South China Sea (NSCS) through a moderately long period of investigation including an observation in the time-series station (SEATS). The spatial variability of BCP was large in the NSCS, ranging from 25.6 mg C m^{-2} d^{-1} to 93.4 mg C m^{-2} d^{-1} for active fluxes and from 66.8 mg C m^{-2} d^{-1} to 155 mg C m^{-2} d^{-1} for passive fluxes. Vertical diffusion flux of DOC was very small compared to both active and passive fluxes. The magnitude of flux was generally lower in the central basin with a calm weather condition and higher in the Dongsha shelf influenced by the shoaling processes of internal waves. Both active and passive fluxes were apparently determined by the inventories of nutrients and chlorophyll *a* in the euphotic zone. In terms of temporal variability of BCP in the SEATS Station, the difference of BCP magnitude was significant between summer and winter seasons but less in inter-annual variability. The internal forcing and climatic conditions are likely critical factors in driving the spatial and temporal variability of BCP in the NSCS.

Seasonal and Inter-annual variability of chlorophyll-*a* in the Gulf of Thailand

*Dudsadee Leenawarat[1], Anukul Buranapratheprat[2], Joji Ishizaka[3]

1. Graduate School of Environmental Studies, Nagoya University, 2. Department of Aquatic Science, Faculty of Science, Burapha University, Thailand , 3. Institute for Space-Earth Environmental Research, Nagoya University, Japan

The Gulf of Thailand (GoT) is a semi-enclosed shallow sea located in the southwest of the South China Sea. This area is important for fisheries and aquacultures for many countries. The seasonal variations of the GoT aredetermined by monsoon systems, while the large inter-annual variability GoT is affected by El Niño Southern Oscillation (ENSO). The ecosystems and abundance of fishery resources may be altered due to ENSO from the results of dry and wet weather during El Niño and La Niña, respectively. However, there are little information to assess how lower-trophic level ecosystem responds to ENSO. In this study, monthly satellite ocean color data from July 2002 to December 2018 was analyzed to compare with sea surface temperature, wind magnitude and direction, and river discharge data to understand the variability. The results showed that chl-a was positively and negatively correlate with wind magnitude and SST, respectively, in the GoT. However, chl-a near coastal area, including the upper GoT, responded to the increase of river discharge. To investigate the interannual variations, the Empirical Orthogonal Function (EOF) analysis have performed to evaluate the spatial and temporal variations of chl-a in the GoT.

Comparison of spatiotemporal variety between *in-situ* and remote surface chlorophyll in the northern South China Sea

*Yun Hsuan Lu[1], Ko Mei Lin[1], Yung Yen Shin[1]

1. Department of Applied Science, R.O.C Naval Academy

The chlorophyll *a* (Chl) plays an important role as an indicator to assess phytoplankton biomass in the ocean. Many studies determine the amount of biomass and the level of primary production based on Chl concentrations. However, the difference between *in-situ* and remote Chl values may be influenced by specific factors of time and space. There will be cause an ambiguity in depicting of the marine biogeochemical cycle, if only a remote Chl is used to explore the marine biogeochemistry. Therefore, we conducted 10 cruise from February 2013 to November 2019 at the northern South China Sea (NSCS), collected and analyzed wide covers of surface Chl to assess diversities of *in-situ* and remote Chl. The measured/remote values of Chl in spring, summer, autumn and winter were 0.12±0.09/0.18±0.01, 0.22±0.02/0.14±0.24, 0.12±0.01/0.11±0.02 and 0.28±0.23/0.38±0.32 mg m^{-3}. The measured surface Chl in summer and winter are higher than the seasons of spring and autumn; the remote Chl is higher in spring and winter than in the seasons of summer and autumn. We can infer that the prevalence of the northeast monsoon and extreme weather events (e.g. typhoons, internal waves) may be main reasons to cause the elevated Chl in winter and summer, respectively. It implies that the satellite data cannot fully reflect the real natures. The measured/remote values in the shelf, slope and basin were 0.26±0.18/0.22±0.08, 0.23±0.15/0.20±0.06 and 0.18±0.09/0.18±0.05 mg m^{-3}. Although, the trend of Chl derived from field-measured and remote-sensed are quite similar, the difference of Chl from *in-situ* and remote in the region of shelf is more apparent than in other areas. It may result from the influence of topography. Our preliminary research shows that the spatiotemporal variety between *in-situ* and remote surface Chl is quite significant and the further utilization of remote Chl needs to be calibrated in the NSCS.

Effects of the Kuroshio meander on phytoplankton in Japanese waters as observed by satellite remote sensing

Satoshi Kitaoka[2], *Takafumi Hirata[1], Keiko Sato[1]

1. Arctic Research Center, Hokkaido University, 2. Faculty of Environmental Earth Science

The Kuroshio current is one of the western boundary currents and known as a thermal energy transporter from low latitudes to to mid-latitudes in the Western Pacific. On the other hand, the Kuroshio is also a unique western boundary current in that it causes a large meander. Indeed, the meander has occurred in 2017 and is still continuing (at the time of writing). In ecological perspective, the Kuroshio is characterized as a carrier of oligotrophic seawater. In spite of the oligotrophy, the Kuroshio water is known for spawning and feeding grounds of commercial/non-commercial fish larvae, explaining a higher fisheries production in the region. Thus, it currently puzzles an ecological representation of the Kuroshio water in that a relationship among nutrient fields, standing stock and productivity of organisms are not well understood. In order to better understand the Kuroshio ecosystems, phytoplankton dynamics, a lower-trophic organism, is investigated using remote sensing data of phytoplankton chlorophyll-a pigment and of phytoplankton community structure inferred from the pigment. Especially time series analysis was conducted to identify temporal scales of their variability from daily scale to decadal scale, thanks to the high-frequency observation by the Advanced Himawari Imager, AHI, and to the long-term observation by the Moderate Resolution Imaging Spectroradiometer, MODIS. In this presentation, we discuss how the temporal variability of different phytoplankton groups (as well as the total phytoplankton community) in the Kuroshio and adjacent waters are affected by the large meander of the Kuroshio occurring since 2017.

Declining catch of Japanese sandeels

*Shin-ichi Ito[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

Sandeels are important fisheries target species in Japan. In addition, sandeels are important forage species for many piscivorous predators and key species in the coastal marine food web. Sandeels habitat on/in gravelly sand sediments and therefore their distribution shift is limited by the distribution of sandy sea floor. That unique characteristic might make sandeels vulnerable to climate variability and climate change. Recently, the catch of sandeels in Japan has decreased. To detect the geographical characteristics of sandeel catch decline, prefectural catch data from Statistics of Agriculture, Forestry and Fisheries was analyzed. Sandeel catches in 38 ocean-facing prefectures from 1956 to 2015 were used. The catch data was firstly log plus one transformed and then anomaly normalized by standard deviation was calculated in each prefecture to avoid the influence of fishery effort differences between prefectures. Since Kochi prefecture has no catch during the analyzed period, we applied principal component analysis to the normalized anomaly data of 37 prefectures. The contribution of the first principal component (PC1) was 28.6% and its score showed a decreasing trend since 1975. The contribution of the second principal component (PC2) was 12.2% and its score showed an increasing trend during 1956-1980 and a decreasing trend during 1995-2015. There are 12 prefectures (e.g. Okayama) which showed positive sing for PC1 and negative sing for PC2, hence sandeel catch drastically declined after 1975. There are 10 prefectures (e.g. Hyogo) which showed positive sings both for PC1 and PC2, hence sandeel catch gradually declined after 1975. Recently, it was reported three species of *Ammodytes* (*A. japonicus, A. heian and A. hexapterus*) distributed around Japan. It was impossible to divide the three species in the historical fisheries catch data, however it is an urgent task to elucidate life histories and distributions of each *Ammodytes* species to develop sustainable management of sandeels in Japan.

Comparative study on respiration of Japanese anchovy (*Engraulis japonicus*) around Japan

*Shin-ichi Ito[1], Chenying Guo[1], Megumi Enomoto[1], Tomoya Aono[1], Michio Yoneda[2], Michiya Matsuyama[3], Takashi Kitagawa[1], Motomitsu Takahashi[2]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Fisheries Research and Education Agency Japan, 3. Kyushu University

Japanese anchovy (*Engraulis japonicus*) is an important species not only as an exploited species but also as prey for variety of predators including marine mammals, tunas, mackerels, flounders, etc. However, the biomass of Japanese anchovy has shown large fluctuation and is one of the main actors of the fish species alternation responding to basin scale climate variabilities. From the stock management views, three sub-populations are defined in Japan: Pacific stock, Tsushima stock (also called the East China Sea stock), and Seto-inland Sea stock. The three sub-population shows difference in weights-at-age and longevity. While the three sub-populations of anchovy share their spawning grounds, the migration route and nursery grounds are divided. In addition, while Seto-inland Sea sub-populations do not show a large migration, Pacific and Tsushima sub-populations make long distance ontogenetic migrations.

All anchovy sub-populations are plankton feeders and mainly conduct filter feeding. Therefore, we hypothesized that different respiration characteristics induce different behaviors and hence growth and migration routes between the anchovy sub-populations. To test the hypothesis, we conducted laboratory respiration experiments using a 5L swimming tunnel. Since anchovy is sensitive and difficult to stabilize by individual, two anchovies were putted in the sealed tank and were measured oxygen consumption rate with various temperatures and velocities. Based on the experiment data, oxygen consumption rate dependencies on temperature, swimming speed, and body weight were determined. In addition, basic oxygen consumption rate at 0 degC temperature without swimming was estimated. Those derived oxygen consumption characteristics were different between the Pacific-stock and Seto-inland Sea stock, while the parameters of the Pacific-stock were similar to Peruvian anchoveta (*Engraulis ringens*) and South African anchovy (*Engraulis capensis*).

Estimation of migratory routes of Japanese sardine in the Tsushima Warm Current area by combining the microscale stable isotopic analysis of otoliths and a data assimilation mode

*Tomoya Aono[1,2], Tatsuya Sakamoto[2,3], Tohya Yasuda[4,3], Motomitsu Takahashi[3], Toyoho Ishimura[1]

1. National Institute of Technology, Ibaraki College, 2. Atmosphere and Ocean Research Institute, The University of Tokyo, 3. Seikai Nat. Fish. Res. Inst., 4. Nat. Res. Inst. Fish. Sci.

Japanese sardine (*Sardinops melanostictus*) has been reported its abundance periodically fluctuates during last 3000 years (Kuwae *et al.*, 2017). More recently the catch of Japanese sardine declined to about 1/150 in 20 years (Fisheries Agency, 2011), but the mechanism of this phenomenon is still undetermined. In order to understand the mechanism of those fluctuations and hence enable future sustainable fishery, it is necessary to elucidate basic ecological information of sardine, such as their spawning place and migration pathway. In that situation, recent progress of analytical technique has allowed us utilize chemical compositions in fish otolith, which is formed in inner ear, to detect the life history of individual fishes. Otolith is a hard tissue composed of calcium carbonate ($CaCO_3$: aragonite), the concentric growth rings are formed from the center of otolith. The stable oxygen isotope ratio ($\delta^{18}O$) of $CaCO_3$ depend on (1) $\delta^{18}O$ of sea water and (2) ambient water temperature. Accordingly, the history of ambient water temperature through the life history of individual fish can be estimated by $\delta^{18}O$ record in the otoliths. Besides, by combining the otoliths $\delta^{18}O$ analysis and an individual-based model, recent study successfully clarified the migration pathway of Japanese sardine in the western North Pacific (Sakamoto *et al.*, 2019).

The purpose of this study is (1) to estimate the migration pathway of Japanese sardine in the Tsushima Warm Current area by combining methods of the high-resolution $\delta^{18}O$ analysis and the data assimilation model, and (2) to extract the biological information of Japanese sardine in the Tsushima Warm Current area.

In this study, we collected the otoliths of Japanese sardine caught in three sampling areas in the Sea of Japan: off Toyama (25/Aug./2016), Tsushima Strait (5/Sep./2016) and off Goto Islands (13/Sep./2016), and analyzed the otoliths in three individuals from each sampling area. The otoliths were continuously milled along the growth ring at every 10days (except near the core) by high-precision micro-milling system (GEOMILL326). After the milling, the stable carbon and oxygen isotopic compositions of otoliths powder were determined by microvolume isotope ratio mass spectrometry system (MICAL3c with IsoPrime100), then the migration pathway of each individuals were estimated based on high-resolution $\delta^{18}O$ analysis of otoliths and the data assimilation model.

As a result, there was no significant difference in the otolith $\delta^{18}O$ histories between the three individuals collected in each sampling area, and also we found similar trend in isotopic shift (experienced temperature) among sampling areas. The estimated location at the time of the hatching and sampling corresponded to the actual observed spawning grounds and the actual sampling area, respectively, which confirmed the consistency of the estimated migration pathways. In addition, it was suggested that all individuals grew in the same place (offshore west of Kyushu) after hatching and migrated to their caught area by different migration pattern from late June to early July. Our experimental study has successfully

The transition of the experienced environment of jack mackerel in the East China Sea

*Tomihiko Higuchi[1], Motomitsu Takahashi[2], Kotaro Shirai[1], Shin-ichi Ito[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Seikai National Fisheries Research Institute, FRA

Jack mackerel *Trachurus japonicus* is distributed on the continental shelf waters along the subtropical Kuroshio Current and the Tsushima Warm Current in the western North Pacific. The East China Sea (ECS) is one of major spawning and nursery grounds for jack mackerel and understanding the recruitment processes of jack mackerel into the fishing grounds in the ECS is important. However, information of how jack mackerel respond to decadal temperature change is limited. Aim of this study is to know the transition of experienced environment of jack mackerel in the ECS from 1960s to 2000s. To estimate the experienced environment, oxygen ($\delta^{18}O$) and carbon ($\delta^{13}C$) stable isotope of jack mackerel otolith were analyzed. Fish samples were taken at ECS in 1960-70s and 2000-2010s (15 individuals, each period). The high-precision micromilling system GEOMILL 326 was used for otolith samples. At every 10 daily rings (20-30 daily rings in section including core), a ring was tracked and used as the boundary of the micromilling area. $\delta^{18}O$ and $\delta^{13}C$ were determined using isotope ratio mass spectrometer (Delta V plus). As a result, there was no significant differences between the two survey periods in the larval-juvenile experienced temperature which is estimated from $\delta^{18}O$. It was considered that both jack mackerel from different periods utilized a similar environment under a changing environment. There was a significant positive relationship between experienced temperature and growth rates based on otolith increment width in the juvenile stage. This suggested that the effect of water temperature on the growth of jack mackerel in early life stage. Thus, there is a possibility that jack mackerel in ECS may adapt environmental changes and select the preferred environment.

Interannual salinity variability in the Western Tropical Pacific and along the Kuroshio

*Chevarria Saravia Ricardo[1], Daniel Andres Lizarbe[1], Takeyoshi Nagai[2]

1. National Agrarian University La Molina, 2. Tokyo University of Marine Science and Technology

A previous study using hydrographic data in the North Pacific shows an interannual variability of salinity, including a basin wide freshening during the period from 2009 through 2017. However, how the basin wide freshening occurs and its influences along the Kuroshio have been still unclear. In this study, daily reanalysis salinity dataset from 2003 through 2018 are analyzed using temporal filters to separate the interannual variability and decadal changes with special emphasize on the salinity anomaly from the western tropical North Pacific (WTNP) to the downstream. The decadal variabilities are obtained by 6-year moving average of the daily data. The interannual variabilities is then obtained by subtracting this averaged decadal data from the daily salinity. Our analysis using maps of lagged correlation coefficients for the interannual variations of salinity along the density surface between σ_θ=25-26 shows relatively high correlation coefficients between WTNP , i.e., the Kuroshio origin and the downstream along the Kuroshio. The advection of the salinity anomaly from the WTNP to the coast of Japan along the Kuroshio takes approximately 3 months. It is found that the variations of the wind stress curl over the WTNP drive the interannual salinity variability with a negative correlation.

Phytoplankton blooms along the Kuroshio due to the Large Meander

*Lizarbe Andres Daniel[1], Ricardo Saravia Chevarria[1], Takeyoshi Nagai[2], Takafumi Hirata[3]

1. National Agrarian University La Molina, 2. Tokyo University of Marine Science and Technology, 3. Hokkaido University

The Kuroshio Large Meander (LM) is known to be highly aperiodic and can last from 1 to 10 years. The stationary cold core formed between the Kuroshio and the southern coast of Japan off Enshunada and approaching warm saltier water on the eastern side of the LM changes the local environment drastically, many commercially valuable fish species distribute differently from the no-LM period, impacting local fisheries. Despite this importance of the LM, the influences of the LM for low trophic levels such as phytoplankton and zooplankton have been still unclear. In this study, satellite daily sea surface chlorophyll data are analyzed in relation to the LM. The results show blooming (positive anomaly of the chlorophyll a concentration) along the Kuroshio path during LM periods, 2004-2005 and 2017-2019, from upstream (Shikoku) to downstream (140ºE). These blooms are started by the triggering meander in both LM periods. Even though the blooming pattern along the Kuroshio region in both LM periods was different, similar positive anomaly patterns emerge inside the meander' s trough, suggesting that submesoscale eddy' s restratification of MLD helps the primary production with upwelled nutrients along the Kuroshio. It turns out that there was no relation between the MLD and the wind stress over the large meander regions. Furthermore, we found a strong relationship between the minimum distance of the Kuroshio axis on a designated station located in Cape Shiono Misaki (St-A) and mean chlorophyll-a anomaly, indicating that every time Kuroshio axis detaches from the shore, mean chlorophyll-a anomaly rises. Also, this tendency seems depending on the Kuroshio recirculation strength off Shikoku.

[A-OS20] Coastal physical processes associated with mixing, eddies, and internal waves

convener:Taira Nagai(Graduate School of Science, The University of Tokyo), Eisuke Tsutsumi(Atmosphere and Ocean Research Institute, The University of Tokyo), Eiji Masunaga(Ibaraki University)

Recently developed observational and numerical approaches have revealed details of physical processes in coastal regions, which can affect large-scale oceanic/atmospheric circulations and ecosystems. This session aims to provide a platform to discuss mixing, eddies, and internal waves in coastal/marginal oceans including estuaries and lakes. This session also covers topics that consider linkages between coastal phenomena and large scale processes in the open ocean (e.g., the Kuroshio Current).

Water exchange between the Bohai and Yellow Seas in response to high winds in winter

*Chao Ma[1,3], Xia Ju[2,3], Xiuquan Wan[1,3]

1. Ocean Univ. China, 2. Inst. Oceanog. 1, MNR, 3. Pilot Natl. Lab. Marine Sci. & Technol.

Based on the observed data as well as Regional Ocean Modeling Systems (ROMS) diagnostic numerical model, we studied the influence of high wind processes on the circulation and water exchange between the Bohai and Yellow Seas (BYS) in winter. The results show that the vertical structure of the Yellow Sea Warm Current (YSWC) is relatively uniform under condition of high winds, showing obvious barotropic features. However, this flow is not a stable mean flow, showing strong paroxysmal and reciprocating characteristics. A comparison of the changes in sea level suggests that the intensity of the northwards upwind flow is consistent with the abnormal fluctuations in the sea level. It indicates that the upwind flow is closely related to the water exchange between the BYS. The impact of high wind processes on the water exchange between the BYS is enormous. It can make the flux through the Bohai Strait, as well as that through the mouth of each constituent bay (i.e., Liaodong Bay, Bohai Bay, and Laizhou Bay) far greater than usual, resulting in a significant increase in the water exchange rate. The exchange capacity, which is about 8% of the total volume of the Bohai Sea, can be completed in a few days. Therefore, the water exchange of the Bohai Sea may be completed by only a few occasional high wind processes in winter.

Eddy Induced Transport of Saline Kuroshio Water Into the Northern South China Sea

*Tao Xing[1,2], Yikai Yang[2]

1. MLR Key Laboratory of Marine Mineral Resources, Guangzhou Marine Geological Survey, 2. South China Sea Institute of Oceanology, Chinese Academy of Sciences

To better understand eddy induced heat and salt transport, a targeted joint hydrographic investigation focusing on an anticyclonic eddy was carried out in July 2017 in the northern South China Sea. In situ and satellite observations together with Hybrid Coordinate Ocean Model output show the transport of subsurface saline Kuroshio water into the northern South China Sea by an anticyclonic eddy. Subsurface high salinity cores are consistent with the anticyclonic eddy centers. The transport of saline Kuroshio water occurs in two stages accompanied by eddy shedding. First, saline Kuroshio water is trapped within the anticyclonic eddy at its generation location. Then, although the salinity within the eddy gradually weakens as the eddy carries the saline water westward, the quantity of saline water shows a sharp increase, dominated by eddy induced salinity advection. A diagnosis of the salinity budget further confirms that the contribution of eddy flow advection is greater than that of mean flow advection. The saline Kuroshio water is trapped and conveyed in this anticyclonic eddy, providing vital evidence and important implications for eddy induced salt transport and water exchange.

A temperature description of vortex street around the Green Island off the eastern coast of Taiwan

*Chia-Ying Ho[1], Hung-Jen Lee[1]

1. National Taiwan Ocean University

For providing essential information for Kuroshio current passing Green Island off the eastern coast of Taiwan, a three-dimensional general circulation model (MITgcm) is used to study the vortex street issue. Real topography derived from the Ministry of Science and Technology Ocean Data Bank and some Hycom hydrographic data are imposed for the model. In the light of different conditions, such as changing the magnitude of the Kuroshio fluxes in summer and winter, two interesting features are worth noting. The model results show that the mixing-layer effects on the vortex streets are more closely associated with the strength of the vortex street upwelling. In the summer case, a low-temperature water mass is usually generated behind the Green-Island when the Kuroshio Current impacts on it. The temperature drop degree resulted from the upwelling water in the wake is over 1°C, which is similar to the von Kármán vortex street. However, the temperature drop degree is moderate when the initial temperature of the model is changed to the winter conditions. While the model boundary fluxes are increased, the temperature drop region is expanded. On the other hand, the low-temperature region is narrowed when the boundary fluxes are reduced.

Summertime Upwelling in the Central South China Sea: Interannual Variability and Associated Dynamics

*Yi-Chia Hsin[1], Mai-Han Ngo[1]

1. Academia Sinica

Based on the 30-year sea surface temperature images, we classify the locations of Vietnamese upwelling centers into three sub-regions: the Northern Coastal Upwelling region (*NCU*; north of 12.5˚N), the Southern Coastal Upwelling region (*SCU*; south of 12.5˚N), and the Offshore Upwelling region (*OU*; east of 110˚E). Variations of upwelling intensities in the three sub-regions are further quantified via the SST-based upwelling index, and possible processes relevant to wind field (including wind stress and its curl) and currents off southern Vietnam are, respectviely, proposed. The outcomes show that as the summer monsoon enhance, the alongshore wind stress strengthens offshore Ekman transport along the coast in the *SCU*, intensifying the coastal upwelling there. At the same time, the enhanced wind stress curl (WSC) dipole off the southern Vietnam strengthens the underlying oceanic gyre dipole, further leading to an intensification of the eastward-flowing jet in-between and southward-movement of the jet. As a result, the scaled up cyclonic gyre north of the jet helps the upwelling occurring in the *OU* region. Besides, accompanying the cyclonic gyre north of the jet, a southward counter-current develops along the eastern Vietnamese coast; further, it restricts upwelling in the *NCU* region but intensifies upwelling in the *SCU* region.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-OS Ocean Sciences & Ocean Environment

[A-OS21] Dynamics of oceanic and atmospheric waves, vortices, and circulations

convener:Yuki Tanaka(Fukui Prefectural University), Ryo Furue(APL/JAMSTEC), Yukiharu Hisaki(University of the Ryukyus), Norihiko Sugimoto(Keio University, Department of Physics)

Oceanic and atmospheric dynamics aims at abstracting general principles from observed phenomena and constructing a system of mathematical models, thereby leading to the understanding, prediction, and parameterization of those phenomena. It provides perspectives for the advancement of sciences in various areas such as wind waves, swells, internal waves, Rossby waves, equatorial waves, tides, eddies, meandering of jets and fronts, general circulation, boundary layers, and ocean-atmosphere coupled modes. It has also been and will continue to be benefited by new uses of ideas and methods from such theories as resonance, nonlinear interaction, spectral analysis, probability, statistics, and dynamical systems. In this session, we solicit presentations on observational, experimental, numerical, and theoretical studies of oceanic and atmospheric dynamics and on exploratory use of new ideas and methods. We also welcome presentations on interdisciplinary studies in fields such as ecosystems, climate, and environment.

Planetary scale waves with about a 4-day period, which are considered to be “Kelvin waves”, have been observed in the equatorial region at the cloud top of the Venus atmosphere[1,2]. It is pointed out that these Kelvin waves could contribute to generate and maintain the atmospheric “super rotation”: the zonal wind circulating Venus 60 times faster than the solid part of Venus[3]. However, the Kelvin waves have not been simulated so far in any Venusian Atmospheric General Circulation Model (AGCM) in the world.

We have developed a Venusian GCM (AFES-Venus), and the Venus AFES LETKF Data Assimilation System (VALEDAS) based on the Local Ensemble Transform Kalman Filter (LETKF) for the first time[4,5]. Using VALEDAS, we have examined the reproducibility of a unique atmospheric structure so-called “cold collar”, a cold latitudinal band encircling the warm polar vortex at about 60–70 km altitudes, in order to elucidate the effects of temperature observations by multiple small satellites[6].

In this study, we prepared an idealized horizontal wind observation that was expected to be obtained from cameras with various wavelengths, and examined the reproducibility of Kelvin wave by varying conditions such as observation altitude, observation area, and time interval. The idealized observation data are created from CCSR/NIES Venus AGCM[7], in which the Kelvin wave was reproduced by forcing it at a lower level.

Fig (a) shows result of a free run forecast (without observation), and (b) shows assimilated result of horizontal wind observation at the altitude of 30 km with 24 hourly. By the data assimilation, the upper propagation of waves with a period of about 5 days at the equator was reproduced. We will also discuss how the observation and this kind of study would be helpful to design the future mission for understanding of Venus.

The study for designing the future Venus atmosphere observing mission of radio occultation measurement among small satellites using data assimilation

*Asako Hosono[1], Yukiko Fujisawa[2], Norihiko Sugimoto[2], Mirai Abe[2], Yukako Kikuchi[3], Tomotaka Yamamoto[4], Yosuke Kawabata[4], Satoshi Ikari[4], Hiroki Ando[5], Masahiro Takagi[5], Itziar Garate Lopez[6], Sebastien Lebonnois[7], Chi Ao[8]

In the Venus atmosphere, there is a unique phenomenon called “cold collar”, where the temperature at 60-80˚ latitude is lower than that of polar region at the altitude of about 65 km. So far, we developed the Venusian atmospheric GCM (AFES-Venus)[1] based on AFES (Atmospheric GCM For the Earth Simulator) and AFES-Venus succeeded in reproducing the cold collar for the first time. However, the temperature difference between the pole and the surroundings is smaller than that of the observations. Recently, introducing the Local Ensemble Transform Kalman Filter (LETKF), we have developed the Venus AFES LETKF Data Assimilation System (VALEDAS)[2]. In this study, we prepare idealized observations assuming radio occultation measurement among small satellites and assimilate them by VALEDAS. The idealized observations are provided from French Venus atmospheric GCM (IPSL VGCM)[3], in which the cold collar is realistically reproduced, and their conditions such as time interval, places and numbers are changed. We investigate the effectiveness of radio occultation measurement among small satellites by the reproducibility of the cold collar. As a result, the cold collar is reproduced if the observations are 2-3 vertical profiles 4-6 hourly, and it is expected that radio occultation measurement among small satellites will be promising to reproduce the polar atmospheric structures by 3 small satellites[4]. However, the cold collar is destroyed in the case which has a lot of observation points and high frequency, because there is a temperature bias between AFES-Venus and IPSL VGCM. In this study, correction of temperature bias between models is conducted. Bellow figures are temperature distribution at 30-90˚N at the altitude about 66 km in the cases which are 72 vertical profiles at temperature observations at 60-85˚N with every Earth hour; (a) is before the bias correction, and (b) is after. It is suggested that the bias correction enables us to correct temperature bias between models. In the poster presentation, in addition to these results, we will show the results considering real orbits.

Verification of wave prediction model by drifting buoy observations

*Yukiharu Hisaki[1]

1. University of the Ryukyus

It is necessary for verification of wave prediction model to compare predicted wave data with in-situ observation data such as buoy data. However, the verification by in-situ observation is limited to coastal wave sensors or moored wave buoys. It is impossible to conduct the verification by the moored wave buoy in the open sea far from the land or in the area with strong current. Therefore, the wave prediction model was verified by drifting buoys of the Japan Meteorological Agency(JMA). The predicted wave data is forced by the ERA interim wind data, and the spatial resolution is 0.75 degrees. We calculated wave parameters from 2017 to 2018. The correlation between wave heights by the JMA drifting buoys and predicted wave heights was about 0.9. The predicted wave heights agree well with observation in both the Pacific and the Sea of Japan. On the other hand, the wave period did not agree well especially in the Sea of Japan. The reason is that wave spectra could not be accurately reproduced by the low spatial resolution wave model due to the short fetch. Next, we compared the predicted wave data considering the current with observed wave data. It is shown that the accuracy of wave prediction improves. The effects of horizontal shear and relative wind on the accuracy of wave prediction were investigated. The relative wind effect the largest.

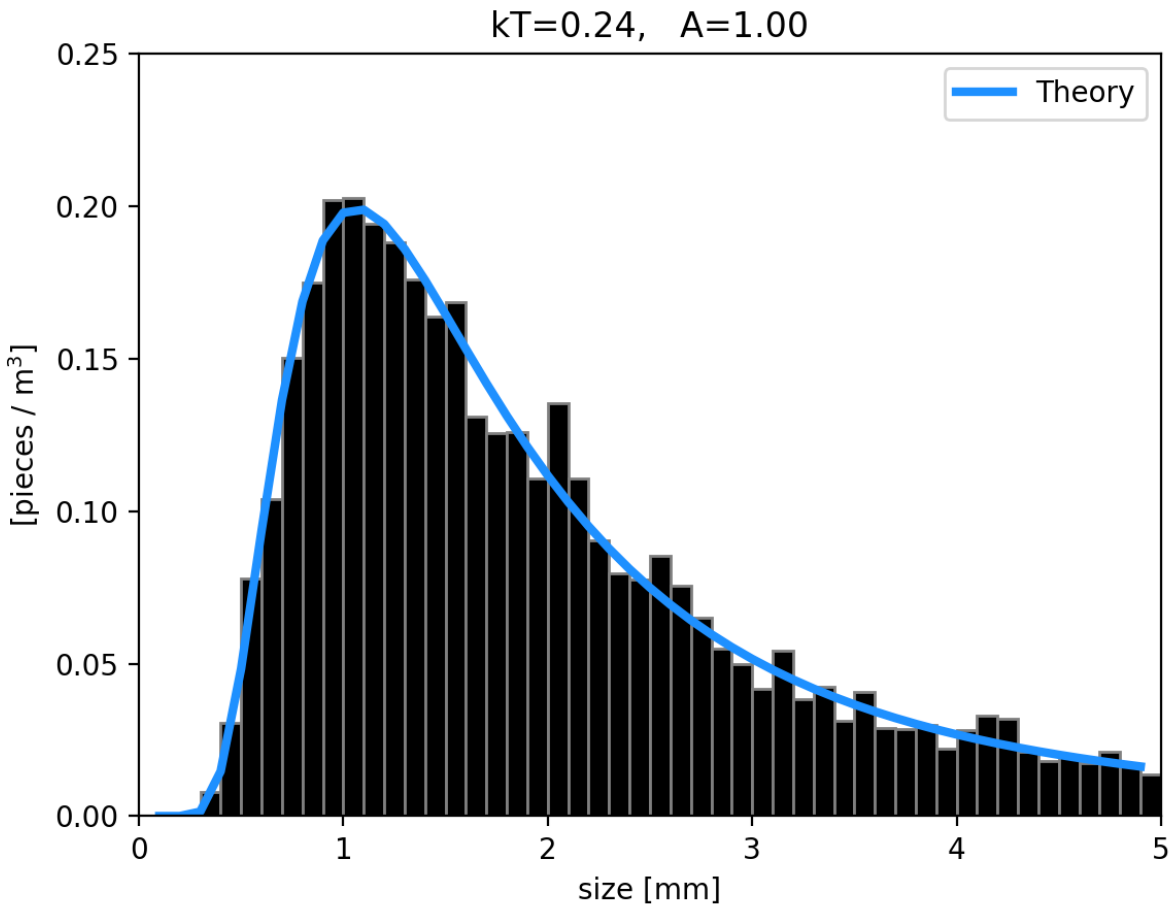
Size distribution of marine microplastics: A statistical mechanics approach



*Kunihiro Aoki[1], Ryo Furue[1]

1. Japan Agency for Marine Earth Science and Technology

The observed size distribution of marine microplastics generally shows, from large to small sizes, a gradual increase followed by a rapid, but smooth decrease (Figure). This decrease is puzzling because breaking up a plastic piece into smaller fragments naturally increases the number of fragments. This apparent discrepancy has led to a speculation that smaller plastic fragments somehow disappear ("missing plastics" problem). The present study aims to provide an alternative explanation for this size distribution, borrowing ideas from statistical mechanics. In our model, we assume that a flat plastic piece is fragmented into n x n equal cells that have a uniform size in a crush event. We further assume that the fragmentation of each piece is caused by “crush energy”, whose magnitude is assumed to be inversely proportional to the size of the cell, and whose occurrence probability follows the Boltzmann distribution. Under these assumptions and the constraint of the volume conservation of the plastics, we finally obtain the size distribution of the fragments, which follows Planck's formula for black body radiation. In our model, the total available "crash energy" is an unknown parameter. After adjusting it for the curve to fit the data, the Planck distribution agrees well with the observed distribution (Figure). In our model, smaller fragments beyond the peak of the distribution are fewer because the probability of getting "crash energy" large enough to produce such small fragments is low. Our formula predicts that the peak of the size distribution shifts to a smaller size and the total amount of the microplastics becomes larger with increasing crush energy. As a future extension, sink of plastic fragments may be included by the inclusion of an analogue of chemical potential.

Interannual modulation of intraseasonal wave activity over the equatorial Indian Ocean

*Tomomichi Ogata[1]

1. JAMSTEC Application Lab

In this study, interannual modulation of intraseasonal wave activity over the equatorial Indian Ocean was investigated using 1.5-layer reduced gravity model. Simulated interannual modulation of 30-day intraseasonal wave activity shows significant reduction of the wave activity during positive Indian Ocean Dipole (pIOD) mode events. Such inactive intraseasonal wave activity suggests that eastward warm water transport by the equatorial/coastal Kelvin wave is reduced. It seems favorable to maintain cold phase of SST in the eastern pole. In presentation, other dominant intraseasonal variability (60-day, 90-day) will be investigated.

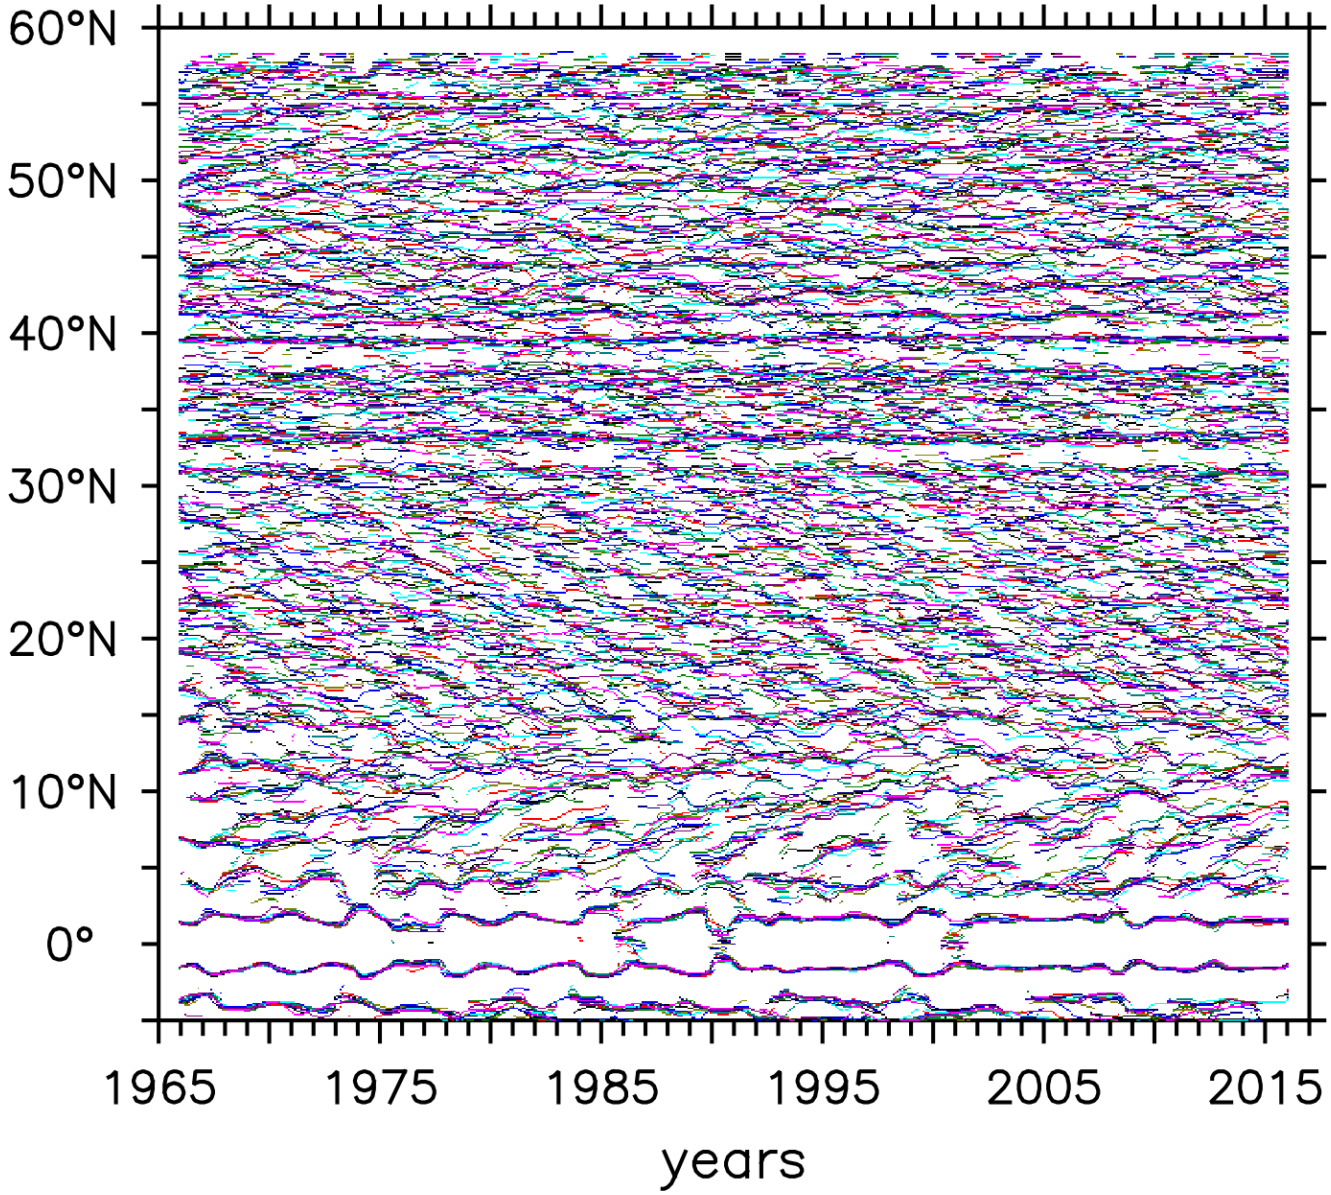
On the statistics of deep zonal jets in the eastern North Pacific in an ensemble of eddy-resolving ocean general circulation model runs

*Ryo Furue[1], Masami Nonaka[1], Hideharu Sasaki[1]



1. APL/JAMSTEC

It has been known for some time that the ocean basins are populated by "deep zonal jets" or "striations". A number of theories have been proposed to explain them, some of them predicting zonal jets at fixed latitudes and others implying that the positions of the jets are random. To investigate how deterministic the zonal jets are in the eastern North Pacific, a ten-member ensemble of long-term integrations of a semi-global, eddy-resolving ocean general circulation model is analyzed.

The figure shows the positions of the axes of eastward zonal jets at 500 m along 140W for all the ensemble members with different colors for different members. The equatorial jets, even their variability, seem to obey deterministic dynamics and some of the tropical jets migrate poleward coherently (similarly between ensemble members), whereas jets further poleward are more or less stochastic. The subtropical jets migrate equatorward and their positions are not very coherent; the subpolar jets are random and without systematic migration. Jets near the coast of North and South America tend to have shorter meridional wavelengths than interior ones. There are a few quasi-barotropic jets which are anchored to steep bottom topographic features and which also appear to trap shallower counter-flows on their poleward and equatorward flanks.

Predictability of interannual-to-decadal variability in eddy activity in the Kuroshio Extension

*Masami Nonaka[1], Hideharu Sasaki[1], Bunmei Taguchi[2], Niklas Schneider[3]

1. Application Laboratory, Japan Agency for Marine-Earth Science and Technology, 2. University of Toyama, 3. IPRC, University of Toyama

Eddies in the Kuroshio Extension have been shown to affect sea surface temperature, the atmosphere aloft, subsurface ocean, and also marine ecosystem. It is therefore important to explore variability and also predictability of the eddy activity in the region to improve our understanding of ocean-atmosphere variability over the North Pacific region. While interannual-to-decadal variability in the eddy activity in the Kuroshio Extension could be partly driven by atmospheric variability over the central/eastern North Pacific, it has also intrinsic variability that is independent from the atmospheric forcing and thus unpredictable. To examine predictability of the variability in eddy activities under realistic conditions, we analyze a ten-member ensemble, of fifty-year integration of an eddy-resolving OGCM driven by time-varying JRA55 reanalysis data. Focusing on interannual-to-decadal variability by the 13-month running mean, eddy activity in the downstream Kuroshio Extension region (32-38N, 153-165E) shows rather limited ensemble spread and uncertainty, and ensemble mean has significant correlation with the observation (correlation coefficient r=0.58). Also, the eddy activity variability highly correlates with the local current speed variability that propagates westward from the central North Pacific. With the propagation, the time series of area averaged current speed in the central North Pacific correlates with the eddy activities in the KE downstream region in four years later (r = 0.59), indicating predictability of the eddy activities. The four-year lagged correlation is also found in the observation. In contrast, in the upstream Kuroshio Extension region (32-38N, 141-153E), the ensemble spread is large and the ensemble mean does not correlate to the observation at all. While possibly model dependent, the result implies that the observed eddy activity in the upstream Kuroshio Extension may have a significant intrinsic component on the interannual time scale.

Surface water pathways in the subtropical-subarctic intergyre frontal zone of the western North Pacific

*Hatsumi Nishikawa[1], Humio Mitsudera[1], Takeshi Okunishi[2], Shin-ichi Ito[3], Taku Wagawa[4], Daisuke Hasegawa[2], Toru Miyama[5], Hitoshi Kaneko[3]

1. Institute of Low Temperature Science, Hokkaido University, 2. Tohoku National Fisheries Research Institute, 3. Atmosphere and Ocean Research Institute, The University of Tokyo, 4. Japan Sea National Fisheries Research Institute, 5. Japan Agency for Marine-Earth Science and Technology

The Transition Domain in the western North Pacific, extending zonally at approximately 40˚N, is a boundary region between the subtropical and subarctic gyres, where a peculiar water mass forms as a result of mixing between the waters of the Kuroshio origin and the Oyashio origin. The Transition Domain is a very important area not only for oceanographic processes such as the inter-gyre exchange of the water masses, but also for mid-latitude climate and biological processes. It is not known, however, how the Kuroshio and Oyashio waters are transported to the Transition Domain and mix. This paper clarifies pathways of the Kuroshio water and the Oyashio water from a Lagrangian point of view, by conducting drifting buoy observations in 2015 and 2017, as well as by particle tracking using a geostrophic surface flow field derived from an absolute sea surface height product. Here we show that the Kuroshio water is carried to the Transition Domain through a narrow path with a width of ~ 50 km via a quasi-stationary jet in the western North Pacific (so called the J1). Time variations likely have important role in supplying the Kuroshio water to the Transition Domain; if a steady climatological flow field were used, the Transition Domain would be occupied by the Oyashio water. Much of the Kuroshio water is supplied at the Oyashio Second Branch and a large-scale meander of the J1, where the eddy strength shows local maxima.Eddy formation mechanisms are also discussed in relationship with the low bottom topographic features.

Genesis of Spiciness Anomaly in the Northeast Pacific

*Yongqing Guo[1], Meng Wei[2]

1. Zhejiang Ocean University, 2. First Institute of Oceanography, Ministry of Natural Resources of the People's Republic of China

Spiciness anomaly is defined as salinity anomaly on certain isopycnal layer. Based on Argo observations, the most significant spiciness anomaly variations in the upper North Pacific are seen in the Northeast Pacific (145°-125°W, 25°-36°N; the study region) within $\sigma\theta$ = 25.0 - 25.4 kg m^{-3} isopycnal layer (the study isopycnal layer). The study region sits exactly at the formation region of the North Pacific Eastern Subtropical Mode Water (NPESTMW). Besides, the region is located at the subpolar front, with cold and fresh water mass in the northeast, and warm and salty water mass in the southwest. This leads a density-compensating feature of NPESTMW, which favours spiciness anomaly process. The genesis of spiciness anomaly on the study isopycnal layer is controlled by subduction of NPESTMW and spiciness anomaly injection processes during late winter. The spiciness anomaly on the ligher $\sigma\theta$ = 25.0 –25.2 kg m^{-3} isopycnal layer is decided by the subducted NPESTMW. The denser $\sigma\theta$ = 25.2 –25.4 kg m^{-3} isopycnal layer does not ventilate. The positive spiciness anomaly on this particular layer is caused by diapycnal mixing across the subduced isopycnal (i.e. spiciness anomaly injecion), while the negative spiciness anomaly is driven by southward advection of subpolar water.

Intensified Deep Ocean Variability Induced by Topographic Rossby Waves at the Pacific Yap-Mariana Junction

*Qiang Ma[1], Jianing Wang[1], Fan Wang[1], Yilong Lyu[1]

1. Institute of Oceanology, Chinese Academy of Sciences

In a deep channel at the Pacific Yap-Mariana Junction, intensified variability of flow and isotherm displacement over 3000-4600 m is revealed by two separate observations: the recent one during 2014-2016, and the two 20 years ago during 1996-1998. Observed velocity and isotherm displacement can reach 45 cm s^{-1} and ~600 m at 4200 m, respectively. Such intensified variability is demonstrated to arise from topographic Rossby waves (TRWs), since vertical profiles of observed currents reasonably conform to TRW features of hyperbolic intensification with depth and highly vertical coherence in phase. Mercator Ocean model outputs reproduce observed TRWs and are used to discuss their energy sources. Both the energetic surface eddy moving across rough topography and mixed barotropic-baroclinic instability of the background flow appear to be the candidates to generate TRWs.

Direct measurements of near-surface upwelling and vertical heat flux in marginal ice zone of the Canada Basin, Arctic Ocean

*EunYae Son[1], Yusuke Kawaguchi[2]

1. Graduate School of Frontier Sciences, University of Tokyo, 2. Atmosphere and Ocean Research Institute, The University of Tokyo

The western Arctic Ocean observation was conducted using R/V "*Mirai*" from October to November 2019. We aim to figure out the oceanic contributions on the delayed onset of seasonal sea ice formation. The 2019 was the remarkable year that hit the lowest and the second lowest records of November and annual sea ice extent, respectively, which are sign of delayed sea ice recovery. The R/V Mirai expedition covers the Beaufort Sea in the western Arctic to conduct hydro-dynamic observations including conventional CTDs, direct microstructure measurement with TurboMap, and upper-water monitoring of temperature with an autonomous instrument, IceBTC60/40 (IceBTC). The IceBTC is a buoy with a 60-m long tether, consisting of 17 thermistors and 3 pressure sensors. The IceBTC was deployed in a marginal ice zone (MIZ) in the Canada Basin where was covered with grease ice. During that, the TurboMap and XCTDs were accompanied in the proximity. The IceBTC observation detected a strong signal of upwelling from the warm Pacific Summer Water (PSW) layer, which locates beneath the cold surface mixed layer. Upward heat flux has changed with the wind regime influencing marginal ice zone. The flux rapidly increased by wind blowing towards open ocean from pack ice, at the same time ice drift speed showed nearly 40 cm s^{-1}. On the other hand, it was stalled down under other wind directions. Surprisingly, a bulk estimate of vertical heat flux towards the ice bottom instantaneously reached 600 W m^{-2}.Our study suggests that the upward heat flux due to PSW might be traditionally underestimated and wind-ice-ocean coupled system can enhance it breaking through strong pycnocline in the marginal ice zone where covered with fragile ice.

Symmetric and Mixed Layer Instability at a Sharp Ocean Front

*Yuki Tanaka[1]

1. Graduate School of Science, The University of Tokyo

Submesoscale processes at ocean fronts play a crucial role in transferring buoyancy, momentum, and tracers in both the horizontal and vertical directions, as well as in cascading energy from large to small scales. Although symmetric instability and mixed layer instability are believed to be two major types of submesoscale instability, clear evidence of them has not yet been obtained in the real ocean. This is partly because theoretical prediction of the dispersion and polarization relations of these submesoscale instability processes in the real ocean is still incomplete; most of the theoretical studies have assumed an infinite ocean with homogeneous negative potential vorticity sustaining the existence of symmetric instability. This idealized situation is quite different from the actual one where negative potential vorticity is confined within a narrow region centered at a front.

Here, we examine symmetric and mixed layer instability created at a realistic front in the surface mixed layer. For this purpose, we performe a linear stability analysis on a meridional–vertical plane with a zonally uniform background field characterized by a sharp front with a narrow region of negative potential vorticity. The analysis shows that symmetric instability is the most unstable mode when the zonal wavenumber of the disturbance is small enough. The symmetric instability is characterized by wave patterns mostly confined within the negative potential vorticity region and nearly aligned with the background isopycnals. As the zonal wavenumber of the disturbance becomes large, the dominant unstable mode is replaced by mixed layer instability. The meridional scale of the mixed layer instability is much larger than that of the symmetric instability, even larger than the width of the front. Furthermore, the zonal phase speed of the mixed layer instability is much smaller than that of the symmetric instability. These clear differences enable us to easily distinguish between the two types of instability even though they are continuous in the dispersion diagram. The results will be useful for identifying the symmetric and mixed layer instability in the real ocean.

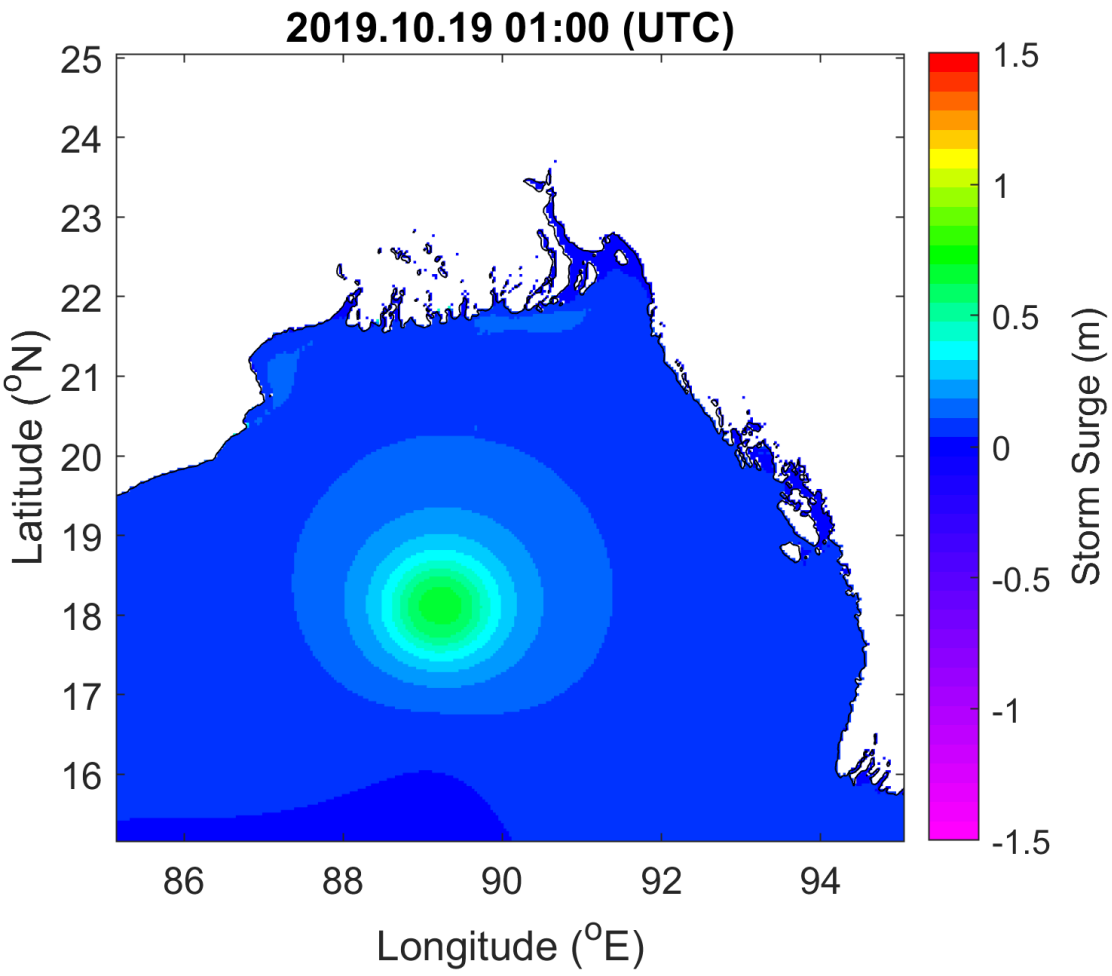
Reconstruct the 1970 Bhola Cyclone and Analysis the Effects of Cyclone Track and Tide to the Flooding Area

*Po-Sen Tseng[1], Tso-Ren Wu[1], CHIA-CHUN HSU[1], Chun-Wei Lin[1], Shun-Chun Chunag[1], Mei-Hui Chunag[1]



1. Graduate Institute of Hydrological and Oceanic Sciences, Nation Central University

Bhola Cyclone caused nearly half a million casualties in the Bay of Bengal in 1970 This research aims to reconstruct the storm surge event and understand the effects of tides and cyclone track on the flooding area. In this study, the numerical simulations were performed with COMCOT storm surge model. The nonlinear shallow-water wave equation was solved on spherical coordinates, and physical terms such as pressure gradient force, wind shear force, bed friction force and Coriolis force were added to the momentum equation. To reconstruct the storm surge event, the tide component was considered by importing tidal boundary forcing from TPXO Global Tidal Solutions. The scenarios take a variety of cyclone track, cyclone moving speed, and cyclone intensity. Sensitivity tests are further introduced to see the storm coincides with high tide.

The results can help to understand the influence of tides and other cyclone parameters on flooding, also provide a practical contribution to the quick alert and disaster control of the storm surge in the Bay of Bengal in the future.

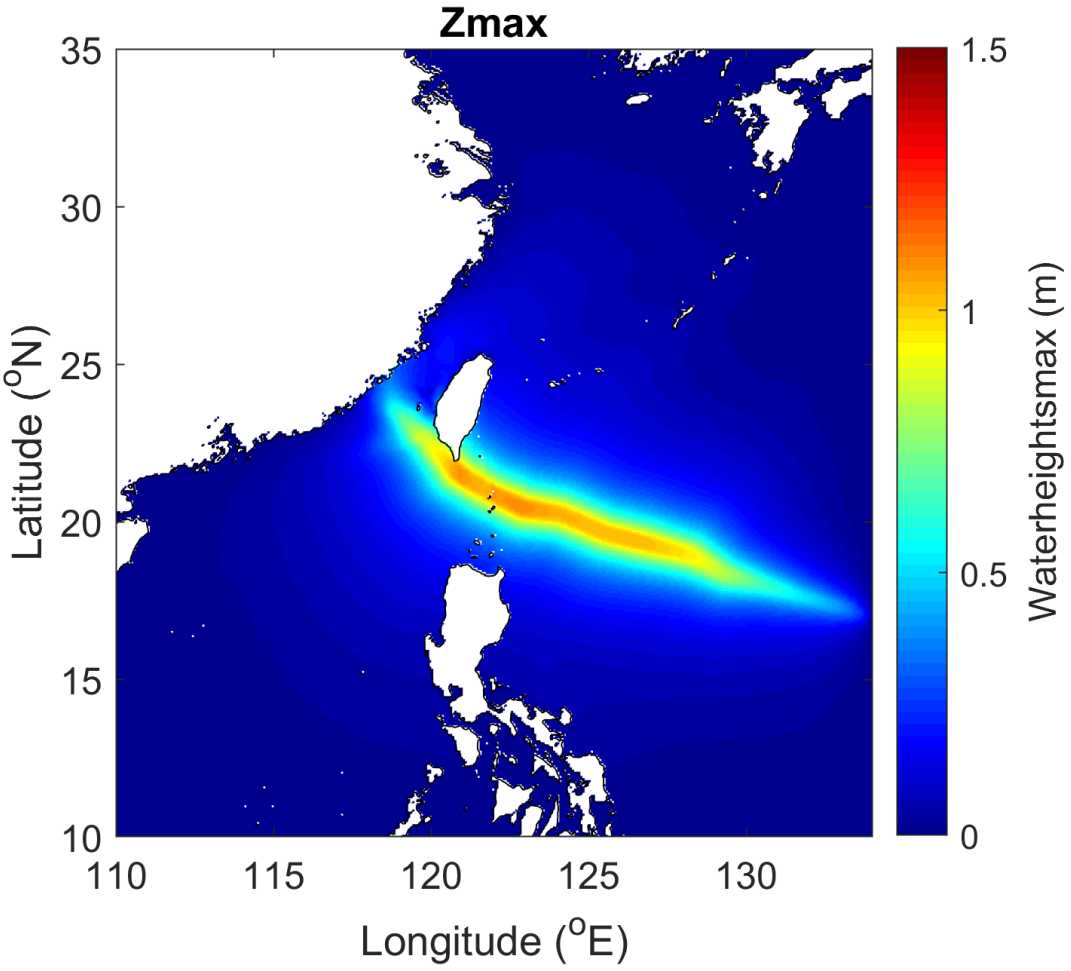
Reconstruct the 1845 Kouhu Storm Surge Event with Ensemble Method



*CHIA-CHUN HSU[1], Tso-Ren Wu[1], Po-Sen Tseng[1], Shu-Chun Chuang[1], Chun-Wei Lin[1], Mei-Hui Chuang[1]

1. Graduate Institute of Hydrological and Oceanic Sciences, National Central University

In 1845, a severe storm surge event occurred in Kouhu, a township in southern western Taiwan. In this event, the storm surge caused more than 10,000 casualties which makes it the most serious storm surge event in the history of Taiwan. However, limited by the technology, no description of the typhoon track in the literature. Considering the dense population on the west coast of Taiwan in recent years, and also a large substation which transports the electric from a large number of offshore wind turbines to the cities in Taiwan. A deep understanding of the storm surge event is important. A non-linear multi-grid COMCOT storm surge model in conjunction with the ensemble method is applied to reconstruct the event and assessing future risks on the western coast of Taiwan. To reconstruct the storm surge event in 1845, cases are chosen from the modern typhoon database as a reference to build test scenarios. Then varying the typhoon track, typhoon moving speed, and typhoon intensity to find the most reasonable one which has the best agreement with the description in the historical documents. Besides, the effect of the tidal component is also considered on the storm surge height and inundation. Further discussion about the coastal hazard assessment is provided.

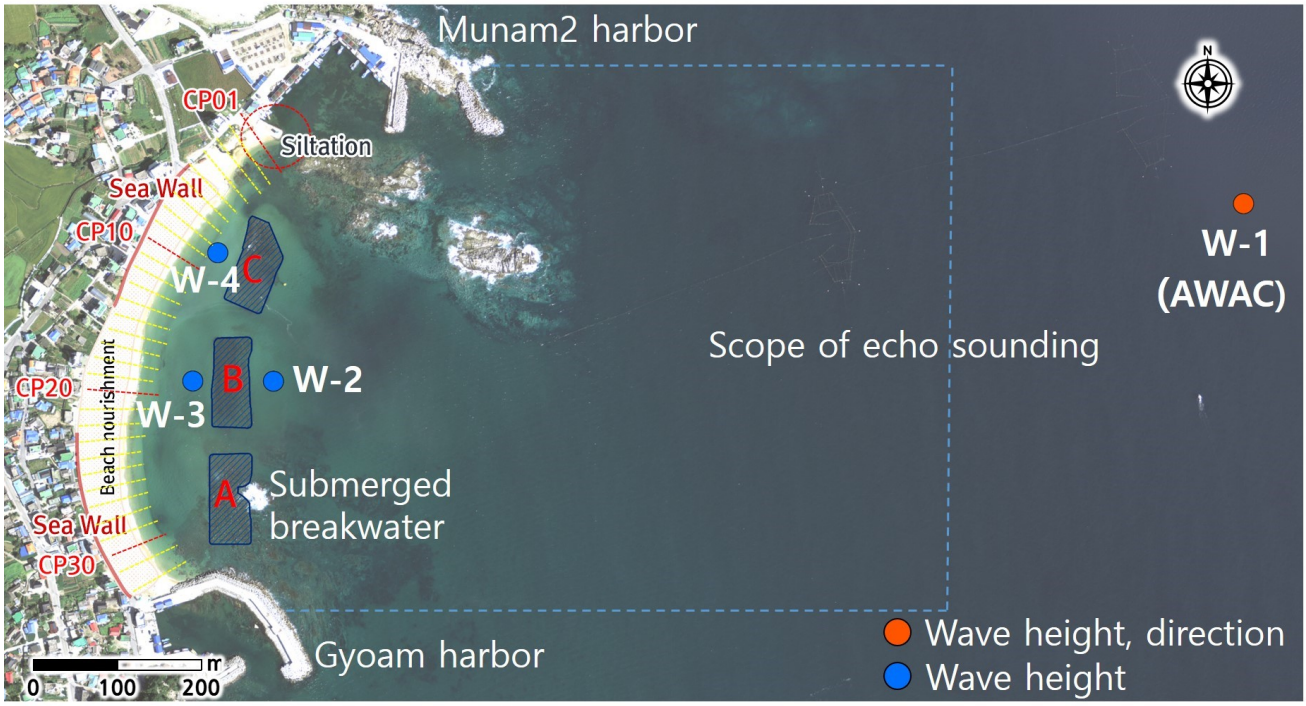
Coastal Geographic Surveying Result on Gyoam beach in South Korea by Integrated Coastal Zone Management

*DongSeob Song[1]

1. Kangwon National University

Coastal erosion is generated by complex interrelationships of causes, influencing factors, and elements and appear by repetitive cycles of erosion and deposit over a long time. An increasing need exists for regional-scale measurements of shoreline change to aid in management and planning decisions over a broad portion of the coast and to inform assessments of coastal vulnerabilities and hazards. In order to prevent coastal erosion, the beach nourishment and the man-made construction, like a submerged breakwater, are widely used, it is desirable to monitor the post nourishment shoreline to evaluate the projects' success.



The Gyoam beach has the typical shape of a pocket beach. The river mouth of the Munam stream had been a sediment source in the littoral cell in the past. However, as the location of the river mouth changed from the Gyoam beach to the Backdo beach, the Gyoam beach was eroded by the blocking of the sediment source, as well as the construction of the coastal road. It is supposed that the coastal erosion was aggravated as the seasonal equilibrium collapsed after the construction of the Munam-2 Harbor. As the CIP progressed, the beach changes were analyzed by season through continuous monitoring in each construction phase. During the construction of submerged breakwaters from the first half of 2014 to the second half of 2016, the south of Gyoam beach was eroded and the northern beach received deposits in the summer, whereas the northern beach was eroded, and the southern areas were deposited during the winter season owing to the seasonal movement of sediments. After the completion of the submerged breakwaters in the second half of 2016 and the beach nourishments from 2016 to 2018, the shoreline is maintaining seasonal equilibrium as of February 2019. According to the stable shoreline analysis, a stable shoreline was not reached near the Gyoam beach on the south of the littoral cell due to the lack of sand volume in the littoral cell; however, as of August 2018, it seems that the total sand volume has been adjusted to some degree. After the implementation of submerged breakwaters, the results show that the fully submerged breakwaters produce more stable and balanced sediment loss/gain in the protected area, and yield more desirable formation of salient behind the breakwaters.

[A-OS22] Physical, chemical and biological processes and variability in the Indian Ocean

convener:Yukio Masumoto(Graduate School of Science, The University of Tokyo), Hiroaki Saito(Atmosphere and Ocean Research Institute, The University of Tokyo)

The Indian Ocean has been recognized to play important roles in regional and global climate systems, material circulations, ecosystems, and their variability, with linked biophysical phenomena that span a wide range of spatial and temporal scales. These phenomena include, for example, diurnal cycling, intraseasonal disturbances, seasonal variations, Indian Ocean dipole events, and decadal to multi-decadal variations as well as secular trends under the global warming stress. In situ and remotely-sensed physical and biogeochemical observations using the Indian Ocean Observing System (IndOOS) and other means are now accumulating high quality data, and research efforts with numerical models and analyses of comprehensive datasets are also being conducted under International Indian Ocean Expedition-2 (IIOE-2) and the Eastern/Western Indian Ocean Upwelling Research Initiative (EIOURI/WIOURI). To advance our understanding of such Indian Ocean phenomena, disciplinary studies are essential, as are interdisciplinary investigations that elucidate the linkages between the physical and biogeochemical/ecological researches realms.
The objective of this session is to share our knowledge on, and to advance our understanding of, all facets of Indian Ocean variability. We invite papers on physical, biogeochemical and ecological aspects of the variability, as well as those related to atmosphere-ocean interactions, over the full spectrum of temporal and spatial scales. Discussions to facilitate mutual interactions among different research communities would also be expected and encouraged.

IndOOS-2: A Roadmap to Better Observations of the Rapidly Warming Indian Ocean

Lisa M Beal[1], Jérôme Vialard[2], Matthew K Roxy[3], *Motoki Nagura[4]

1. Rosenstiel School of Marine and Atmospheric Science, University of Miami, 2. Institut de Recherche pour le Développement (IRD)/LOCEAN, 3. Indian Institute of Tropical Meteorology (IITM), 4. Japan Agency for Marine-Earth Science and Technology

Over the last decade the Indian Ocean has absorbed 30% of the global oceanic heat uptake and the fate of this heat and its impact on future change is unknown. Projections foresee accelerating sea level rise, more frequent extremes in monsoon rainfall, and decreasing oceanic productivity. Almost two-thirds of humanity live around the Indian Ocean, many in countries dependent on fisheries and rain-fed agriculture. Coastal population growth is conflating with climate change to further increase exposure and vulnerability of these populations. The Indian Ocean observing system (IndOOS), established in 2006, is a multi-national network of sustained oceanic measurements that underpin understanding and forecasting of weather and climate for the Indian Ocean region and beyond. However, gaps in the IndOOS have so far limited forecasting efforts, left large discrepancies in the basin energy budget, and kept us in the dark about ecosystem stressors. A three-year, international review of the IndOOS by more than 60 scientific experts provides a roadmap to an improved observing network —IndOOS-2 —that can better meet future scientific and societal challenges. Core findings include the need for 1) chemical, biological, and ecosystem measurements alongside physical parameters; 2) better resolved upper-ocean processes to yield improved sub-seasonal to seasonal forecasts; 3) expansion into the western Arabian Sea; and 4) expansion into key coastal regions and the deep ocean to better constrain heat and freshwater changes. IndOOS-2 will require new resources and partnerships, creating opportunities for Indian Ocean rim countries to enhance their monitoring and forecasting capacity as part of a growing Global Ocean Observing System community.

The imprint of climate variability on the Maritime Continent surface ocean biology

*Eko Siswanto[1], Takanori Horii[1], Iskhaq Iskandar[2], Jonson Lumban Gaol[3], Riza Yuliratno Setiawan[4]

1. Japan Agency for Marine-Earth Science and Technology, 2. Sriwijaya University, 3. IPB University, 4. Gadjah Mada University

Understanding how the ocean surface biology will respond to climate variability is one of the important factors of climate change impact assessment, particularly the change in ocean biology represented by phytoplankton biomass or chlorophyll-a concentration (Chl-a). This is because phytoplankton are the base of the ocean food web from which carbon biomass and energy will be transferred to higher trophic level organism production (e.g., fish catch) hence affecting human life. Situated between Indian and Pacific Oceans, the Indonesian Maritime Continent (IMC) biophysical properties are greatly affected by both the Indian Ocean Dipole (IOD) and the El Nino-Southern Oscillation (ENSO) climate variations. All papers assessing the impacts of climate variability on Chl-a in the IMC were based on the datasets including the periods of concurrent IOD and ENSO events and mainly focused on the eastern Indian Ocean. The fingerprints of single IOD (positive or negative IOD) and single ENSO (El Nino or La Nina) events on surface ocean Chl-a have not been separately identified. Utilizing more than two-decade ocean color data we identified the fingerprint of climate modes, both during concurrent and single events. During concurrent positive IOD (+IOD) and El Nino years Chl-a mainly in the eastern Indian Ocean (west of Sumatra and south of Java), the Banda Sea, and the Arafura Sea tended to increase which was associated with upwelling as can be indicated by low sea surface height anomaly (SSHA). On the other hand, in the coastal areas surrounding Borneo, New Guinea, and the eastern coast of Sumatra, Chl-a tended to decline which was attributed to low rainfall. In contrast, during concurrent negative IOD (–IOD) and La Nina Chl-a in the eastern Indian Ocean, the Banda Sea, and the Arafura Sea tended to decline which was associated with downwelling indicated by high SSHA. On the other hand, in the coastal areas especially surrounding the Borneo, and the eastern coast of Sumatra, Chl-a tended to increase which can be attributed to high rainfall. The imprint of single +IOD (–IOD) on Chl-a resembled that of concurrent +IOD and El Nino (concurrent –IOD and La Nina) but with lower magnitudes of Chl-a changes. There was almost no distinct imprint on Chl-a associated with single El Nino and single La Nina events. The imprint of IOD on the IMC’ s Chl-a was obviously stronger than that of ENSO, even in the western Pacific Ocean where strong correlations between biophysical variables and Nino3.4 index were observed.

Particulate organic carbon distribution and primary production of Java-Sumatra upwelling system of Eastern Indian Ocean

*Edwards Taufiqurrahman[1], A'an Johan Wahyudi[1]

1. Research Center for Oceanography - Indonesian Institute of Sciences

The Eastern Indian Ocean region, particularly in south of Java and west of Sumatra, has been known for its periodical upwelling. The upwelling occurs during southeast monsoon period from June to October. During that time the upwelling center moves westward alongside the southern Java coast and then northward to the equator alongside western Sumatra waters. Upwelling will trigger the enhancement of primary productivity and then followed by changes on the organic carbon fixation in the ocean. Although the upwelling system in this area and its effect on the primary productivity are widely known, but a systematic study on its impact on the organic carbon variability is rarely conducted. We plan this research to find how the distribution of the particulate organic carbon related to the primary productivity and upwelling variability. It will be conducted in August –September (following the upwelling period) as part of the RV Hakuho-maru research cruise. The area observed is Java-Sumatra upwelling area. Seawaters will be sampled for the chlorophyll and particulate organic carbon content. With added satellite data, the upwelling strength can be determined and then correlated with the primary productivity and vertical-horizontal distribution of the particulate organic carbon.

The Pathways and Timescales of Indonesian Throughflow

*ISKANDAR MOCHAMAD RIZA[1], Toshio Suga[1], Kelvin John Richards[2], Hideharu Sasaki[3]

1. Graduate School of Sciences, Tohoku University, 2. International Pacific Research Center, University of Hawaii, 3. Application Laboratory, Japan Agency for Marine-Earth Science and Technology

The major of Indonesian Throughflow (ITF) pathways are divided into two main routes, they are the western and eastern pathways. The properties differences of ocean circulation from these two pathways were examined by using Lagrangian particles in the high-resolution ocean model. The daily and monthly data fields also applied in the Lagrangian framework to see the discrepancies of the flows and crossing time. The particles originating from Mindanao need less than ~3 months to reach Makassar Strait and the same time needed to leave this strait to the southern end of Makassar Strait. The particles mostly flow out to the Indian Ocean via Timor Passages, Ombai Strait and Lombok Strait and associated with the upper ocean pathways. The eastern path originated from the north and south equator. The particles leaving the Lifamatola Strait to reach the Banda Sea and coming from the inflow both have broad of crossing time from ~3 months to ~1 year. The eastern path is concentrated in the 500-1000m depth range. Timor passages show as the strongest currents in the outflow channel in the eastern path. The application of the monthly fields in the Lagrangian framework shows the larger number of particles crossing the threshold section associated with the Lagrangian transport and faster crossing time

Observation in the Java-Sumatra upwelling region during positive IOD in 2019

*Iwao Ueki[1]

1. JAMSTEC Japan Agency for Marine-Earth Science and Technology

The positive dipole event in 2019 is one of the stronger events in the record and produced extreme forest fire in Australia and deadly flooding in Africa. The event started in May, took the peak in October and terminated in January 2020. Under the eastern Indian Ocean upwelling research initiative (EIOURI), JAMSTEC installed a surface mooring at 5S 100E from December 2018 for capturing upper ocean and meteorological variables associated with upwelling and IOD. Also we conducted research cruise in the Java-Sumatra upwelling region by Barunajaya I in cooperation with Badan Pengkajian dan Penerapan Teknologi (BPPT). Acquired data by CTD and LADCP observation indicate strong upwelling feature in the Java-Sumatra upwelling region. The details will be shown in the presentation.

A role of eastward-propagating intraseasonal oscillation in controlling coastal upwelling southwest of Sumatra

*Takanori Horii[1], Iwao Ueki[1]

1. Global Ocean Observation Research Center, Japan Agency for Marine-Earth Science and Technology (JAMSTEC)

Coastal upwelling along the southwestern coast of Sumatra and Java is closely associated with El Niñ o/Southern Oscillation and occurrence of the Indian Ocean Dipole (IOD). In this study, we used a combination of observational data and satellite-based datasets, and investigated the role of eastward-propagating atmospheric intraseasonal oscillation (MJO/ISO) in controlling the coastal upwelling system. Intraseasonal coastal upwelling events frequently occurs in June-September, in response to anomalous southeasterly alongshore winds, with weak (strong) amplitude along the coast of Sumatra (Java). Observational data reveal that due to salinity stratification and thick barrier layer southwest of Sumatra, subsurface cold-water upwelling signal tends not to reach to mixed layer. We also found that the coastal upwelling signal tends to be suppressed by eastward-propagated downwelling Kelvin waves which was driven by anomalous equatorial westerly winds 15-30 days ago. Implications of these observational results for understanding the IOD will be discussed.

Institute for Extra-cutting-edge Science and Technology Avant-garde Research (X-star), Japan Agency for Marine-Earth Science and Technology, 5. Department of Ocean Sciences, Tokyo University of Marine Science and Technology, 6. Atmosphere and Ocean Research Institute, The University of Tokyo

Nitrous oxide (N_2O) is a trace gas that contributes to both global warming and stratospheric ozone depletion. Its major sources are nitrification and denitrification by microorganisms in soils and waters. Emission of N_2O from the ocean to the atmosphere is estimated to take account for 20% of global N_2O sources. It has been known that production of N_2O is enhanced in the oxygen minimum zone (OMZ) and regions such as Arabian Sea and Eastern tropical Pacific act as strong N_2O source to the atmosphere because of turbulent fluxes from the thermocline. Although OMZ is also found in the northern part of eastern Indian Ocean, Bay of Bengal, N_2O saturation in the surface water and calculated flux to the atmosphere have been reported to be substantially lower than those in the western counterpart, Arabian Sea. Moreover, vertical N_2O profiles obtained in the western and central Bay of Bengal by the previous studies were significantly different, the latter showing only a small increase of N_2O in OMZ. In this study, we aimed at revealing vertical and meridional profile of N_2O and its production/consumption processes in the eastern Indian Ocean by concentration and isotopic analyses of N_2O and related species.

Seawater samples were collected at 9 stations along 88˚E meridian (16˚N–20˚S) from 8 to 27 November, 2018 during the KH18-6 cruise of R/V *Hakuho-maru*. At each station, samples taken at 14–15 depths in the range of 0–5000 m were subsampled into 230 mL glass vials followed by addition by 1 mL saturated $HgCl_2$ solution for sterilization and by sealing with butyl rubber stoppers. Each was then preserved at 4–6˚C in the dark. Concentration and isotope ratios of N_2O ($\delta^{15}N$, $\delta^{18}O$, and SP, ^{15}N-site preference in NNO molecule) were measured using a gas chromatograph-isotope ratio mass spectrometer (GC-IRMS) equipped with a gas extraction and cryogenic concentration unit.

Concentrations of N_2O in the surface water were 6–7 nmol kg^{-1} which corresponds to saturation of 99–115% with respect to the atmosphere. The values obtained at four stations in the Bay of Bengal (5–16˚N, 88˚E) were lower than those observed in the western Bay of Bengal (10–20˚N, 80–88˚E) in March–April 1991 and were similar to those obtained in the central Bay of Bengal (7–15˚N, 85–89˚E) in February 1995 and 1996. At each station, the concentration increased with depth and showed a maximum around the bottom of thermocline (150–300 m in the Bay of Bengal and 300–1000 m at southern stations). The subsurface N_2O maxima in the Bay of Bengal were coincided with the core of OMZ, and the highest concentration of 136 nmol kg^{-1} was observed at the northern most station. The highest value observed in this study is larger than that reported in the west and central Bay by a factor of two and ten, respectively. Isotope ratios of N_2O showed a linear relation with inverse concentration, but the relationship was different between surface layer (0–40 m), thermocline or upper OMZ (100–250 m), lower OMZ (250–1000 m), and deep layer (> 2000m).
The enhanced accumulation of N_2O in OMZ in the Bay of Bengal compared to past studies suggests two possibilities: (1) there is a large seasonal variability in the vertical diffusion of N_2O in this region because

©2020. Japan Geoscience Union. All Right Reserved.

mixed layer depth is largely affected by wind and rainfall driven by monsoon, flow rate of fresh water from the rivers, and so on, (2) N_2O production rate has been increased during the past 20 years due to change in local oxygen or nutrient concentrations. If (1) is the case, the accumulated N_2O might be emitted to the atmosphere in a month scale and the Bay of Bengal would act as a significant source. Isotopic signatures of N_2O source (end member value) were estimated using the relationship between isotope ratios and concentration for each layer in the Bay of Bengal for the first time. By comparing the end member values with the isotopic ranges of known N_2O production and consumption processes, which was deduced from isotope fractionation factors in the literature and isotopic signature of N_2O precursors obtained by this study or deduced from the literature, we estimate that N_2O is produced by both archaeal nitrification and denitrification in the upper OMZ whereas it is produced mainly by denitrification in the lower OMZ.

Nitrate isotopes in the Bay of Bengal

*Chisato Yoshikawa[1], Akiko Makabe[1], Yohei Matsui[1], Sakae Toyoda[2], Makio Honda[1], Naohiko Ohkouchi[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Tokyo Institute of Technology

Nitrogen isotopic composition of nitrate ($\delta^{15}N_{Nitrate}$) is widely used as a tracer of ocean-internal nitrogen cycling (consumption and regeneration) and ocean-external nitrogen inputs and losses (N_2-fixation and denitrification). A $\delta^{15}N_{Nitrate}$ value increases, in conjunction with nitrate depletion, due to an isotopic effect during nitrate assimilation by phytoplankton. When denitrification occurs in the water column, a $\delta^{15}N_{Nitrate}$ value extremely increases due to a strong isotopic effect. N_2-fixation produces fixed nitrogen with a $\delta^{15}N$ value of ~0‰, as nitrogen fixers take up N_2 gas with little isotopic effect. Here we determined $\delta^{15}N_{Nitrate}$ and $\delta^{18}O_{Nitrate}$ along 88°E in the Bay of Bengal during the cruise KH-18-6-leg2 of R/V *Hakuho-Maru*. The nitrate concentrations were below 1 μM in the surface water of the whole area. Especially, the nitrate depleted water spreads out below the depth of 400 m at the station near 20°S. The $\delta^{15}N_{Nitrate}$ values were expected to increase toward the surface in conjunction with nitrate depletion unless ^{15}N depletion by N_2-fixation and ^{15}N enrichment by denitrification are dominant. The $\delta^{15}N_{Nitrate}$ showed 5‰ in the bottom and deep waters and increased to 7‰ in the intermediate water. The horizontal maximum of the $\delta^{15}N_{Nitrate}$ in the intermediate water was found at the northern edge site where the oxygen concentration dropped below 1 μM. The ^{15}N enrichment in the intermediate water suggests the nitrate in the Indian Central Water is affected by benthic or water-column denitrification. The $\delta^{15}N_{Nitrate}$ once decreased to 6‰ in the subsurface water and then increased to the surface. The horizontal minimum of the $\delta^{15}N_{Nitrate}$ in the subsurface water was found in the nitrate depleted water near 20°S. The ^{15}N depletion in the subsurface water suggests one of the sources of surface nitrogen is the remineralized nitrogen originated from N_2-fixation. In the presentation, we will discuss the nitrogen cycle of the Bay of Bengal in more detail by using the $\delta^{18}O_{Nitrate}$ values.

[A-OS23] Atlantic climate variability, and its global impacts and predictability

convener:Ingo Richter(JAMSTEC Japan Agency for Marine-Earth Science and Technology), Hiroki Tokinaga(Research Institute for Applied Mechanics, Kyushu University), Andrea Taschetto(University of New South Wales), Noel S Keenlyside(Geophysical Institute Bergen)

The Atlantic Ocean is subject to pronounced climate variations that occur on a wide range of time scales, including interannual variability in the equatorial and subtropical regions, and Atlantic multi-decadal variability (AMV), which has been linked with the Atlantic meridional overturning circulation (AMOC). These are connected to other climate variations across the globe. The AMV, e.g., has long been known to have global impacts, such as changes in the Indian, Asian and South American summer monsoons, and changes in the Pacific associated with the "global hiatus". Interannual variability in the equatorial and subtropical Atlantic has also been shown to influence global climate, including over Asia, while the freshening of the North Atlantic by melting of the Greenland ice cap is expected to influence all ocean basins via atmospheric bridges. Likewise, misrepresentation of the Atlantic can have global ramifications in climate models. Misrepresentation of the AMOC, e.g., has been associated with model biases in the entire Northern Hemisphere.

This session seeks observational, modeling, and theoretical studies on the mechanisms that determine the Atlantic mean climate and variability, as well as the predictability and global impacts of such variability. We also seek studies that evaluate climate model performance in the region. Topics include atmosphere-ocean-cloud interactions in the tropical Atlantic; two-way interaction with other ocean basins; relationships between tropical and mid/high latitude variability; air-sea interaction along the Gulf Stream and its influence on cyclones and storm track evolution; variability in the Benguela upwelling region; influence of Agulhas leakage on the South Atlantic; coupled climate model biases in the region and their impacts; AMOC and long-term climate change.

An evaluation of the performance of CMIP6 models in the tropical Atlantic: mean state, variability, and remote impacts

*Ingo Richter[1], Hiroki Tokinaga[2]

1. JAMSTEC Japan Agency for Marine-Earth Science and Technology, 2. Kyushu University, Kasuga, Fukuoka, Japan

General circulation models of the Coupled Model Intercomparison Project Phase 6 (CMIP6) are examined with respect to their ability to simulate the mean state and variability of the tropical Atlantic, as well as its linkage to the tropical Pacific. While, on average, mean state biases have improved little relative to the previous intercomparison (CMIP5), there are now a few models with very small biases. In particular the equatorial Atlantic warm SST and westerly wind biases are mostly eliminated in these models. Furthermore, interannual variability in the equatorial and subtropical Atlantic is quite realistic in a number of CMIP6 models, which suggests that they should be useful tools for understanding and predicting variability patterns. The evolution of equatorial Atlantic biases follows the same pattern as in previous model generations, with westerly wind biases during boreal spring preceding warm sea-surface temperature (SST) biases in the east during boreal summer. A substantial portion of the westerly wind bias exists already in atmosphere-only simulations forced with observed SST, suggesting an atmospheric origin. While variability is relatively realistic in many models, SSTs seem less responsive to wind forcing than observed, both on the equator and in the subtropics, possibly due to an excessively deep mixed layer originating in the oceanic component. Thus models with realistic SST amplitude tend to have excessive wind amplitude. The models with the smallest mean state biases all have relatively high resolution but there are also a few low-resolution models that perform similarly well, indicating that resolution is not the only way toward reducing tropical Atlantic biases. The results also show a relatively weak link between mean state biases and the quality of the simulated variability. The linkage to the tropical Pacific shows a wide range of behaviors across models, indicating the need for further model improvement.

Decadal variability of the Benguela Niño/Niña

*Hiroki Tokinaga[1]

1. Research Institute for Applied Mechanics, Kyushu University

The Benguela Niño/Niña is a dominant mode of sea surface temperature (SST) variability along the southwest African coast, with large amplitudes in austral fall. While interannual characteristics and mechanisms of this event have been extensively investigated by previous studies, its decadal fluctuation remains unclear. By synthesizing historical climate observations, we show that decadal SST variability in the Angola-Benguela area (ABA) is affected not only by local air-sea feedback but also by remote forcing from the North Atlantic and Pacific. On decadal time scales, the Benguela Niños (Niñas) tend to co-occur with negative (positive) SST anomalies in the tropical North Atlantic. This SST pattern is not confined in the tropical Atlantic but characterized by SST tripole in the whole North Atlantic, with a negative (positive) North Atlantic Oscillation-like SLP anomaly pattern. The strengthening (weakening) of the Azores high cools (warms) the tropical North Atlantic and weakens (strengthens) cross-equatorial trade winds, making favorable conditions for development of the Benguela Niño (Niña). The Pacific Decadal Oscillation also contributes to decadal SST anomalies in the tropical North Atlantic through atmospheric teleconnection. We will discuss how these remote forcings affect the decadal fluctuation of the Benguela Niño/Niña events.

Climate change in the tropical Atlantic

*Noel S Keenlyside[1], Lander Crespo[1], Shunya Koseki[1], Ingo Richter[2], Lea Svendsen[1]

1. Geophysical Institute, University of Bergen and Bjerknes Centre for Climate Research, Norway, 2. JAMSTEC, Japan

The tropical Atlantic SST have warmed by about 1 degree over the historical period, with greatest warming in the east, along the African coast and in the Gulf of Guinea. Experiments performed from the Coupled Model Intercomparison Projects (CMIP) indicate that models fail to reproduce this warming pattern, instead showing a rather uniform warming. Future projections with these models also tend to show rather uniform warming. In constrast. results from anomaly coupled models indicate that model biases impact the ability of climate models to simulate warming patterns in the tropical Atlantic. Here we investigate the role of model biases on climate change in the tropical Atlantic in the CMIP experiments. In addition, we have analyzed impacts of global warming on tropical Atlantic climate variability, and we assess the sensitive of the results are to model biases.

The extraordinary Atlantic Nino of 2019/2020

*Ingo Richter[1]

1. JAMSTEC Japan Agency for Marine-Earth Science and Technology

From December 2019 onward there was an increase in equatorial Atlantic sea-surface temperatures (SST), with anomalous warming in the eastern part of the basin. While such interannual warm events (also known as Atlantic Ninos) are a common occurrence in the region, the 2019/2020 event stands out for two reasons: 1) It is the warmest event to occur in at least two decades, thereby punctuating a period of relatively low variability in the equatorial Atlantic. 2) Its timing was unusual, as Atlantic Niños almost exclusively develop in boreal spring and peak in summer.
Here we analyze SST, surface winds, surface heat fluxes, and sea-surface height to explain the unusual development of the 2019/2020 event. Preliminary results suggest that it was primarily driven by surface heat fluxes rather than by ocean dynamics. We further attempt to put this event into the context of previous studies that have argued for a decrease of equatorial Atlantic variability in recent decades.

Impact of springtime cross-equatorial SST gradient on the Atlantic Niño/Niña

Takaaki Yokoi[1], *Hiroki Tokinaga[1]

1. Research Institute for Applied Mechanics, Kyushu University

A strong linkage between the Benguela Niño/Niña and Atlantic Niño/Niña events suggests that the same forcing may trigger the two phenomena in different seasons. On the other hand, several Atlantic Niño/Niña events have occurred without strong Benguela Niño/Niña events. When the Atlantic Nino (Nina) occurs following the Benguela Niño (Niña), springtime sea surface temperature (SST) anomalies in the tropical North Atlantic tend to be negative, acting to weaken the cross-equatorial SST gradient and southeasterly trade winds. On the other hand, when the Atlantic Nino (Nina) occurs without the Benguela Niño (Niña), SST anomalies in the tropical North Atlantic tend to be positive, consistent with non-canonical Atlantic Nino events suggested by previous studies. We will show a heat budget analysis for these Atlantic Nino/Nina events.

Investigating South American monsoon during mid-Pliocene

*Andrea Taschetto[1], Gabriel Pontes[2], Ilana Wainer[2], Alex Sen Gupta[1]

1. Climate Change Research Centre and ARC Centre for Excellence in Climate Extremes, University of New South Wales, Australia, 2. Department of Physical Oceanography, University of São Paulo, Brazil

South America receives more than 50% of its total annual rainfall from November to March, when convection increases over the Amazon Basin and the South Atlantic Convergence Zone (SACZ) strengthens, forming the South American Monsoon System (SAMS). Extreme SAMS events have great economical and societal impacts (e.g. agriculture, housing subject to flooding, water supply). Evaluation of possible changes in South America rainfall associated with warmer scenarios is of urgent demand. Here we investigate how Southern Hemisphere rainfall may had been different during the mid-Pliocene Warm Period (~3Ma), a time of mean global warming between 2-3ºC that share characteristics of the currently CO2-induced warming. We examine simulations undertaken as part of the Pliocene Model Intercomparison Project and performed climate model experiments using the atmospheric component of the NCAR Community Earth System Model (CESM) to understand the mid-Pliocene climate as well as to provide insights on possible rainfall changes in a warmer world. We show that higher rates of warming in the North Atlantic compared to the South Atlantic generated an interhemispheric temperature gradient that in turn enhanced the southward cross-equatorial energy flux by up to 48%. The enhanced energy flux equator resulted in a strengthening of the Southern Hemisphere Hadley circulation, that in turn intensified the South Atlantic Subtropical High. These atmospheric changes weakened and displaced the SACZ poleward. In addition, the intensified energy flux equator shifted the Atlantic Inter-Tropical Convergence Zone northward, weakening the contribution of oceanic moisture advection to the Amazon Basin and the SACZ. Curiously those changes in the mid-Pliocene relative to present day climate are not accompanied by significant variations in the Atlantic Meridional Overturning Circulation. The evaluation of the mid-Pliocene adds a constraint associated with differing rates of warming between hemispheres.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-OS Ocean Sciences & Ocean Environment

[A-OS24] Exploring new frontiers of oceanic mixing research in the next decade

convener:Toshiyuki Hibiya(Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo), Ichiro Yasuda(Atmosphere and Ocean Research Institute, The University of Tokyo), Lakshmi Kantha(Aerospace Engineering Sciences, University of Colorado, Boulder, Colorado, USA)

Mixing plays many important roles in the global ocean through a variety of different processes. In the upper ocean, mixing affects the sea surface temperature and hence air-sea interactions, which in turn influence the state of the atmosphere on a variety of time scales. Mixing in the deep ocean maintains the abyssal stratification of the world's oceans and influences the global overturning circulation, which in turn affects long-term climate. Ocean mixing modulates the transport and dispersal of dissolved and suspended materials, including pollutants, plankton and fish larvae. It also plays an important role in the oceanic food chain in so far as primary productivity, which occurs predominantly in the euphotic zone, is affected by nutrient uptake from the deep associated with ocean mixing.

 Microstructure profilers are being increasingly and routinely used to measure turbulence in the oceans, including the deep. Mixing models with more inclusive physics are being developed. Increasing computer power is making it possible to include sophisticated mixing models in global circulation models. As such, it is time to take stock of where we stand at present and explore the frontiers of mixing research over the next decade to advance our knowledge and utilize it for societal benefit.

 This session encompasses a wide variety of aspects of mixing within the water column from the surface to the seabed, as well as the impact of mixing on key physical, biological, and chemical processes, such as those mentioned above, with special attention to new findings obtained through improvements in oceanographic instrumentation, mixing models and the use of supercomputers. Observational, theoretical, experimental, and numerical approaches are all welcome. In this session, we particularly encourage discussion that can confirm how far our understanding of related topics has advanced and help define the new frontiers of ocean mixing research to be tackled in the next decade.

Synchronized interdecadal periodic variations behind regime shifts in Pacific Decadal Oscillation

*Masaki Hamamoto[1], Ichiro Yasuda[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

Interdecadal climate variability over the North Pacific is examined using a 298-yr (1700-1997) Pacific Decadal Oscillation (PDO) index reconstructed from tree-ring records. Three statistically significant variations including the bi-decadal (~20yr), the tri-decadal (~30yr), and the multi-decadal (>50yr) variations are identified. The latter two variations exhibit 'phase-lock' features respectively with the bi-decadal variation: zero-crossings of the tri-decadal (multi-decadal) variation and the bi-decadal variation take place within significantly short duration. Above-mentioned characteristics imply that the two variations with longer timescale receive notable influence from the bi-decadal variation. These three variations together explain phase reversals identified using an instrumental 119-yr PDO index (1900-2018) including the period after 1997, where only the observed PDO index covers. Besides, these variations provide a viewpoint which integrates two contrary perspectives on the climatic regime shifts presented by previous studies. We further discuss possible linkages between these variations and the 18.6-yr lunar nodal cycle, as well as a phenomenon known as subharmonic resonances, which involves excitements of longer variations in nonlinear systems.

Keywords: regime shift, Pacific Decadal Oscillation, phase-lock, 18.6-yr lunar nodal cycle

Role of the vertical mixing in the bottom water warming in a new ocean state estimate using tidally induced mixing parameterization

*Satoshi Osafune[1], Shuhei Masuda[1], Nozomi Sugiura[1], Toshimasa Doi[1], Tadashi Hemmi[1]

1. Japan Agency for Marine-Earth Science and Technology

Decadal repeat of modern, high-quality, full-depth, hydrographic section observation has revealed the basin-wide warming of the bottom water in the Pacific Ocean, which cannot be neglected for precise estimation of the global heat balance. An ocean state estimate has shown that surface warming around Antarctica can remotely induce bottom water warming in the northern North Pacific through the propagation of internal Kelvin and Rossby waves more quickly than expected from the thermohaline circulation timescale. However, this wave response must depend on the background structures of density and temperature, which are determined by a balance between advection and diffusion. We investigated the bottom water warming in our new ocean state estimate that uses vertical mixing schemes based on well-known tidal energy distribution and discuss the mechanism especially focusing on the role of the vertical mixing.

Keywords: vertical mixing, data assimilation, bottom water warming

Global distribution of the ocean vertical diffusivity derived from an ocean tracer inverse model approach

*Akira Oka[1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

The ocean vertical diffusivity is important for controlling the distribution of various ocean tracer including the temperature and salinity. Recent studies clarified that its spatial distribution is very inhomogeneous but the global coverage of its direct measurements from turbulent mixing observations are not enough and its quantification is still difficult. On the other hand, recent observational data about the ocean tracer including temperature and salinity are increasing significantly and dataset covering the global ocean is available. The inversion of ocean velocity distribution from ocean tracer has been reported in the previous studies (e.g. Wunsch, 1996). In the same way as this velocity inversion, some studies tried the inversion of the ocean vertical diffusivity (e.g. Ganachaud and Wunsch, 2000) but there are few studies which discuss its detail 3-dimmensional distribution. By using an ocean tracer inverse model and an ocean general circulation model, I have tried the inversion of the ocean vertical diffusivity from the ocean tracer observations. In this presentation, I will report my attempt and discuss how observed temperature/salinity distribution is useful for obtaining the 3-dimmensional distribution of the ocean vertical diffusivity.

Keywords: ocean vertical diffusivity, ocean tracer, inverse model, adjoint method

A theoretical and observational study of the vertical decay scale of tidal mixing over rough seafloor topography

Takahiro Yanagimachi[1], *Toshiyuki Hibiya[1]

1. Department of Earth and Planetary Science, Graduate School of Science, University of Tokyo

There are much limited studies for tidal mixing enhanced over abyssal rough seafloor, compared with that in the surface mixed layer and/or in the interior ocean. Part of the reason is that direct observation of abyssal turbulent mixing requires special instrument as well as enormous time and cost, leaving the most universal method to estimate abyssal turbulent mixing in terms of finescale parameters. The most widely used parameterization for tidal mixing over abyssal seafloor is the one proposed by Jayne and St. Laurent (2001). However, this parameterization contains several ambiguities; in particular, although the vertical decay scale of tidal mixing over rough seafloor topography is usually assumed to be constant at 500 meters, recent field observations show that it varies depending on the roughness of the seafloor topography and the amplitude of tidal flow.

In the present study, using a microstructure profiler called VMP-X, we conducted detailed field observations at two locations (Station 1 and Station 2) with different seafloor topography of the Izu-Ogasawara Ridge to examine the spatial and temporal variations of the vertical profile of turbulent dissipation rates off the seafloor. At the same time, we carried out numerical simulations using high-resolution vertical two-dimensional numerical model incorporating the realistic seafloor topography and the spatial and temporal variations of tidal velocity to clarify the physical mechanism behind the observed results.

The vertical decay scales of turbulent dissipation rates off the seafloor at both stations were observed to vary with the amplitude of tidal flow. The decay scale of turbulent dissipation rates at Station 1 was observed to increase with the increase of the tidal flow amplitude, whereas the decay scale of turbulent dissipation rates at Station 2 was observed to decrease with the increase of the tidal flow amplitude.

We next investigate the generation of internal waves at each station using the results of the numerical simulations. At Station 1, the vertical decay scale extending higher up off the seafloor is attributed to the continuous generation of upward propagating internal lee waves with harmonic frequencies of M_2 tidal forcing, consistent with the theoretical prediction by Bell (1975). At Station 2, on the other hand, the dominant process of turbulent mixing is density overturning just over the steep sloping bottom that occurs as the amplitude of tidal flow increases, so that the vertical decay scale of turbulent mixing shows the dependence on the amplitude of tidal flow, quite contrary to that at Station 1.

These results indicate that microstructure observations combined with the information of roughness of the seafloor topography and the amplitude of tidal flow are absolutely necessary to improve the parameterization of tidal mixing over rough seafloor topography.

Estimation of energy source of near-inertial oscillations observed at abyssal depths in Main Gap of the Emperor Seamount Chain

*Daigo Yanagimoto[1]

1. Atmosphere and Ocean Research Institute University of Tokyo

Prominent peaks near the inertial frequency (local f is 9.24×10^{-5} rad s^{-1} and actual peak frequency is 1.05 f) in clockwise rotary spectra were found at 5445-meter and 5855-meter depths in the deepest, widest gap in the Emperor Seamount Chain, called “Main Gap”, with mooring observation at 39° 20′ N, 169° 56′E (5895-m bottom depth) from 10 June 2016 to 25 June 2017. Band-passed current speed focused to the near-inertial frequency has a tendency of seasonal change; it was the lowest during the period from July to October 2016, the highest during the period from November 2016 to January 2017, and decreased toward June 2017. This temporal variation coincides roughly with the time series of 10-m wind speed above the mooring site according to the ERA5 dataset. The actual peak frequency (1.05 f) which is slightly higher than the local f indicates the southward energy propagation of the inertial oscillation from the northern surface according to Garrett (2001). Estimation of its ray shows that it would be generated at the surface by wind around 42°30'N (depending on the assumption of spatial distribution of buoyancy frequency) and its energy would propagate southward beyond Nintoku Guyot.

Characteristics of Vertically Propagating Near-inertial Internal Waves in the Japan Sea Excited in Northern Area

*Akie Sakai[1], Tomoharu Senjyu[2], Kosuke Mori[3], Takahiro Endo[2]

1. Department of Earth System Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, 2. Research Institute for Applied Mechanics, Kyushu University, 3. Okinawa Marine Science Support Section, Okinawa Institute of Science and Technology Graduate University

Near-inertial internal waves (NIWs) have been considered to be an important agent for mixing. Near-inertial oscillations had been observed in the deep sea of the Japan Sea, and they are suggested to be the effect of NIWs induced by wind. However, the propagation processes of NIWs are unclear. In this study, velocities from current meters in the deep sea were calculated to estimate the generation regions of NIWs in the deep sea. The frequency of near-inertial oscillations observed in the current meters at Stn. PM5 (134º41' E, 37º42' N) from Oct 12, 2017 to Oct 14, 2018 had lower than the local inertial frequency at Stn. PM5. The current at the deeper depth was more blueshifted than shallower one. This result suggests that the NIWs observed in different depth in the same station were excited in different regions. The characteristics of NIWs based on the climatological density also suggested the NIWs reaching the deep sea are generally excited in the northern area in few degree lower latitude.

Near-inertial shear and widespread intensified thermocline mixing in a seasonally stratified shelf sea

*Wei Yang[1]

1. Tianjin University

Mixing within and across the thermocline in seasonally stratified shelf seas controls nutrients supply from depth, laying the foundation for the growth and distribution of primary producers. Thermocline mixing is nevertheless suppressed by the strong stratification, as a result of which nutrients are usually depleted in the euphotic zone, substantially limiting new productivity. Here we show for the first time that there is widespread intensified thermocline mixing in the summer stratified Yellow Sea with the average thermocline dissipation rate and vertical eddy diffusivity to be 2.2×10^{-7}W $kg^{-1}$and $4.4\times10^{-5}m^2s^{-1}$, respectively. Analysis of mooring and shipboard velocity measurements reveals the presence of energetic downward-propagating near-inertial waves. These waves appeared to have induced strong velocity shear across the thermocline, which generated the observed intensified thermocline turbulence. These results have important implications for nutrients cycling and the maintenance of primary productivity in seasonally stratified shelf seas.

The estimation of the vertical mixing in double diffusive favorable regions of the Indian Ocean by CTD-attached microstructure measurement

*Yusuke Sasaki[1], Ichiro Yasuda[1], Katsuro Katsumata[2], Shinya Kouketsu[2], Hiroshi Uchida[2]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Japan Agency of Marine-Earth Science and Technology

Although it is suggested in several previous studies that double diffusion is a potentially effective contributor to vertical mixing, it is still challenging for estimating how double diffusion vertically transports heat and salt quantitatively. During the cruise of R/V Mirai along the I08N and I07S sections (MR19-04), microstructure measurements were carried out by fast response thermistors FP07, which were mounted on the CTD rosette. We obtained micro-temperature profiles in salt finger (diffusive convection) favorable regions such as tropical and subtropical zones (Antarctic zones) of the Indian Ocean. The high value of thermal variance dissipation (χ) in these double diffusion favorable regions potentially indicates the enhanced thermal vertical diffusivity, although we should also consider the contribution from the horizontal thermal diffusion. In addition, we discuss the difference of thermal variance spectral shape between double diffusion and turbulence.

Keywords: double diffusion, turbulence, microstructure measurement

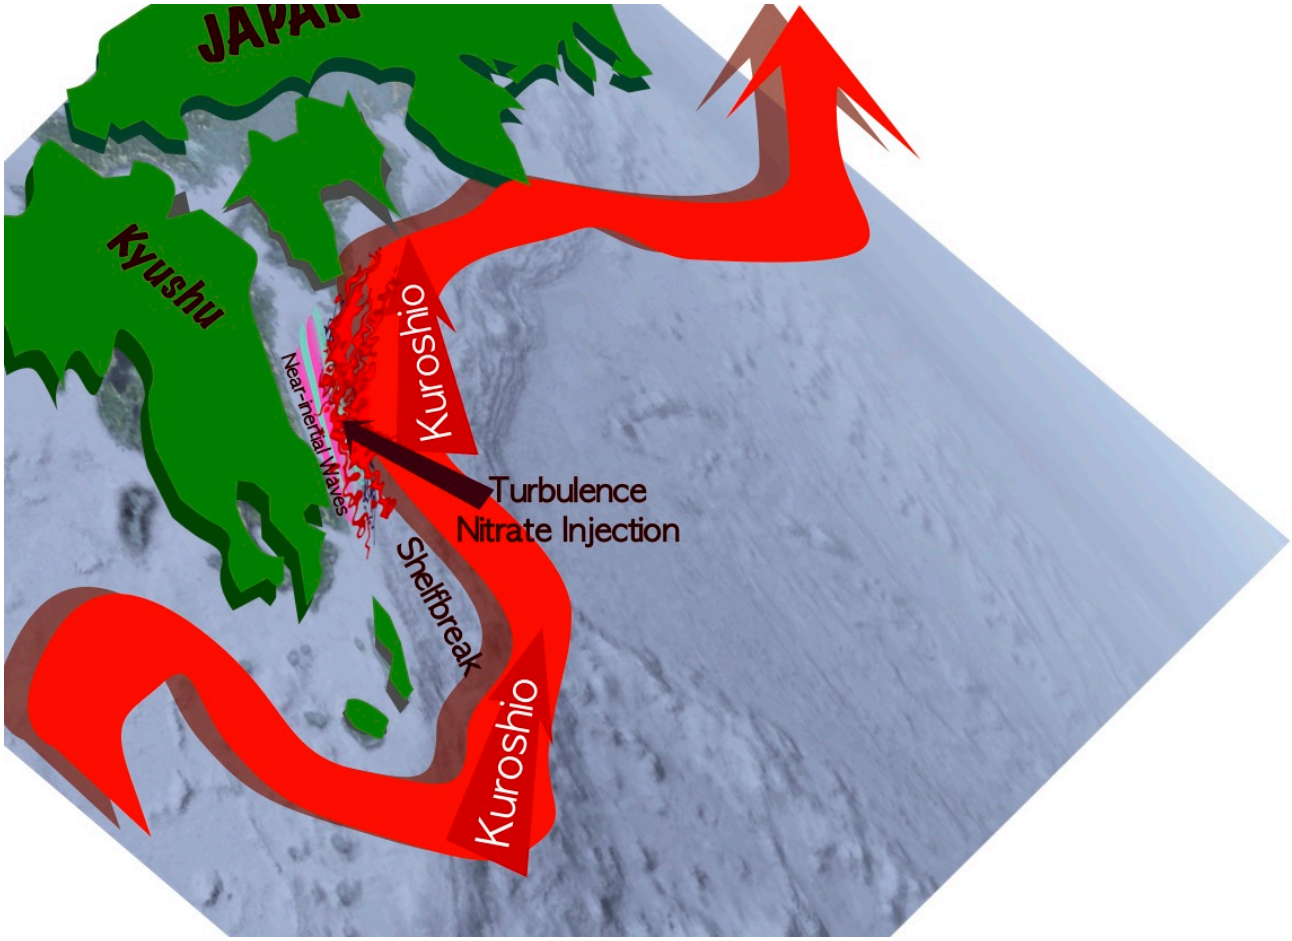
Turbulence, internal waves, and associated nutrient supply caused by the Kuroshio southeast of Kyushu



*Duran Gomez Silvana Gloria[1], Takeyoshi Nagai[2]

1. Graduate School of Tokyo University of Marine Science and Technology, 2. Tokyo University of Marine Science and Technology

While surface layers of the Kuroshio Current have been known for being nutrient poor, previous studies reported that the Kuroshio carries a large amount of nutrients in dark subsurface layer. Despite of this, it has been unclear whether these subsurface nutrients can be supplied to the upper layers on the continental shelf in the south of Japan. Results published recently, by the author, showed that the Kuroshio flowing on the shelfbreak induces very strong turbulent dissipation rates O(10^{-7} W kg^{-1}) associated with bands of large amplitude near-inertial internal wave shear, leading to a large diffusive nitrate flux to euphotic zone of >O(1 mmol N m^{-2} day^{-1}). However, questions remain of how these near-inertial internal waves are generated, trapped and induce mixing, and how much contributions to the phytoplankton increase arise. In this study, using a nested high-resolution numerical model, we successfully reproduced these observed features, described above, including banded shear near the Kuroshio. In the presentation, more detailed results will be shown for the lower trophic responses using a coupled ecosystem model.

Revisit of typhoon's effect on biogeochemistry in the western Pacific subtropical-oligotrophic region

*Makio Honda[1], Yutaka Yoshikawa[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Kyoto University

Comparative study for biogeochemistry between the western North Pacific subarctic eutrophic region (SAER) and subtropical oligotrophic region (STOR) (K2S1project, Honda et al. JO 2017) revealed that primary productivity in STOR is comparable to or higher than that in SAER. In their study, it was proposed that mesoscale cyclonic eddies contribute to nutrient supply to support primary productivity. On the other hand, it was evaluated that, based on the observation and vertical one-dimensional model (1D model), typhoon passing over the buoy site (KEO) plays minor role in the nutrient supply. However, many previous studies have reported typhoons effects on biogeochemical environments through intense turbulent mixing and upwelling. In addition, it was criticized that the numerical simulation by using the 1D model is less precise in evaluating the typhoon’s effect. Thus, we initiated the revisit of typhoon’s effect on the physical and biogeochemical environments using three-dimensional model (3D model). As preliminary experiment, we performed experiments with axis-symmetric wind stress of virtual typhoon with parameters (e.g., radius and transition speed) similar to observed ones in the STOR, and compared the typhoon effects simulated in the 1D and the 3D models. It was found that, after the virtual typhoon passed, the Ekman upwelling and the near inertial internal wave as observed at the ocean buoy in 2014 at subtropical time-series station KEO appeared in 3D model simulation. It was also found that, in addition to the 1D effect (wind-induced turbulent mixing effect), these 3D effects make the simulated nutrient (N) supply to upper 50 m larger. In future, numerical simulation with actual parameters of observed typhoon data and the associated meteorological / physical oceanographic / chemical oceanographic data will be conducted in order to evaluate typhoon effect on biogeochemistry. In addition, variable case studies will be conducted and it will be discussed what kind of typhoon impact on the subtropical-oligotrophic biogeochemistry significantly.

Study on the vertical mixing and nutrient supply off the east coast of the Kamchatka

*kimura shino[1]

1. The Univercity of Tokyo

The western subarctic North Pacific and the marginal seas of the Bering Sea and the Okhotsk Sea are known as the areas of world-highest biological CO_2absorption, where the nutrients and carbon significantly decrease from spring to autumn by biological production. This nutrient loss must be compensated by vertical turbulent nutrient transport across the clines of nutrients and density, however diapycnal nutrient supply has not been observed because no turbulence observation has been performed in this area. In the present study, by using the simultaneous observations of turbulence and nutrients performed in the joint Russia and Japan expedition from July 23 to September 14 in 2018, turbulence structure and turbulent nutrient transportwere examined for the first time in the area off the Kamchatka Peninsula. Near at the pycnocline between 150m to 200m depth (potential density 26.5-26.6) corresponding to the maximum density stratification and buoyancy frequency N,′not only turbulent energy dissipation rate ε but also turbulent diffusivity)took the maxima, even though could be decreased for large N. Since the verticalnutrient gradients were also the maxima at pycnocline, vertical turbulent nutrient transporttended to take the maxima, indicating the enhanced turbulence processes of efficient upward nutrient transport. Since these maxima were located just below the dichothermal (temperature minimum) layer representing the base of the previous winter surface mixed layer,it is suggested that the enhanced turbulence plays a role in upward transport of salt and nutrients and in supplying nutrients to the surface mixed layer exposed to surface in winter.Time-series observations of moored multilayer current measurements in the Kamchatka Strait revealed the continuous maxima of vertical shear of horizontal velocity from broad frequency bands from semi-diurnal, near-inertial, diurnal and low-frequency waves at the maxima of turbulent mixing and vertical gradients of density and nutrients. Since the amplitude of downward energy propagating near-inertial wave was attenuated below the pycnocline,breaking of the wind-generated near-inertial waves could contribute to strengthening turbulence and mixing. The observed turbulent vertical nutrient transport across the pycnocline in the offshore of the Kamchatka Peninsula accounts for 20-30% (20% nitrate, 30% silicate, 26% phosphate) of the biological drawdown of nutrients from March to August with the data of Yasunaka et al. (2014).

Reproduction of Iron-rich Intermediate Water in the Subarctic North Pacific by High-resolution Biogeochemical Model

*Hatsumi Nishikawa[1], Humio Mitsudera[1]

1. Institute of Low Temperature Science, Hokkaido University

Recent observation studies suggest that iron supply from sediment on the northwest continental shelf of the Okhotsk Sea plays an important role in the subarctic primary production (e.g. Nishioka et al., 2013). Dense shelf water (DSW) takes up iron from sediment, thereby transporting iron into the Okhotsk Sea intermediate water. However, observational data is still limited. In this study, we aim to reproduce the iron-rich intermediate water and the iron circulation, using a high-resolution iron circulation model. Our first version model did not reproduce iron-rich intermediate water. Biogeochemical model developed by Parekh et al. (2005) set total ligand concentration to be constant in all places. Recent observations, however, suggest that ligand concentration varies with sea area and water depth. Therefore, we conducted a new experiment with the ligand concentration changed in the vertical direction. The iron concentration of the intermediate water became higher in the new experiment than in the first experiment. Our model also reproduced high biological production, which utilizes the iron-rich intermediate water. In addition, we investigated effect of the tide and the18.6-year cycle.

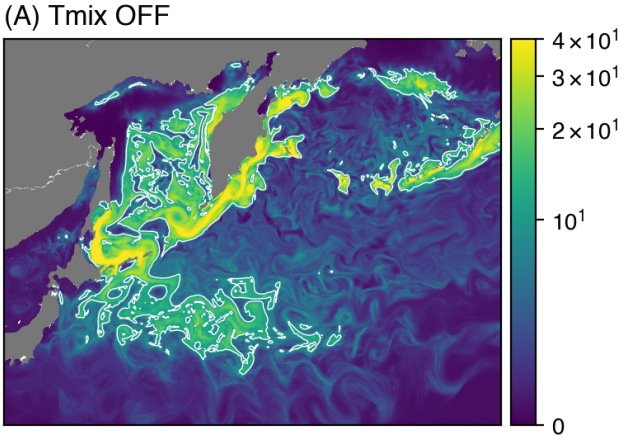
Role of tidal mixing on biogeochemical cycling in the northwestern North Pacific

*Kazuhiro Misumi[1], Tsubono Takaki[2], Daisuke Tsumune[2]

1. Planning Group, Central Research Institute of Electric Power Industry, 2. Environmental Science Research Laboratory, Central Research Institute of Electric Power Industry

The northwestern North Pacific is one of the regions with the highest net primary production and the largest seasonal variation in pCO_2 due to carbon uptake by marine phytoplankton. The northwestern North Pacific is adjacent to marginal seas such as the Sea of Okhotsk and the Bering Sea, where strong vertical mixing is caused by breaking internal waves generated by tidal currents and rough submarine topography. It is speculated that the vertical mixing in the straits drives the large pCO_2 variation in the northwestern North Pacific by pumping up nutrients abundant below the surface water, but the quantitative relationship between the tidal mixing and pCO_2 variation is still unclear.



In this study, a marine ecosystem-biogeochemical cycle model was developed targeting on the northwestern North Pacific to investigate the effects of tidal mixing on the primary production in the northwestern North Pacific. ROMS (Regional Ocean Modeling System) was used for the ocean model, and BEC (Biogeochemical Elemental Cycling) model was used for the ecosystem-biogeochemical cycle model. The resolution of the physical model was set to 1/12˚ to realistically reproduce the marine physical characteristics of the northwestern North Pacific: the subtropical and subarctic circulations, the Kuroshio-Oyashio confluence zone and the formation of the North Pacific Intermediate Water. The BEC model incorporates the five nutrient cycling (nitrate, ammonia, phosphate, silicate, iron) and carbonate system geochemistry, and can simulate the dynamics of large and small phytoplankton. The vertical mixing due to tide was calculated by converting the energy conversion rates calculated by a tide model into vertical diffusion coefficients by a parameterization.

The results of the cases where the vertical mixing due to tide was not considered (Tmix OFF) and considered (Tmix ON) showed a clear difference in the concentrations of phytoplankton biomass in the northwestern North Pacific (Figure: monthly mean phytoplankton biomass concentrations on April, units are in $mmolC/m^3$, the while line represents 10 $mmolC/m^3$ and colors above it are filled in log scale). The increase in phytoplankton biomass was remarkable in the straits, suggesting that vertical mixing due to tides increased the net primary production locally by pumping nutrients up. In addition, the increase in the biomass was also observed periphery of the straits and the Kuroshio-Oyashio confluence zone. The increase in the periphery of the straits is likely attributed to horizontal transport of biomass and/or nutrients by eddies, while the increase in the confluence zone is likely because tidal mixing changed a large-scale vertical structure of nutrient, which increased nutrient entrainment by the surface boundary layer mixing.

Interannual variations in primary productivity in the North Pacific western subarctic gyre (WSG), assessed by using settling particle delta N-15

*Yoshihisa Mino[1], Makio Honda[2], Fujiki Tetsuichi[2], Minoru Kitamura[2], Naomi Harada[2]

1. Nagoya University, 2. Japan Agency for Marine-Earth Science and Technology

Stable delta N-15 of particles trapped at 500 m of station K2 showed higher values in winter and lower in summer. This pattern would reflect mainly seasonal change in surface layer ammonium delta N-15 due to isotopic fractionation by light-controlled nitrification and the subsequent ammonium assimilation by phytoplankton. As a result, particle delta N-15 variations at K2 were significantly correlated with primary productivity (PP) (R^2= 0.94), which is attributable to their respective dependencies on light condition in the upper mixed layer. By applying this relationship to the time-series particle delta N-15, we here constructed monthly mean PP at K2 during 2010–14. The estimated PP ranged from 89 to 790 mg m^{-2} d^{-1} (in carbon equivalents) with the annual maximums appeared in Jun to Aug. As for the seasonal means in each year, we found an increasing trend of spring PP (Apr–Jun) while summer PP (Jul–Sep) decreased with time. If this indicates that the initiation timing of phytoplankton bloom became earlier during 2010–14, it would result from less light limitation in spring 2013–14 than before due to a reducing upper ocean mixing. With data in 2015–2019, interannual variations in the WSG productivity are addressed further.

Seasonal dynamics of zooplankton at station K2, NW Pacific, reconstructed from archived ADCP data

*Minoru Kitamura[1], Motoyo Itho[1]

1. Japan Agency for Marine-Earth Science and Technology

By using the archived mooring ADCP data, we obtained time-series of acoustic backscattering strength at station K2 (47ºN, 160ºE), the western subarctic North Pacific. In the pelagic water column, main acoustic scatterers are thought to be zooplankton. Actually, many researches showed that the acoustic backscattering strengths have good correlation with zooplankton biomasses in many area of the oceans. In this study, we reconstructed zooplankton dynamics using the acoustic backscattering strength as proxy of zooplankton biomass. ADCPs were moored at 370-400 m in depths at the K2 from 2015 summer to 2018 summer. The echo intensities recorded by ADCPs were converted to acoustic backscattering strength (Sv) in dB according to the following equation (Deines, 1999);

$$Sv = C + 10\log_{10}((T_x + 273.16) \times R^2) - L_{DBM} - P_{DBM} + 2\alpha R + K_c(E - E_r)$$

where C is an empirical constant, T_x is the temperature of the transducer, R is the range along the beam to the scatterers, L_{DBM} is the transmit pulse length, P_{DBM} is the transmit power, α is the absorption coefficient, K_c is a conversion factor for eco intensity from counts to dB, E is the echo intensity in counts, and E_r is the reference echo intensity which was taken as the instrument-specific lowest measured value over the mooring period. Although we could not obtain the acoustic data between sea surface and ca 30 m in depth due to side lobe effect of sound, four years time-series of backscattering strengths between 30 and 350 m was successfully collected. In the poster, we will describe seasonal variability and diel change of acoustic backscattering strength at K2. During the summer of 2016, strong current velocity was observed and the moored ADCP sank down to 660 m in depth. We will also discuss zooplankton dynamics during the event.

Variations in egg production rates of *Calanus sinicus* (Copepoda: Calanoida) estimated by gonad morphology

*Kiyotaka Hidaka[1], Shinji Shimode[2], Takashi Fushima[2]

1. Japan Fisheries Research and Education Agency, 2. Yokohama National University

Ocean mixing brings nutrients to surface layer, which in turn enhance phytoplankton production. Phytoplankton can increase in number and biomass in a short time by cell division, hence increase of cell abundance or chlorophyll concentration can be seen nearby the area of nutrient supply. In contrast, multicellular zooplankton, e.g. copepods, takes time to increase in number, as improvement of food condition brings increase in egg production first. It takes several days to weeks for the development of the eggs to the adults and thus biomass increase in multicellular zooplankton would occur away from the area of nutrient supply, which makes it difficult to be distinguished. Here, we developed a method to estimate egg production rate (EPR) of *Calanus sinicus*, one of the dominant copepods around Japan, based on the observation of gonad morphology. Niehoff and Runge (2003) first established the method for *C. finmarchicus* and EPR can be estimated without culture experiment. The method was applied to the time series sample collected around the Tosa Bay and we found the long-term fluctuation of the EPR of *C. sinicus,* which was different to its abundance fluctuation.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-OS Ocean Sciences & Ocean Environment

[A-OS25] Continental-Oceanic Mutual Interaction: Planetary scale Material Circulation

convener:Yosuke Alexandre Yamashiki(Earth & Planetary Water Resources Assessment Laboratory Graduate School of Advanced Integrated Studies in Human Survivability Kyoto University), Yukio Masumoto(Graduate School of Science, The University of Tokyo), Swadhin Behera(Climate Variation Predictability and Applicability Research Group, Application Laboratory, JAMSTEC, 3173-25 Showa-machi, Yokohama 236-0001), Takanori Sasaki(Department of Astronomy, Kyoto University)

The main purpose of this session is to promote discussion on mutual interaction between Continental zone and Oceanic zone. The global-scale material circulation induced by River runoff through oceanic general circulation as major topic on Continental-Oceanic Interaction, where the ENSO / IOD influence into continental climate as major topics on Oceanic-Continental Interaction. Numerical simulation and field observation of radionuclide transport from continental zone into ocean and its potential impact is also important topics of this session. The session also extend discussion on planetary hydrology and oceanography focusing on subsurface ocean in Jupiter's moon & Ancient Martian Oceanography & Hydrology by possible application of terrestrial GCM into Ancient Mars. In addition, impact of planetary radiation environment induced by Solar Energetic Particles on the transition of surface hydrological environment will be focused.

Nuclear Science and Engineering Center, Japan Atomic Energy Agency (JAEA),

The enhanced magnetic activity of the young sun was an important in the atmospheric evolution and dynamics of the early solar system. Lower solar luminosity associated provided planets a cooler atmospheric and surface environment on the early Earth and Martian surfaces and required production of potent greenhouse gasses in their atmospheres. Within these environments, the dose of ionizing radiation from solar energetic particles (SEPs) from the young Sun could have played an important role in the early phases of planetary habitability. Here, we present a theoretical model of the exposure of the early Mars to high fluence and hard spectra SEPs from the young sun by evaluating the possible magnitude and frequency of solar flares by using possible star spot area, derived from their rotational period. We evaluated annual and maximum flare energy in different cases of sunspot areas for 3%, 5% and 10% of their surfaces. The maximum dose at the Martian top of the atmosphere reaches 5.86 x 10^3Gy (2.65 x 10^2 Sv) at the time when the sunspot area is ~10% of the solar surface. Early atmospheric condition and possible hydrological cycles could have been affected by this strong ionizing radiation.

The internal ocean in a closure environment

*Hiroaki Sato[1], Tomomi Kubo[1], Ami Hashimoto[1], Hayate Hirai[1], Yusaku Miyashita[1], Yosuke Alexandre Yamashiki[3], Katie Morgan[2]

1. Kyoto University, 2. University of Arizona, 3. Graduate School of Advanced Integrated Studies in Human Survivability Kyoto University

The inner ocean created in Biosphere 2 was a unique structure, imitating the major components of the surface of the Earth inside of a closed environment. During SCB2 (Space Camp at Biosphere 2) all participants joining the camp evaluated the vertical structure of the internal artificial ocean and its basic physical parameters. We found that the all parameters are quite uniform due to the continuous mixing process in the facility. There were some regions where not enough mixing was found with characteristic local ecosystems cultivated inside of the artificial ocean. In this survey we discuss the ideal form of a space colony on the surface of other terrestrial planets and advantages and disadvantages of creating an “artificial ocean” inside of the structure. A certain atmospheric pressure is needed to maintain water in liquid form on the surface of those structures. On a smaller scale, the hydrological cycle may not be able to maintain certain salinity level in the ocean components, at the same time, freshwater should be used for drinking water and irrigation. The ocean, as the dominant component of the Earth, has a certain difficulty in maintaining in a different environment, and it may have specific characteristics for providing new earth-like environments essential for human life.

Japanese small water supply facility and depopulation

*Sayaka Hori[1]

1. Kyoto University

The population decline in Japan is expected to change the function of its local small water supplies. Those water supplies would no longer be able to independently maintain their public function such as services that have formerly taken for granted. The population is decreasing in 40 prefectures among all 47 in 2018. Only seven prefectures are increasing populations. In the depopulated area, shortage of human resources and lack of financial sources are a situation without waiting, and without the aid of the national government, the future will be challenging to maintain the small village any longer. The youth was leaving their hometown, and the old residents take care of its local small water supply's utilities. What kind of immediate action can be taken becomes a bottleneck. The progress of depopulation is inevitable, and many of the problems that are occurring in rural areas are the area where community power is gone.

Not more than 100 population served by piped water is not governed by Water Law. National Water Law does not have a broader application range for small water supplies. It is difficult to extend an application range, that considered in a limited way. Rural residents who live in the region unruled by Water Law, they operate and maintain drinking water by themselves to live.

The Waterworks Law was newly revised to show measures to compensate for the limitations of the water supply projects and strengthen them. Usually, the ordinance still plays a role to compensate for deficiencies in the law. Regarding the management of small-scale water supply, the management situation for each area is also different, so detailed arrangements are in place according to the ordinance. It is very common to enact a local law supplementary against an opaque legal system on the national level. For example, there is no law so-called Groundwater Law, and many local municipalities make an original ordinance supplementary to manage local groundwater resources as the common property. Enacting an ordinance can be said to be the law to complement loopholes of Water Law.

In this research, we conducted interviews and literature surveys on the small scale water supply present problem and situation, and also, we explore the new future image of Japan's small scale water supply project after the revision law enforcement exploratory. As a result, the current small water supply facility situation is not enough to make complementary or alternative solutions to support rural water supply issues. We still need to discuss how to promote the new revision concept in practice.

A Method to Forecast Extreme River Discharges from Typhoon Hagibis 2019 and Western Japan Floods 2018

*Josko Troselj[1], Han Soo Lee[1]

1. Graduate School for International Development and Cooperation, Hiroshima University

Introduction and Objective

As a result of climate change impact, record breaking disasters are occurring every year with unprecedented amounts of heavy rainfalls, typhoon intensities and associated coastal sea disasters which bring huge amounts of river water and associated nutrients pollution towards river mouths and into coastal sea zones, where they greatly decrease sea water quality and can negatively impact marine environment for several days or weeks. To mitigate negative impact of such disasters, it is important to develop forecasting or nowcasting of extreme river water levels during flood events, but it is still not well developed due to high uncertainty of its occurrence and absence of available historical data for unprecedented rainfall events.

Troselj et al. (2017) quantitatively evaluated the impact of extreme freshwater outflow to the coastal ocean due to typhoon passage by combining river and ocean models using hourly time step data and remote-sensing technology. With the advance of weather forecasting systems and specific availability of forecasting typhoon trajectory and intensity, we aim to be able to apprehend freshwater impacts on the coastal marine environment in advance of typhoon events.

Objective of the study is to show how to utilize methodology developed in the previous study to forecast the most recent extreme flood events occurred in Kanto region of Japan due to passage of Typhoon Hagibis in October 2019 and in Hiroshima region of Japan due to an unprecedented rainfall induced disaster in July 2018.

Methods

We continued the study from Troselj et al. (2017) by testing how river mouth discharges for 9 first class rivers calibrated in the previous study on Typhoons Chataan 2002 and Roke 2011 could have been nowcasted during the passage of Typhoon Hagibis in 2019. We assumed that we had available input meteorologically forecasted data which corresponds to MLIT observed data after the event. Furthermore, the same methodology was applied for heavy rainfall events of 2005 and 2018 for Ota River basin in Hiroshima, Japan, because these events had similar rainfall patterns.

Discussions

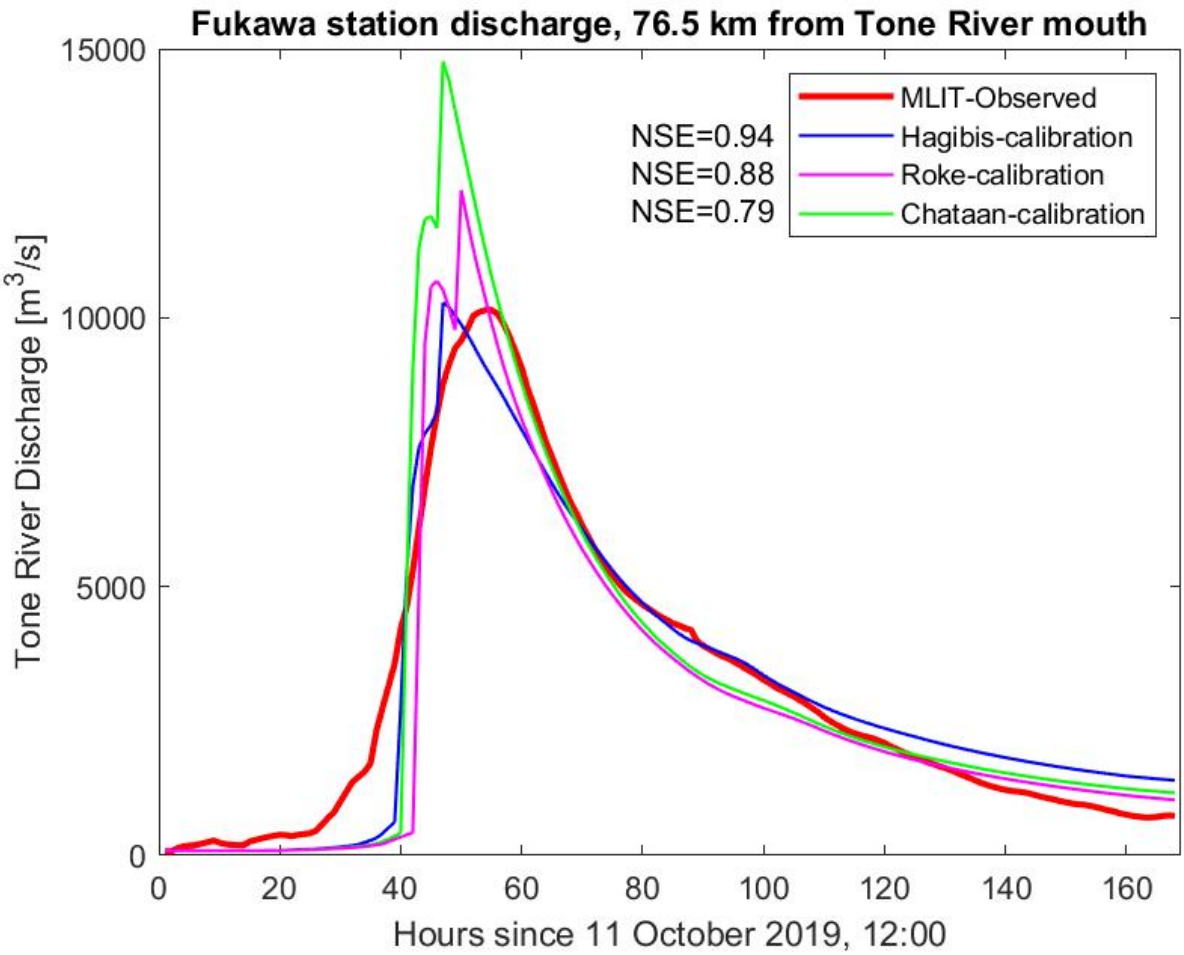
We showed that the model used in the study has the capability of simulating extreme discharge events by calibration using previous extreme Typhoon case events with similar trajectory. When using calibrated river basins parameters from Typhoons Chataan and Roke for projection of the Typhoon Hagibis, the

©2020. Japan Geoscience Union. All Right Reserved.

calculated Nash-Sutcliffe efficiency values (NSE) have mostly been bigger than 0.8 and 0.9, respectively. Exceptions are the most northern rivers Mabechi and Takase which did not show a significant fit due to being located too far away from the trajectory of the Typhoon Hagibis. These results suggest that our models calibrated on Typhoons Roke or Chataan cases can be successfully applied to forecast river runoff values from other similar extreme precipitation events, and furthermore newly calibrated parameters from Typhoon Hagibis can be used as an additional forecasting tool.

Results for cross-calibration and cross-validation of the heavy rainfall events of 2005 and 2018 for Ota River basin in Hiroshima will be finalized and similarly discussed before the JpGU conference, when MLIT releases Ota River discharge data for 2018.

Summary



The extreme discharge events have a lot of uncertainties and differences among their physical processes. However, we emphasize their similarities by calibrating river basin response to particular rainfall and afterwards using the calibrated parameters of the basin to forecast the river discharge from a future event with similar forecasted rainfall pattern.

Scientific illustration and Computer Graphics of exoplanets in *Exo* Kyoto’ s extrasolar planet catalog

*Nami Kimura[1], Yosuke Alexandre Yamashiki[1], Hiroaki Sato[1]

1. Kyoto University

The Exoplanetary database ExoKyoto possesses several different components concerning the habitability, together with the illustration of newly discovered planets. In this platform we generate texture of ocean planets for most of the cases, assuming that the surface of those planets are covered with the similar type of terrestrial ocean. The texture are selected based on the estimated physical characteristics of discovered exoplanets. In addition to these scientific images, we make 3D animation with the adobe After effects plugin,OPB which supports physical base shading and implements bump mapping and environmental reflection. The adjustable parameters are 3D objects, Radius, Position, Rotation XYZ, Material, Maps, UV, Render etc. Users can create realistic planets by adjusting these parameters. In this study we’ ll discuss the motivation and scientific validity in using such imaginary ocean planet for the scientific outreach purpose.

Methodology for Recognizing Marine Creature by Using Neural Network Based Image Recognition in Shirahama Area: Example of *Dendronephthya gigantea*

*Okamura Shin[1], Yamashiki Yosuke[1]

1. Graduate School of Advanced Integrated Studies in Human Survivability Kyoto University

At the 10th Conference for the Convention on Biological Diversity (CBD / COP10) that was held in Nagoya, Aichi Prefecture in October 2010, some global goals were set that form the core of the Strategic Plan for Conserving Biodiversity 2011-2020. The meeting agreed to take urgent and effective action to halt the loss of biodiversity by 2020. One of the goals of Aichi is that by 2020, at least 17% of terrestrial and inland waters, and 10% of coastal and marine waters, especially those that are particularly important to biodiversity and ecosystem services. However, to achieve this goal, several problems need to be overcome. For example, it is unclear where to set up new protected areas and how to expand existing ones. When considering the spatial design of a protected area, it should be considered that protected areas should be located in areas where many species live or areas where valuable organisms are distributed. Therefore, it can be said that spatial distribution information of various species that constitute biodiversity is indispensable for the spatial design of protected areas. From the above background, it can be said that it is necessary to accumulate information on the spatial distribution of various species that constitute biodiversity from the viewpoint of ecosystem protection. It is especially required to collect and accumulate information on seawater environment from the viewpoint of ecosystem protection. Currently, the International Oceanographic Data and Information Exchange (IODE) is known as an international oceanographic data and information exchange system, and the Ocean Biographic Information System (OBIS) is responsible for the database part. OBIS is a database that holds records of the appearance of marine life, and data is collected from various parts of the world. However, OBIS has a problem which is the quantity of data is not enough. Specifically, of the 250,000 species of marine life that have been discovered, only about 120,000 species exist in this database, and only about 56,000 species out of about 33,000 species in the Sea of Japan. In addition, OBIS has spatial data bias because these data are difficult to obtain underwater position information. It has also been found that maintaining these databases requires a great deal of effort. Confirmation work by specialists is required to specify the species, and it is considered that the more data the data amount, the more difficult it becomes. Given this background, I would like to propose a method for identifying species using image recognition. Specifically, we hope to use machine learning to create a comprehensive species-specific model. Such a model reduces the time and effort required to maintain for specialists, and enables species to be confirmed in various regions. We believe that this will affect various areas such as strengthening the marine database, concomitant ecosystem maintenance, and fisheries. In this paper, a classification model of *Dendronephthya gigantea* was created by using underwater image data acquired in the Shirahama area and convolutional neural network. As a result, we observed 83% of accuracy for gray scaled image classification task for *Dendronephthya gigantea.* From our results, it was confirmed that the accuracy did not get better for 60 iterations. This behavior seems to have caused over-learning was confirmed. In particular, the reason why there is no change in accuracy in train step and accuracy in test is considered to be that certain image data is extremely difficult to recognize. Therefore, it is considered necessary to select the data to be used in order to achieve high accuracy.

Continental-Oceanic Material and Non-Material Interaction: Investigating Methodologies for Heterogenous Dataset Integration

*Andrea Yuri Flores Urushima[1], Yosuke Alexandre Yamashiki[1], Takeshi Ise[1], Yoh Yamashita[1]

1. Kyoto University

This research aims to develop a methodology that allows to correlate the human perception of watersheds' change with oceanic water quality change due to run off from a hydrographic system. This will be done through correlating heterogenous datasets from natural and social sciences between 2003-2019 with a focus on the case study of Yuragawa watershed. This investigation will discuss research pathways that potentially allow to relate Chlorophyll-a variation at river mouth with the results from the text mining analysis of articles which mention the Yuragawa River from newspapers' database. This research responds to recent trends addressing complex systems, such as the European FuturICT Project, that emphasizes the relevance of combining heterogenous datasets, of both quantitative and qualitative data, from natural and social sciences. This is a preliminary study that aims at investigating the possible threads of correlation between two types of datasets that are rarely analysed together. While text mining has been increasingly used to investigate social behavior prediction, chlorophyll-a data has been mainly used in natural sciences as a bio-chemical description of water nutrients. The relevance of using newspaper text mining data to analyze environmental change is that this type of data allows to combine cognitive and emotional perception of human everyday life needs to the analysis of natural changes.

Toward a global SPH simulation of an icy moon with internal ocean

*keiya murashima[1], Takanori Sasaki[1], Natsuki Hosono[2], Yosuke Alexandre Yamashiki[1]

1. Kyoto University, 2. Japan Agency for Marine-Earth Science and Technology

There are some traces of existence of internal ocean in some icy moons, such as a plumes of vapor of Europa and Enceladus. Since liquid water would be essential for the origin of life, it is important to understand the development of inner sea, especially the temperature distribution/evolution inside the icy moons. Thus, we aim to simulating the development of an internal ocean of an icy moon by 3-dimensional numerical fluid calculations using Smoothed Particle Hydrodynamics (SPH) method.

It is considered that the balance between the tidal heating caused by tidal acceleration and radiative cooling sustains liquid water beneath the surface of an icy moon. So, we added viscosity, conductive heat transfer and radiative cooling terms into the governing equations of SPH method. In addition, we take latent heat of phase transition into consideration. We will report the progress of our project toward a global SPH simulation of the internal ocean.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-HW Hydrology & Water Environment

[A-HW30] Hydrology & Water Environment

convener:Ayumi Kotani(Graduate School of Bioagricultural Sciences, Nagoya University), Takeshi Hayashi(Faculty of Education and Human Studies, Akita University), Keisuke Fukushi(Institute of Nature & Environmental Technology, Kanazawa University), Masahiro Tanoue(School of Engineering, The University of Tokyo)

We focus on various issues of water cycle and environment and aim to answer questions of hydrological and earth system sciences; 1) surface, subsurface and evapotranspiration processes of water cycle, 2) natural and anthropogenic hydrothermal systems, 3) environments issues and studies on a watershed or global scale, 4) water-related issues with ecological, environmental, and geochemical aspects, and 5) other issues in hydrological sciences. We welcomes presentations regarding various kinds of approaches and techniques such as field survey, remote sensing, isotope tracers, numerical simulation, and theoretical analysis. This session is jointly hosed by societies of water-related geoscience (Geochemical Society of Japan, Japanese Association of Groundwater Hydrology, Japanese Association of Hydrological Sciences, and Japan Society of Hydrology and Water Resources), and accepts wide-range research topics related to water cycle and environment described above.

Impact of climate change on the surface water balance and groundwater level in the Kurobe River basin, Japan

*Takuya Matsuura[1], TEBAKARI TAICHI[1]

1. Toyama prefectural University

The purpose of this study is to clarify the impact of climate change on the surface water balance of the Kurobe River basin using distributed water balance model. The impact of climate change on the groundwater level of the Kurobe River alluvial fan was clarified by using the infiltration estimated water balance analysis as the boundary condition of the three-dimensional groundwater model.

It has been pointed out that the late 21st century of temperature under RCP 8.5 scenario increase by 2.6-4.8 ℃ anomaly relative to 1986-2005. In the future, climate change is projected to raise the temperatures and reduce both snowfall and snowmelt, which is projected to alter snow melting and thus affect water resources and groundwater environment in the Kurobe River catchment. There are many studies on climate change impact on river flow and surface runoff. The impact of climate change on groundwater environment is predicted to change the groundwater level and the recharge area, but there is no quantitative impact assessment study just yet.

In this study, we assessed the impact of climate change on water resources and groundwater levels using the results of several future prediction models. We used two future scenarios (Representative Concentration Pathways RCP2.6 and RCP8.5). This study use the 2014 land use data from the Ministry of Land, Infrastructure, Transport and Tourism, Japan. The layer structure of the groundwater model was created using 731 columnar data. The calculation time interval is daily for water balance analysis and monthly for groundwater analysis.

As a result of comparing the present climate (1981-2000) and future climate (2081-2100) under RCP2.6 and RCP8.5, it was clarified that the daily mean precipitation and solar radiation in the Kurobe River basin are not changing. In the case of RCP2.6 scenario, the daily mean temperature did not change between the present climate and the future climate. On the other hand, the RCP8.5 scenario, estimated that the daily mean temperature in the Kurobe River basin rise by 3.6 degrees in the future. As a result of the rise in temperature, the annual snow water equivalent in the Kurobe River basin decrease by 298 cm (50%), the peak of snow water equivalent is 8 days earlier than the current climate and the time of snow melts is the 22 days shifts earlier. In Kurobe River basin, the surface runoff and infiltration the peak timing shifts earlier (25 days) because of an earlier snow melt caused by global warming. As a result of estimating the water resources in the Kurobe River basin, the water cycle in the Kurobe River basin changed significantly in the futur. The main source of groundwater recharge in the Kurobe River alluvial fan is the Kurobe River, and changes in the water cycle of the Kurobe River are projected to have a significant impact on groundwater. As a result of three-dimensional groundwater analysis, it was clarified that the groundwater level of the alluvial fan increased from February to March and decreased from May to June in future.

Assessment of the precipitation characteristics and identification of urban flooding hotspots for an Indian satellite town

*Osheen Mehta[1], Mitthan Lal Kansal[1]

1. Indian Institute of Technology Roorkee

The rapid urbanization and population explosion have become major issues all around the world. Several satellite towns are developed to accommodate the ever-increasing population of metropolitan cities around the world. Gurugram, a prominent satellite city in the national capital region (NCR) of India, has faced frequent urban floods in recent years. Urbanization, besides having adverse impacts on hydro-climatic conditions, has led to a rapid increase in the impervious area. This seals the upper soil layers and thus generates excessive surface runoff causing urban floods. The problem of flooding has impacted public health and society as well as resulted in economic losses. Keeping this in mind, the present study makes an attempt to assess the extreme precipitation characteristics and identify the hotspots in Gurugram from the urban flooding point of view. The trend analysis of 1-day maximum rainfall series has been carried out for a period of 63 years (1951-2013) using the non-parametric Mann-Kendall (MK) test. The hotspots are identified through the rainfall-runoff modelling using the storm water management model (SWMM) developed by the Environmental Protection Agency (EPA), considering the criteria of the discharge rate, flooding hours and volume of flood. In order to initiate actions for its management, the prioritization of the potential hotspots is suggested through the multiple criteria decision analysis (MCDA) technique of choosing by disadvantage (CBD). The MK test results indicate an increase in the high-intensity rainstorms in recent years, leading to frequent urban floods. Further, it has been noticed that the urban drainage problem gets aggravated due to silting and choking of the Najafgarh and Badshahpur drains which ultimately joins the river Yamuna in the northern part of Delhi. This study will be helpful to devise effective planning and management strategies for the Gurugram town under the rapid urbanizing scenario.

Dynamics of terrestrial water storage in three major river basins over Peninsular India

*Abhishek .[1], Tsuyoshi Kinouchi[2]

1. Indian Institute of Technology Roorkee, 2. Tokyo Institute of Technology

Synergic impacts of natural and anthropogenic factors such as climate variability and excessive water consumption have led an unprecedented stress on the global water resources with higher concern for the developing nations. Peninsular Indian region has been highlighted as highly non-resilient to hydrological extremes such as droughts. Three major river basins namely, Mahanadi, Krishna, and Godavari having a combined geographical area share of 22 % of the total geographical area of India, and almost similar hydrogeological conditions were selected for the long term assessment of the terrestrial water storage (TWS) dynamics. Five gravity anomaly solutions (two mascon based products and three spherical harmonic based products) from different data processing centers were accessed and processed to get equivalent water thickness and subsequently utilized for understanding the TWS dynamics in terms of the relative anomaly. Generalized three-cornered hat (GTCH) method was employed to get the combined TWS data series corresponding to the minimum uncertainties. The resulting anomaly series showed a piecewise TWS trend of -1.21mm yr^{-1} and -18.81 mm yr^{-1} from April 2002 to June 2010 and July 2010 to May 2017 respectively in Mahanadi basin. The piecewise TWS trends in Krishna and Godavari basins are -12.55 and -4.45 from April 2002 to June 2010, and -30.95 and -10.41 mm yr^{-1} from July 2010 to May 2017, respectively. Despite the different patterns of trends until June 2010, all three basins are showed a high rate of decline in TWS (volume equivalent of 18.17, 54.53, 21.75 km^3, respectively) thereafter. These declining trends of TWS highlight the need of the conjunctive water management strategies, and policymaking in the region for achieving a sustainable and efficient water use at the basin scales.

Comparing constant dispersivity with scale-dependent one: for heated water injection case

*Ye-Chen Lin[1], Hund-Der Yeh[1]

1. National Chiao Tung University

Prior studies indicated that the thermal dispersivity generally nonlinearly increases with the distance from a heat flow source in a porous medium. Such dispersivity is termed as scale-dependent dispersivity (SD). However, the existing analytical models for injecting heated water into an aquifer, e.g., aquifer thermal energy storage system, usually assume the dispersivity as a constant to obtain analytical solutions. A question arises here: Is it possible to use a fixed value of constant dispersivity (CD) to represent SD one? To address the question, this study first develops a finite-element model adopting a SD formula to describe the dispersion process due to heated water injection in a confined aquifer. Then, an analytical model considering the CD is used to compare with the aforementioned SD model. The results from this study show that a CD can be found by using an average value of the thermal frontal position over the entire operating period to approximate SD one.

Human activity affects river flows and water-related hazards (Veldkamp et al., 2018). Global water models are indispensable tools for the assessment and prediction of water availability and demand under climate change. Through analysis of historical simulations and future projections, we can gain insights about past and current trends, and plan for efficient future water use. This study evaluates ten models that follow a common protocol and contribute with simulations for the global water sector of the Inter-Sectoral Impact Model Intercomparison Project phase 2b (ISIMIP2b). We analyze the equations used by the models to model the water use. We identify and present similarities and differences among them regarding: (1) how human activity is parameterized by global water models; (2) what are the water withdrawal sources, (3) what are the sinks of the return flows, (4) how many reservoirs are included in the models; (5) what type of reservoirs are included; (6) if and how the reservoir operations are included; (7) how land use, land management and land cover change are represented in the models.

Discussion on the correlation between professional characteristics and willingness to pay for ecosystem services

*Li-chun Peng[1], Yu-pin Lin[1], Wan-yu Lien[1]

1. National Taiwan University

Abstract

Most decision-making processes would take the economic practice as the core component. To recent years, more and more decision-making processes have centered the environmental consideration as one of the major components because of raising awareness and concern of climate change. This study continues the previous published results to simulate the effects of ecosystem services by climate change, and further to conduct a trial to quantify the change. Based on provided new information, we use the Contingent Valuation Method to explore the non-market value of ecosystem service functions.

Through a questionnaire survey to collect expert opinions in the fields of water resources, ecological engineering, and social sciences, we aim to understand the willingness of experts to pay for maintaining ecosystem service functions and the due level they are willing to pay. The correlation between personal experience and professional fields as well as their willingness are statistically analyzed. Our result shows that income and willingness to pay are positively correlated. In addition, the average willingness to pay for experts who have experienced the participation in ecosystem service related research projects is higher than those who have no experience in related research projects. This result allows us be more thoughtful in planning the integration of climate-change related ecosystem services into our decision-making process.

Seasonal variability of stable isotopes in precipitation over Indonesia observed for 2010-2018

*Kimpei Ichiyanagi[1], Takayuki Uesugi[1], Rusmawan Suwarman[2], Halda Aditya Belgaman[3], Masahiro TANOUE[4]

1. Kumamoto University, 2. Bandung Institute of Technology, 3. Badan Pengkajian dan Penerapan Teknologi, 4. Shibaura Institute of Technology

This study reveals the seasonal variability of stable isotopes in precipitation over Indonesia based on weekly rainfall sampling from 2010 to 2018 at 63 stations belong to Indonesia Agency for Meteorological, Climatological and Geophysical (BMKG). More than 4,300 samples were collected and analyzed stable water isotopes ($\delta^{18}O$ and δD) by using the Cavity Ring-Down Spectroscopy (Picarro, L2120i) in the Hydrology Laboratory of Kumamoto University, Japan. Daily rainfall amount data was used from the Global Satellite Mapping of Precipitation (GSMaP) by JAXA/EORC. Monthly mean $\delta^{18}O$, δD, and d-excess values weighted by the rainfall amount was calculated from the dataset.
The Cluster analysis was used to distinguish the spatial grouping of seasonal variability of monthly rainfall. As a result, there are three clusters in this region. Clusters 1 has clear seasonal patterns with the highest in the dry season and lowest in the wet season which stations are located in central Indonesia around Java Sea. Cluster 2 shows opposite patterns of the Cluster 1 located in east Indonesia. There is not significant seasonal variation in Cluster 3, which stations are located in the Java Island near the Equator.
From monthly mean $\delta^{18}O$ data at 40 observation sites, multiple regression analysis was performed using latitude, longitude, and rainfall amount as explanatory variables. A significant correlation was observed from May to December, while not significant in other months. Especially from January to March, monthly mean $\delta^{18}O$ in rainfall has not any significant correlations with these three variables because the $\delta^{18}O$ values are spatially uniform over this area.

Finding the optimal time for the integration in Lagrangian analysis for the best estimation of moisture sources.

*Raquel Nieto[1], Luis Gimeno[1]

1. University of Vigo

Moisture transport from their sources (continents/oceans) towards their sinks establishes the connection between evaporation and continental precipitation (or the available moisture). Different methods have been used to establish source-sink relationships for the atmospheric water vapour. The major part of the studies has used Lagrangian approaches to investigate the changes in the net water vapour along a large number of back trajectories to infer the moisture sources for precipitation falling in a target region. However, the results derived from these approaches are very sensitive to the integration time of the trajectories used in the analyses. The use of different time periods to find sources and sinks of moisture could alter the initial results, the subsequent analyses, and the interpretations.

We present here the annual and monthly optimal integration time for Lagrangian methods for the best estimation of sources of moisture. To do that we have implemented a Lagrangian moisture transport approach using the FLEXPART model with data from the European Centre for Medium-Range Weather Forecasts (ECMWF) Interim Re-Analysis (ERA-Interim) (Dee et al., 2011). This reanalysis (the most appropriate for representing the hydrological cycle), covers the period from January 1979 to the present, and contains data at 6-h intervals with a spatial resolution of 1°x1º in latitude and longitude for 61 vertical levels (1000 to 0.1 hPa).

To achieve the optimal integration time we have compared the monthly precipitation estimated by the Lagrangian approach to gridded data such as ERA-Interim, GPCP and/or MSWEP precipitation. All the data was downscaled to 0.25 degrees using linear interpolations and aggregated over monthly intervals for the common period 1980 - 2015.

ATMOSPHERIC MOISTURE SOURCES ASSOCIATED WITH EXTREME PRECIPITATION DURING THE PEAK PRECIPITATION MONTH

*Luis Gimeno[1], Marta Vazquez[1,2,3], Raquel NIETO [1], Margarida Liberato[2,3]

1. Environmental Physics Laboratory (EPhysLab), CIM-UVigo, Universidade de Vigo, Ourense, Spain, 2. Instituto Dom Luiz (IDL), Faculdade de Ciências, Universidade de Lisboa, 1749-016 Lisboa, Portugal, 3. Escola de Ciências e Tecnologia, Universidade de Trás-os-Montes e Alto Douro, Vila Real, Portugal

The moisture transport is a crucial element in the understanding of the continental precipitation and its extremes. In this work, a Lagrangian approach was used to investigate the contribution of the main oceanic and continental global moisture sources to extreme precipitation during the peak precipitation month (month showing higher climatological precipitation). This was done for every grid point using four different precipitation thresholds to define precipitation extremes. Compared with the climatological sources, it is remarkable the increase of the contribution for extreme precipitation of the North Atlantic and the Mediterranean Sea sources over Eurasia, the Indian Ocean over Australia, the North and South Pacific sources over North and South America respectively and the South Atlantic source over Africa

SEASONAL VARIATION OF DISSOLVED TRACE ELEMNTS IN LAKE KIBA-GATA

*Ariunsanaa BATERDENE[1], Seiya NAGAO[2], Keisuke Fukushi[2], Kohei Sakaguchi[1], Tetsuya Matsunaka[2]

1. Graduate School of Natural Science and Technology Kanazawa University, 2. Institute of Nature and Environmental Technology, Kanazawa University

This study addresses the changes in dissolved trace element concentrations of the Lake Kiba-gata, which is located at Komatsu City, Ishikawa Prefecture, Japan and is a small, shallow and semi-closed environment. The water chemistry of trace elements is an important issue since it is a micronutrient for the growth of a phytoplankton and involves many environmental problems in water quality.

Surface water samples were taken from 6 points that evenly scattered across the lake territory and one inflow river during April 2017-January 2020 in monthly intervals for understanding spatio-temporal distribution of the main and trace elements. The water samples were vertically collected at KBG3, central part of the lake, with 0.5 m depth interval from surface to 2.0 m depth.

The seasonal variation of trace elements as Fe and Mn are observed significantly in horizontal and vertical distribution. The higher concentration of Fe and Mn in surface water was detected in the station near the river mouth in December to February and the lower concentration was observed in summer season. The dissolved iron concentration decreased with increasing depth in winter season at the central part of the lake but shows increasing trend with water depth. There is positive linear correlations between concentration of trace elements (Fe and Mn) and NH_4^+ and a negative correlation with lake water pH. The results indicate that the redox condition maybe related to the spatial and temporal variation of Fe and Mn in Lake Kiba-gata.

This research was supported by Functional materials based on Mongolian natural minerals for environmental engineering, cementitious and flotation processes (No. J11A15) sub-project under the Mongolian –Japanese Engineering Education Development Project.

Study on the origin of hot spring water using the deep part of Inubohsaki Onsen’ s core.

*Satoko Tezuka[1], Mana Kamata[1]

1. Chiba Institute of science

Inubohsaki Onsen in Choshi, Chiba is a Na-Cl type hot spring sourced from groundwater at a depth of 1000 m or more. In previous studies, we have reported that Inubohsaki Onsen is derived from 10,000 to 20,000 years old seawater, and has a different chemical composition from current seawater due to geological effects. In this report, the purpose of this study is to obtain information on the origin of the source of Inubozaki Onsen from the relation between the composition of rocks in the Atagoyama Group, which is considered to be the core of the source well and the hot spring water dissolved components. Hot spring water was collected from the source well of Inubosaki Onsen “Kuroshio-no-yu” and the amount of ions was determined by ion chromatography. The components and crystal phases of a 1280-1290 m deep drilling core and Atagoyama rock were measured by X-ray fluorescence and X-ray diffraction measurements, respectively. The component concentrations of hot spring water tended to be higher for Cl^- and Ca^{2+} and lower for Na^+, K^+ and Mg^{2+} than current seawater. The contents of core and rock main components were in the order of Si >> F > Al > Ca > K. These contained quartz, Mg-calcite, albite and chlorite. These results indicate that the presence of the calcite that elutes Ca^{2+} and the ion-exchangeable silicate minerals that take up Na^+, K^+ and Mg^{2+} in seawater and release Cl^- and Ca^{2+} to hot spring water relate to the origin of the source.

The Mu Us desert is located in the semi-arid area of Northwestern China. The major environmental problem is desertification. To effectively control and prevent desertification, a policy called “Returning Farmland to Forest and Grassland” has been implemented since 2000 which resulted in large afforested areas. Groundwater is an important source of water for the local people and ecosystems. The influence of these trees on the hydrological cycle and groundwater resources has not been studied in detail and accurate experimental data are needed to quantify how trees affect effective infiltration, groundwater recharge and water table dynamics. We designed four lysimeters: two with different depths to groundwater and bare soil as well as two additional lysimeters again with two different depths to groundwater and each with a planted tree (Salix Psammophila). In all the lysimeters, we monitored profiles of soil water content and the groundwater dynamics. The data suggest that the presense of tree increases the minimal amount of rainfall to trigger infiltration. Moreover, no groundwater recharge was observed for the vegetated lysimeters. The trees triggered a significant drop of the water table. These data have important implications for future water resources management.

Development of a Multi-function Water Depth Sensor in the Irrigated Paddy Fields for Water Resource Management and Precision Agriculture

*Chun-Yen KUO[1]

1. National United University

Water resource management is one of the most critical issues in the worldwide area. Taiwan area is lack of water resources due to that the main rainfall is concentrated in summer seasons and the water storages in rivers and dams are also difficult. In Taiwan, the water consumptions for agricultural purposes are around 71% of the total water use, and the water use for irrigated paddy fields is close 72% of the agricultural water use. Therefore, the water use for irrigated paddy fields is around 50% of the total water use in Taiwan. Similar water consumptions situations were also found in Japan and some southeast Asian countries. A systematic, real-time and optimal management for the water use in irrigated paddy fields is the most critical issue in the water resource management in Taiwan. The Internet of Things (IoT) connects the physical devices, software, appliances and sensors, which is able to inter-operate within the existing internal infrastructure, which provides the opportunities for more effective, precise and economic benefit of water resource management. Moreover, the Precision Agriculture is a farming management concept based on observing, measuring and responding to inter and intra-field variability in crops to optimize the yields while preserving resources, which was considered as one of the key components of the third wave of modern agricultural revolutions. Indeed, the Precision Agriculture is one of the implementations of the IoT. However, one the most critical points for these applications of IoT is to develop a useable and multi-function sensor.

This research focuses on the development of a multi-function water depth sensor for the irrigated paddy fields based on the concept of continuous conductivity measurements in different depths of the water in the irrigated paddy fields. According to the experimental results, the conductivity profiles can precisely indicate the depths of water level in the irrigated paddy fields. Moreover, a wireless sensor network system (WNS) will also be constructed to detect and collect the conductivity data from different sensors located in different fields and water channels. This information can be used to optimize the water use for the irrigated paddy fields by cooperating a water gate to control the water flow into the field, resulting the saving of water resource for paddy fields. Then a systematic and real-time using the concepts of IoT for the optimal management of the water use of irrigated paddy fields can be constructed.

Additionally, the fertilizer substances (for example the nitrogen, phosphate, potash) drawn in the paddy fields will alter the measured conductivities in the fields. This proposed multi-function water depth sensor based on the continuous conductivity measurements can indicate the approximate concentrations of the fertilizer substances in the fields. A series of tests were also conducted using the proposed water depth sensor to measure the conductivities of the samples which were added different concentrations of chemical fertilizers into the collected water from the real paddy field. A linear relationship was found between the measured conductivities and the concentrations fertilizer (presented by ammonia nitrogen) added in the samples. This finding indicates that this proposed depth sensor can also measure the approximate concentrations of the fertilizer substances in the fields, and provides the multiple information in the paddy field. On the other hand, this proposed sensor can be used as an early warning when the irrigation water was polluted by the discharged wastewater, especially form the industrial

wastewater.

Both of the peasants and the governor of the water use of irrigation system can connect to the on-line sensor system. The governor can use this information from the system to optimal the water use for paddy fields even for the other agricultural purposes, and also provide a basis for the development of the Precision Agriculture. The peasants can also more effectively manger the water depth in their paddy fields by using a cell phone to connect to this on-line sensor system.

Dynamic calibration of tipping-bucket rain gauges and flow meters for precise measurements of rainfall partitioning

*Shin'ichi Iida[1], Takanori Shimizu[1], Yoshinori Shinohara[2], Tomo'omi Kumagai[3], Darryl E. Carlyle-Moses[4], Delphis F. Levia[5]

1. Forestry and Forest Products Research Institute, 2. University of Miyazaki, 3. University of Tokyo, 4. Thompson Rivers University, 5. University of Delaware

Tipping-bucket rain gauges (TBRGs) and flow meters (TBFMs) are widely applied to measure gross rainfall (*GR*), throughfall (*TF*), stemflow (*SF*) and other water fluxes, including outflow from trenches (e.g., Freer et al., 2002; Liang et al., 2011; Iida et al., 2017). However, it is well known that TBRGs and TBFMs commonly underestimate the inflow of water (e.g., Edwards et al., 1974). Basically, these instruments measure the inflow of water by counting tips of buckets. Thus, if water flow continues during bucket tipping, a certain amount of water is not captured by the bucket, and finally is underestimated (e.g., Iida et al., 2020). To evaluate the inflow of water precisely, calibration of TBRGs and TBFMs is required. We recently tested eleven types of TBRG and TBFM based on the dynamic calibration procedures (Shiraki and Yamato, 2004; Iida et al., 2012), and obtained the calibration curves (Iida et al., 2012; 2018; 2020; Shimizu et al., 2018). In this presentation, we show the simple and handmade equipment necessary to generate constant inflow of water, and the difference in calibration results among various TBRGs and TBFMs. Finally, the effects of applying dynamic calibrations on measurements of rainfall partitioning into interception loss ($I = GR - TF - SF$) are investigated.

We calibrated three TBRGs (0.2 mm tip, type RG-3M [Onset Computer Corp.] and type Rain Collector II [Davis Instruments]; 0.5 mm tip, type OW-34-BP [Ota keiki seisakusho Co., Ltd.]), and eight TBFMs (50 mL tip, type UIZ-TB-50; 100mL tip, type UIZ-TB-100; 200 mL tip, type UIZ-TB-200; 500 mL tip, type UIZ-TB-500 [Uizin Co., Ltd, Tokyo.], 200 mL tip, type TXQ-200; 400mL tip, type TXQ-400 [Ikeda keiki seisakusho Co., Ltd.], and 500 mL tip [Yokogawa Electric Corp.]) (Iida et al., 2012; 2018; 2020; Shimizu et al., 2018). At first, the static amount of one tip (c) was determined. We dripped water into the bucket with an injector until it tips. Then, c was calculated as the difference in mass of injector between initial and final conditions. Constant inflows of water (q) with different intensities were generated by the handmade equipment and applied to various TBRGs and TBFMs. We measured the time interval between tips (t), and obtained the actual amount of one tip (v) as the product of q and t. We derived the scaled amount of tip ($V = v/c$) and inflow ($Q = q/c$) as dividing them by the static amount of tip (c) (e.g., Shiraki and Yamato, 2004).

The relationships between Q and V were fitted reasonably by quadratic equations for all TBRGs and TBFGs (Iida et al., 2012; 2018; 2020; Shimizu et al., 2018). Rain Collector II and UIZ-TB-100 showed the largest underestimation among TBRGs and TBFMs, respectively, and 10% underestimation was detected when $Q > 0.14$ (s^{-1}) and $Q > 0.12$ (s^{-1}), respectively. The calibration curves for 7 of 8 TBFM lay within ±2% of that of TXQ-400 when $Q < 0.2$ (s^{-1}) (e.g., Shimizu et al., 2018; Iida et al., 2020). Thus, there are some possibilities that most types of TBFMs have similar calibration curves with TXQ-400 (Shimizu et al., 2018). By applying the calibrations, effects on the interception loss (I) ranged from -20% to +4% (Iida et al.,

©2020. Japan Geoscience Union. All Right Reserved.

2018). Therefore, to evaluate *I* precisely, the application of dynamic calibrations on *GR*, *TF* and *SF* measured by TBRG and TBFM are highly recommended.

Department of International Environmental and Agricultural Science, Tokyo University of Agriculture and Technology, Tokyo , Japan

Understory vegetation has the important effect that cannot be ignored on Evapotranspiration. In this study, Structure from Motion (SfM) was used to reconstruct understory vegetation structure by a manual low-flying drone under the canopy with radial paths in a line thinning plantation and a spot thinning plantation made by Japanese cedar and cypress. By generating Orthomosaic image and dense point cloud data, we then extracted Excess Green Index (ExG) and Canopy Height Model (CHM), combining with understory biomass data from field harvesting to establish a quantitative relationship between the CHM and biomass, which was then used to map biomass and vegetation coverage in the study area. The results indicated that (1) a flight height of 7-10 meters is more conducive to understory vegetation reconstruction, with a photo quality greater than 0.8 and a point cloud density of more than 20 points/cm ^{2} . (2) a regression cubic model based on the CHM has acceptable accuracy and biomass estimate capability ($P<0.01$), with a coefficient of determination of 0.75. (3) compared with the spot thinning, the understory biomass under the line thinning scenario was higher(average biomass 3.03kg/m^2). (4) vegetation coverage based on the ExG index of visible light analysis was affected by ambient light(strong sunlight on a sunny day), and it cannot reflect the seasonal changes of understory vegetation biomass. These results disclosed the potential of the dense point cloud from drone SfM for estimating understory biomass. With this method, we will measure more than 5000m^2 of headwater catchment in the future.

Seasonal changes in the canopy water balance of Japanese plantation forest

*Linh Thuy Pham[1], Yuichi Onda[1], Xinchao Sun[2], Sean Andrew Hudson[1], Janice Elaine Hudson[1], Yupan Zhang[1], Chiu Wei Chen[3]

1. University of Tsukuba, 2. Tianjin University, 3. Tokyo University of Agriculture and Technology

Stemflow, throughfall, and canopy interception are some of the most critical parameters for hydrologic behavior and watershed management. When rainfall occurs within a forest ecosystem, small amounts of rainfall will be trapped by the tree canopy (Canopy interception –Ic) until it becomes saturated and canopy storage is exceeded, throughfall (TF) –precipitation which reaches the forest floor by passing through or dripping from the canopy, will occur. When the trunk storage capacity is exceeded, water will flow down the tree trunk and reach the ground as stemflow (SF). Among the factors that can affect canopy water balance, seasonal change is one that requires further investigation (because of the differences in meteorological parameters). Previous research on canopy water balance and interception loss has mostly focused on the growing season - when plants have a greater demand for water (Ahmadi et al, 2009). However, it is also critically important to know the amount of water that will be in the water budget of the catchment delivered via stemflow and throughfall because it helps to better regulate streamflow between seasons, especially in the dry season. (Hewlett, 1982). In Japan, 60% of coverage is the forest with 44% being plantation forests. However, the plantation forests are not well managed with a very high density of trees, leading to undeveloped understory vegetation cover which causes low soil infiltration, low groundwater levels, high soil runoff, and soil erosion. To combat these negative processes silvicultural activities such as thinning, especially strip thinning - in which plantations are thinned parallel to the direction of the slope - have been widely adopted in Japan. The research site was in mountain Karasawa - covered by dense cypress plantation forest, located in the northeast of Sano city, Tochigi prefecture of Japan, where strip thinning was implemented on November of 2011. During thinning, 50% of trees were cut, stand density was lowered from 2198 to 1099 trees/ha, and the basal area was reduced from 50.4 to 26.2 m^2/ha. Canopy water balance parameters were recorded from November of 2010 (1 year before thinning) until November of 2012 (1 year after thinning). Throughfall was measured by 20 tipping rain gauges distributed in 2x2 m grid under the canopy, stemflow was collected with a polyvinyl tube around the trunk, connected with a draining hole to a bucket equipped with an Odyssey water level probe. Meteorological factors such as rainfall, temperature, humidity, wind speed were recorded by the weather station. After analysis, the data showed some changes in the canopy water balance before and after thinning, and also some differences between seasons. Within the partitioning of Pg, TF has the largest proportion (64.2%), followed by Ic (25.2%) and SF (10.6%). After thinning, the TF rate increased to 12%, the SF rate decreased to 4%, and the Ic rate decreased to 8%. With the decrease in Ic, there will be more water in the soil matrix during the dry season. TF, SF, and Ic amounts tend to be higher in summer and autumn but lower in winter and spring. TF and SF also tended to be higher during summer and autumn, but Ic rate is higher during winter and spring.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-HW Hydrology & Water Environment

[A-HW31] Surface and subsurface hydrologic models: From uncertainty analysis to water management

convener:Tomochika Tokunaga(Department of Environment Systems, University of Tokyo), Rene Therrien(Laval University), Philip Brunner(Center for Hydrogeology and Geothermics, University of Neuchatel), Jiaqi Liu(The University of Tokyo)

Surface and subsurface hydrologic models (SSHM) simulate the relevant components of the water cycle that affect surface water and groundwater. Such models thus constitute important tools to support water resources management. For example, model predictions are used to manage increased water use, water pollution, droughts and floods.

Nevertheless, significant challenges are inherent to the development and application of SSHMs. One critical issue is the limited amount of data to inform model parameters. Moreover, automated calibration and a comprehensive uncertainty analysis of large-scale SSHMs are rarely carried out because of their high computational cost. In addition, there is a large uncertainty associated with the conceptualization of the relevant processes and the parametrization of subsurface heterogeneity, which can undermine the reliability of the predictions made.

For this session we seek presentations that focus on numerical simulations tools for water resources management and present solutions for pressing scientific challenges such as model calibration, uncertainty analysis or the conceptualization of the surface and subsurface and the relevant processes. Presentations that showcase examples where numerical modelling tools are employed for water resource management at emergency situations (e.g. earthquakes, tsunamis, droughts or stormfloods) are also encouraged.

The management of abandoned forest plantations in Japan has received significant attention in the past decade, specifically relating to increasing discharge from headwaters catchments through the reduction of evapotranspiration loss (Komatsu et al 2019). While the surface water balance and its associated processes are understood in these catchments, the responses to thinning, especially the response of groundwater recharge has not received enough attention. Additionally, the difficulty and cost in acquiring field measurements of evapotranspiration and runoff makes large spatial-scale forecasts of groundwater availability and recharge difficult. Further, where individual catchments are monitored, the spatial scale is often too small for water resource managers to effectively use in groundwater storage and recharge estimates. Here, we present a model that describes the effects of forest thinning on groundwater recharge rates calculated from stand density and accepted empirically derived models of evapotranspiration components and climate data. Data used in the model include forest inventory data and Japan meteorological agency climate station data. Model inputs are tree height and age, precipitation, and daily received solar radiation. The model output is mapped as a 250m^2 grid cell to make a GIS database of potential groundwater recharge rates. A simple model using widely available data and able to resolve a large spatial scale models such as this is of great importance to water resource managers especially in areas dependent on surface water who are looking to ground water as stream discharges vary due to climate change. The development of this model represents an interdisciplinary approach to problem solving as forest hydrologists and geomorphologist can share discipline specific knowledge of forest hydrologic processes to engineers, water resource managers and other stakeholders allowing them to make sustainable management decisions of plantation lands and water resources.

Developing a new data assimilation technique based on polynomial chaos expansion theory for hydrologic prediction

*Jongho Kim[1], Vinh Ngoc Tran[1]

1. University of Ulsan

Data assimilation (DA) has become popular in the hydrologic prediction, focusing on the improvement of accuracy and efficiency. In this study, we proposed a new surrogate filter using polynomial chaos expansion (PCE), which aims not only to ensure accuracy in streamflow forecasting by updating the model states and parameters but also to significantly improve the computational efficiency. We presented here eight different approaches which can be classified into two main categories: either time-invariant filters (surrogate filters needed to be built once and can be applied to multiple forecast periods) or time-variant filters (surrogate filters needed to be rebuilt at each forecasting time). Besides, an optimal framework that is necessary during the construction of surrogate filters was proposed to optimize the hyper-parameters of PCE with appropriate criteria, thereby increasing the efficiency in building a surrogate filter and avoiding the over-fitting phenomenon of PCE. These approaches proposed were verified with both single and dual ensemble Kalman filters (EnKFs). Applicable results of surrogate filters with both synthetic and real data experiments illustrate that (1) most of these surrogate filters can account for different sources of uncertainty like original EnKF; (2) All surrogate filters provide relatively good forecasting results with small lead times. However, time-variant filters are capable of providing predictive results as well as providing more appropriate posterior parameters than time-invariant filters; therefore, with long lead times, the forecast of time-invariant filters is less accurate than other filters; (3) surrogate filters have significantly increased performance compared to original filters at a faster rate of up to 500 times, significant in forecasting, mainly when it is applied to large domain or complex models. Generally, results from both real and synthetic studies suggest that the proposed filter guarantees the effectiveness and usefulness with a significant improvement in the computational performance for hydrologic prediction.

Junction angles of river channels in uplifted basins and the effect of contributing area: Model experiments and comparison with natural cases

*Ryosei Hirosaki[1]

1. Graduate school of science and technology, Kanazawa University

The previous study pointed out that the most likely junction angle of river channels are roughly affected by the climate of the basin and/or the closeness between surface processes and a groundwater aquifer (Devauchelle et al., 2012; Seybold et al., 2013; Kirchner et al., 2017). However, the previous statistics did not take accounts into the scale of converging rivers. In this study, we discuss the relationship between the difference in contributing areas of merging channels and the junction angles, based on physical model experiments simulating uplifted river basins that drain artificial rainwater, along with the comparison to natural cases. The experimental results showed that the junction angle tended to be large as time passed during which the uplift continued, although further investigation is needed because the number of junctions in the experimental basins were small. Despite of such tendency, the angle of each junction seemed to fluctuate with time randomly, so we combine the data of different time as different basins to enlarge the population for statistics. After such treatment, there was a tendency that the larger the difference in contributing area was, the more restrictive around 90˚the junction angle was. Besides, analysis of two natural river basins, Yakushima and Mt. Aso, showed a similar relationship between the river scale and the range of junction angle. These are thought to be caused by the effect of the valley slope formed by the larger river.

Keywords: Confluence angle, uplift, Contributing area

Quantifying uncertainty in soil hydraulic parameters for the dual porosity model using null-space Monte Carlo method - implications for uncertainty in potential groundwater recharge estimation

*Sakambari Padhi[1], R Rangarajan[2], Tomochika Tokunaga[1], Philip Brunner[3]

1. The University of Tokyo, Japan, 2. CSIR-NGRI, India, 3. University of Neuchatel, Switzerland

Estimating groundwater recharge is important to sustainably manage water resources and assess their vulnerability to pollution. Numerical water flow and tracer transport models of the vadose zone have been widely used to estimate potential groundwater recharge under different soil surface and climate conditions. Nevertheless, these parameter-based models require a large number of model parameters and input data. Uncertainty in these model parameters thus can result a large uncertainty in groundwater recharge estimation.

Inverse modeling is conventionally used to estimate model parameters, which could often lead to non-unique solutions. Monte-Carlo (MC) methods generate many different parameter sets which can be used by the model to match the observed data with some acceptable level of mismatch instead of a single ‘‘best’’ estimated parameter set.

This study was carried out in the over-exploited Indo-Gangetic alluvial plains of Punjab, India under grass cover to understand natural recharge, where its high water demand is causing a significant drawdown of the groundwater in the alluvium aquifer.

Time series soil moisture content (SMC) data and tritium tracer profile data have been used to estimate soil hydraulic parameters and solute transport parameters in order to predict potential groundwater recharge. Single and dual-porosity models of water flow and solute transport, implemented in HYDRUS 1D computer program, were used to calculate potential recharge from SMC and tracer profile data, both sequentially and simultaneously. Potential recharge was predicted for 1000 randomly generated parameter sets using a null-space Monte-Carlo method (NSMC) proposed by Tonkin and Doherty (2009) and implemented in the parameter estimation software PEST. NSMC is calibration constrained and significantly reduces computational cost as compared to other MC methods.

Results indicate that when soil hydraulic parameters were estimated from SMC alone, the parameter set could not predict tracer transport behavior, though a better fit to SMC was obtained, calling for a cautioned approach to estimate recharge from SMC alone.

Histograms for certain soil hydraulic parameters obtained from non-linear uncertainty analysis display bi-modal characteristics for the dual porosity model implying that the data are from different sets of population representing different retention and hydraulic conductivity functions. Majority of predicted recharge (50%) on the other hand showed a narrow range of 0.002 cm to 0.2 cm in contrast to previously reported recharge prediction of 4.1cm to 16.1 cm as calculated from tritium mass balance approach for Punjab, India (Datta and Goel, 1977). This shows that recharge calculated from vadose zone tritium profile assuming piston flow is significantly overestimated. Hence, quantifying uncertainty in predicted recharge could help in proper management of groundwater resources.

Impacts of earthquake-induced surface elevation changes on flooding: a case example from Mobara area, Japan

*Mao Ouyang[1], Ito Yuka[1], Tomochika Tokunaga[1]

1. The University of Tokyo

Earthquake-induced surface elevation changes may affect the extent of flood inundation. We have studied the possible effect of earthquake-induced elevation changes in the Mobara area, Japan, as a case example. Based on our dynamic flood modelling results, around 10 % additional inundation areas were calculated to be exacerbated by the ground elevation changes in the flood event of the year 2004. However, variety of uncertain variables were included in the modelling approach. Here, we present some important issues associated with the uncertainty in flood inundation impacts of earthquake-induced surface elevation changes. We selected topographic representation, saturated hydraulic conductivity, and the inundation projection technique for this discussion as uncertain variables/methodology. Results revealed that the choice of the resolution of DEM and the threshold water depth to discuss the extent of floods greatly affected the appearance of the inundation areas. In this presentation, we summarize the influence of these uncertainties on flood modelling and discuss the effective ways in balancing the efficiency and reliability of the approach and results.

Modeling of tsunami-induced seawater intrusion into unconfined coastal aquifers: uncertainties analysis and water management

*Jiaqi Liu[1], Tomochika Tokunaga[1]

1. The University of Tokyo

Tsunami-induced seawater inundation causes vertical seawater intrusion into coastal aquifers. Assessing future risks of seawater intrusion in tsunami-prone zones can provide essential information supporting disaster preparedness and water management. We investigated seawater intrusion and aquifer recovery processes under the future Nankai earthquake and tsunami scenarios at Niijima Island, Japan. Both 2D and 3D numerical groundwater models were developed to solve variable-density flow and mass transport in unsaturated-saturated porous media using the code, FEFLOW. Our analysis suggests that the tsunami inundation height, the rainfall recharge rate, hydraulic conductivity, and bedrock structures are the primary sources of uncertainties in the simulation results. The simulations indicated that the maximum amount of seawater intrusion during the tsunami was controlled by the total unsaturated void space of the soil beneath the inundation area. After the tsunami, directions of seawater movement and flushing time depended on the pre-tsunami groundwater flow conditions and bedrock structures. Some groundwater was found to be survived from seawater intrusion, and showed the potential to provide water supply in an equivalent amount of the pre-tsunami level without worsening the recovery process. The simulated attempt to remove the intruded seawater from a polluted well could accelerate aquifer recovery but might not be practical due to the cost of maintaining intensive pumping over years.

Groundwater level fluctuations and land use changes in the basaltic aquifer of Narmada basin (Central India)

*Sakshi Ramesh Shiradhonkar[1], Tomochika Tokunaga[1]

1. Department of Environment Systems, University of Tokyo

In an extremely populated country like India, with agriculture as its economic backbone and nearly 90% of water has been utilized for agriculture and related activities, a strategic water management approach is necessary to avoid unsustainable exploitation of fresh water resources. Understanding the drivers behind the changing trends and their magnitude with respect to the water resources can provide information to support managing and developing water resources in a better way. During 2003-2016, an apparent increase of TWS (terrestrial water storage) was evident from GRACE (Gravity Recovery and Climate Experiment) satellite data in the central west of India where the Narmada river basin is situated whereas TWS trends were declining in north and south of India. In this study, the part of the Narmada river basin was chosen as the study site to discuss the possible reasons for the observed increase of TWS in the area. In this area, between 2003 and 2016, two major dams (Indira Sagar dam (2005) and Omkareshwar dam (2008)) were constructed, and the canal systems were developed in the area. Moreover, several water bodies were developed in the non-canal command areas (non-CCA). The objectives of this study were set to (1) understand the possible effects of the canal system on groundwater level behaviour in the Indira Sagar canal command area (CCA) and in the non-CCA within the basaltic aquifer domain, and (2) analyse the land use change, especially the surface water bodies. The groundwater levels were analysed based on two timelines, i.e., before and after canal construction in dry pre-monsoon and rainy monsoon seasons. The canal construction began by around 2007, from Indira Sagar dam towards the west until 2012-2013. The area to the south of the Narmada river is divided as CCA and Non-CCA based on the canal irrigation scheme. After the canal construction, on an average, about 2 m rise was observed in the well water levels during pre-monsoon while 1.1 m in monsoon seasons. Mann-Kendall’ s statistic test was performed on the groundwater well levels situated in non-CCA during dry pre-monsoon, rainy monsoon seasons and annually. Out of the 20 studied wells, only the ones situated near local water bodies showed significant/insignificant increasing trends while all the others which were spatially located far from any surface water body indicated declining trends. The changes in land use land cover (LULC) pattern were studied using Landsat 5, Landsat 7 ETM+, and Landsat 8 OLI/TIRS imageries in the region. The area used for surface water storage increased from about 1% to about 12% in between 2003 and 2013. The water from rainfall and Narmada river are perhaps the major sources for developing these water bodies, since both the major dams are built across the Narmada river. Based on the statistics and the interpretations, groundwater storage has been increased after the canal operation than before, likewise the area of surface water body expanded during 2003-2016, this may at least partly explain the reason why GRACE demonstrates increasing TWS trends in central west region of India.

Estimation of stemflow using forest inventory data and funneling ratio for Japanese cedar and Japanese cypress plantations

*Seonghun Jeong[1], Kyoichi Otsuki[2], Yoshinori Shinohara[3], Akio Inoue[4], Ryuji Ichihashi[5]

1. Graduate School of Bioresources and Bioenvironmental Sciences, Kyushu University, 2. Kasuya Research Forest, Kyushu University, 3. Faculty of Agriculture, University of Miyazaki, 4. Faculty of Agriculture, Kindai University, 5. Shiiba Research Forest, Kyushu University

Even though the previous studies of stemflow (*SF*) had considered the portion of *SF* of gross rainfall (*GR*) minimal, the latest researches have demonstrated that the forest stand structure for specific species largely determines the stemflow ratio (*SF*/*GR*). This study develops two estimation models of *SF*/*GR* with commonly-available forest inventory data. A set of 25 *SF*/*GR*s and the forest inventory data (stand density (*SD*), total basal area (*BA*), mean diameter at breast height (*DBH*), and mean tree height) were collected from the previous studies of Japanese coniferous plantations (Japanese cedar and Japanese cypress). To further investigate the relation between *SF*/*GR* and forest stand structures, extra stand-structural variables (mean basal area, mean stem surface area, and total stem surface area) were derived from the inventory data, and the stand-scale funneling ratio (FR_{stand}) assessing the efficiency of funneling rainwater was examined. Of all the standard variables, *SD* solely determined the *SF*/*GR*, providing the best-fitting positive single linear regression equation as a density-based *SF*/*GR* model with a root mean square error (RMSE) of 2.4%. This model has a weak point for sustainable forest water management because the effect of tree growth over time on *SF*/*GR* cannot be reflected, but is a useful tool with the most commonly available forest inventory data for practical forest water management. On the basis of the strong correlation of the FR_{stand} with *DBH*, a size-based *SF*/*GR* model was developed with an RMSE of 2.0%. This model is adequate for sustainable forest water management because the effects of not only the *SD* but also tree growth on *SF*/*GR* can be reflected as the *SF*/*GR* approximately increases as a root of *DBH*. These models exploited from the common forest inventory data have potential implications in evaluating and controlling *SF* by forest water management and in developing similar models in other species and regions.

[A-HW32] Material transportation and cycling in aquatic ecosystems; from headwaters to coastal areas

convener:Syuhei Ban(The University of Shiga Prefecture), Adina Paytan(University of California Santa Cruz), Takahiro Hosono(Faculty of Advanced Science and Technology, Kumamoto University), Morihiro Maeda(Okayama University)

This session aims to synthetize watershed sciences in order to understand dynamic processes in transportation and cycling of materials and nutrients in aquatic environments from headwaters to coastal areas. The session will integrate various inter-disciplinary researches including limnology, ground water hydrology, coastal oceanography, meteorology, pedology, sedimentology, forestry, agriculture, fishery, ecology, social science and so on. This session calls for ideas on new methods for understanding the watershed sciences, such as tracer and molecular techniques, hydrological modeling, paleontological approaches, and chemical analyses, in order to elucidate physical, chemical and biological mechanisms for shedding light on natural phenomena and their spatio-temporal variations in complex and dynamic aquatic systems under human and climate impacts. Both laboratory and field studies, social-scientific evaluation of ecosystem services and social-ecological systems will be also welcomed. Through this session, we would like to facilitate interdisciplinary collaboration among participants to create new knowledge on watershed sciences.

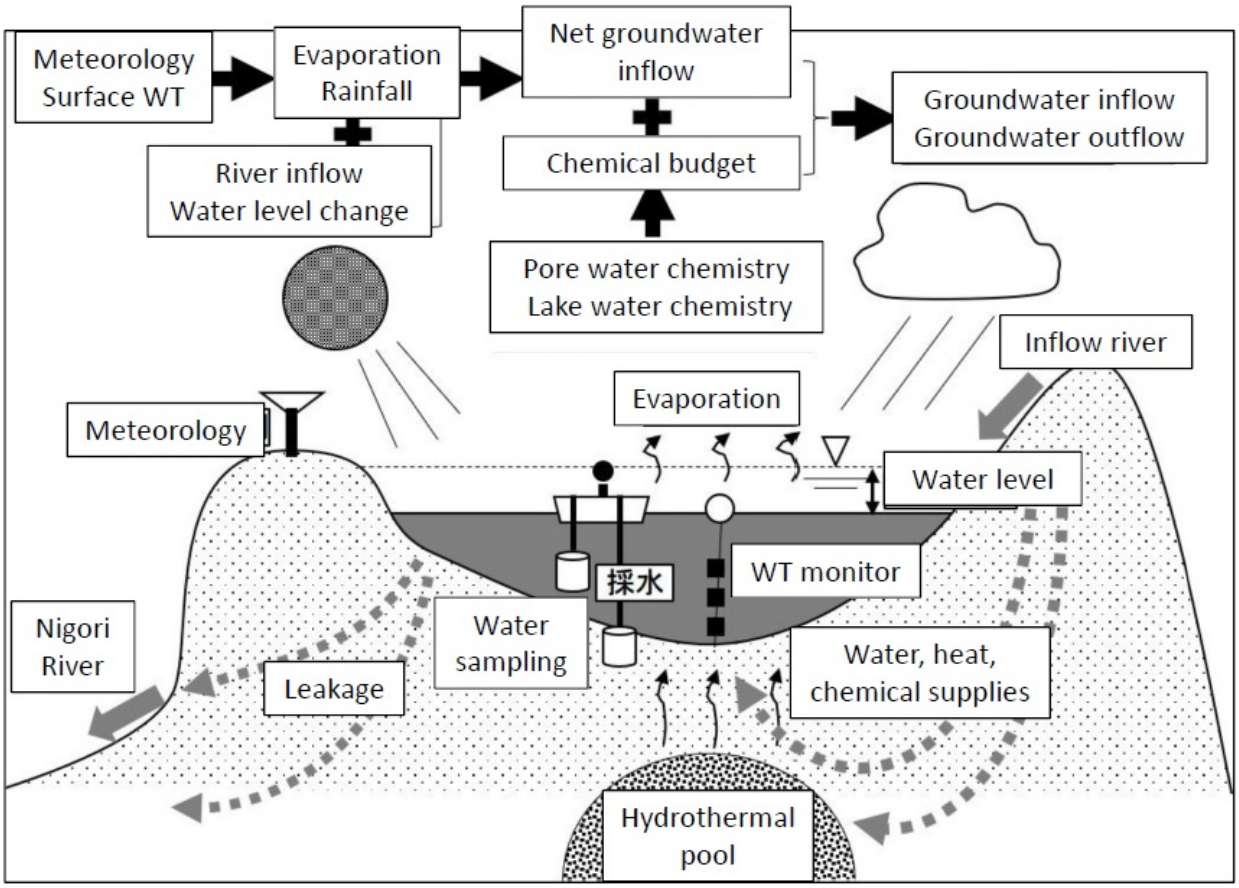
Estimates of hydrological, thermal and chemical budgets of Okama Crater Lake, Zao Volcano, Japan: A preliminary study



*Kazuhisa A. Chikita[1], Akio Goto[2], Jun Okada[3], Satoshi Miura[4], Mare Yamamoto[4]

1. Arctic Research Center, Hokkaido University, 2. Center for Northeast Asian Studies, Tohoku University, 3. Volcanology Research Department, Meteorological Research Institute, , 4. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Faculty of Science, Tohoku University

In order to clarify a groundwater flow system below Zao Volcano, hydrologcal, thermal and chemical budgets of a crater lake, Okama, are estimated (see the schematic diagram). Since June 2019, profilings on a boat and meteorological observations at lake shore have been carried out. Also, using a mooring system, seven temperature loggers were vertically fixed at the deepest point to obtain thermal storage changes of Okama. This is a preliminary report about approaches for the estimates and some observational results in June - October 2019. Okama is at 1550 m asl with ca. 26 m at maximum depth and pH=3.2-3.7. The Okama water leakes into the Nigori River as groundwater, which could affect the ecosystem in the downstream region. In October 2019, Typhoon No. 19 attacked the lake with a rainfall of 396 mm per 15 hr. The heavy rainfall produced high sediment load into the lake, and formed the sedimentary delta at lake shore. Thereby, the infilling of the lake was probably proceeded.

How the precipitation to the catchment effect on the lake water level using depth meter moored in north Lake Biwa

*Maho Iwaki[1], Kazuhide Hayakawa[2], Naoshige Goto[3]

1. Lake Biwa Museum, 2. Lake Biwa Environmental Research Institute, 3. The University of Shiga Prefecture

Lake water levels are balanced by short-term events, such as direct rainfall, seiches, river inflow due to precipitation in the catchment land area and subsurface flow, evaporation (both at the lake surface and in its catchment area), and groundwater inflow and outflow. Each factor controlling the water level of a lake has a unique temporal and spatial scale. To understand complex lake level changes, it is better to have a spectral analysis that can separate the waves into several periods, and to determine on which time scale these processes are dominant. The shape of the response function reflects the lake system itself, such information will further be helpful to lake resource managers. If we could know the effect of rapid response of the water level, it makes possible to determine the precipitation retention time at the surface (above the impermeable layer) of a catchment area and how long it takes precipitation to reach the lake. By calculating the impulse response function using the data obtained by the depth meter installed in the mooring system in Lake Biwa from 2017 to 2018, we discussed how long it takes rainfall to reach the lake through the river. We observed water depth (10-min intervals) in the northern basin of Lake Biwa in August 2017 to October 2018, we calculate the response functions the rainfall to lake level during a severe heavy rainfall event. We could separate the delay time, direct rainfall into the lake and rapid river inflow. A response of 6-8 hours has been confirmed in analysis of water level by FFT (Fast Fourier Transform) (Iwaki et al. 2014), since the first mode of seiche is about 4 hours, then, the cause is hypothesized to be river inflow, however it was unclear why the response appeared clearly. Then we try to identify the delay time of rapid response (< 12 h) after rainfall. We could identify that the delay time of 6-8 hours may be due to the inflow by approximately 20-25 km rivers found in the North Lake Biwa. The proposed method can be used to evaluate the impacts of rivers on the lake, and the results can help to clarify the lake metabolism and lake managements.

Observation for the spatial variation of lacustrine groundwater discharge (LGD) in the northern basin of Lake Biwa by multi-layer measurement of radon (^{222}Rn)

*Mitsuyo Saito[1], Shin-ichi Onodera[2], Yusuke Tomozawa[2], Kunyang Wang[2], Syuhei Ban[3], Noboru Okuda[4]

1. Graduate School of Environmental and Life Science, Okayama University, 2. Graduate School of Integrated Arts and Sciences, Hiroshima University, 3. School of Environmental Sciences, The University of Shiga Prefecture, 4. Research Institute for Humanity and Nature

Primary productivity in freshwater lakes and reservoirs are usually controlled by phosphorus (P). Lacustrine groundwater discharge (LGD), direct discharge of subsurface water to lake, is regarded as a potential nutrient paths, including phosphorus from a catchment to lake water environment. Some researchers have pointed out the presence of LGD into Lake Biwa, however, its spatial variation including deep groundwater discharge from offshore lake bed has not been well examined. In the present research, we aimed to observe the spatial variation in LGD to the northern basin of Lake Biwa by multi-layer measurement of radon (^{222}Rn).

The field campaigns were conducted several times from 2017 to 2019. ^{222}Rn is a radioactive element of uranium (^{238}U) series with 3.8 day of half-life. ^{222}Rn is a powerful tracer of groundwater discharge because it generally enriched in groundwater than surface water. To examine the spatial variation in LGD, ^{222}Rn concentration in lake water was measured in eastern and western transects with different depths (5m, 10m, 20m, and 60m). At each station, ^{222}Rn was measured in different depths (surface, intermediate, and bottom) to observe both of shallow and deep groundwater discharge.

^{222}Rn concentration was totally higher in the bottom than surface layer at each station. It suggests LGD from lake bed. The highest ^{222}Rn was observed in the bottom layer at 20m-deep station on the eastern transect in some periods. This result suggests LGD from offshore lake bed via deep groundwater discharge.

Effects of disturbance events on primary production in the northern basin of Lake Biwa

*Naoshige Goto[1], Maho Iwaki[2], Shuhei Ban[1], Kazuhide Hayakawa[3]

1. The University of Shiga Prefecture, 2. Lake Biwa Museum, 3. Lake Biwa Environmental Research Institute

The effects of environmental factors on primary production by phytoplankton were elucidated at a site in the center of the northern basin of Lake Biwa, Japan. Chlorophyll *a* concentration, which is used as an index of phytoplankton biomass, and photosynthetic photon flux density (PPFD) were measured continuously at depths of 5, 10 and 15 m from August 2017 to February 2018. Monthly measurements of photosynthetic activity were performed using a pulse amplitude-modulated chlorophyll fluorometer, and photosynthesis-PPFD curves were produced throughout the observation period; these results were then used to calculate daily gross primary production per unit area. Primary production ranged from 0 to 3.92 g C m^{-2} d^{-1} (1.11±0.83, mean±SD) during the observation period, tending to be higher in spring (April-June) and summer (July-September), and lower in fall (October-December) and winter (January-March). In addition, primary production peaked in the late spring of 2018, with high production levels in this period attributed mainly to two large species in the Chlorophyceae (*Staurastrum dorsidentiferum* and *Micrasterias hardyi*). The meteorological events, such as typhoons and/or heavy rain, greatly affected the light and nutrient conditions in the water column and had a marked influence on primary production. In general, meteorological events increased the supply of nutrients and other essential material inputs from the terrestrial environment into the lake. However, such extreme weather events were also associated with increases in the supply of large amounts of sediment in runoff, greatly increasing the turbidity of the water column and decreasing primary production for a period of several weeks. These marked changes in environmental conditions were associated with the dominance of large-celled phytoplankton in blooms. Temporal variation in primary production was highly dependent on PPFD (R^2 = 0.46), although the contribution of biomass (chlorophyll *a*) to primary production also increased during the algal blooms (R^2 = 0.36).

Estimation of lake water circulation mechanism in Lake Tazawa based on Physico-chemical characteristics

*Arata Katamura[1], Takeshi Hayashi[2], Daizo Ishiyama[1], Yasumasa Ogawa[1]

1. Graduate School of International Resource Sciences, Akita University, 2. Faculty of Education and Human Studies, Akita University

Lake Tazawa, located in Akita Prefecture, is the deepest lake in Japan. The elevation of the lake surface is around 249 m and the maximum depth of the lake is 423.4 m. Acidic water of Tama-River has been introduced to the lake since 1940 for electricity development. As the result, the rapid acidification of the whole lake water had progressed and most kinds of fish had been killed by the acidification. After that, a neutralization treatment of acidic river water began in 1991 and the neutralized river water has been introduced to the lake. According to Akita Prefectural Government (2015), the water qualities of the shallower and deeper layers of the lake were different from 1991 to the beginning of 2000s, and they became almost uniform since around 2003. This fact suggests the possibility that the circulation mechanism of lake water has been changed and the turnover has occurred since around 2003 (Boehrer et al., 2008; Ishiyama et al., 2013). However, the circulation mechanism of the large amount of lake water in the lake has not been clarified. Considering the results of previous studies, the two possibilities of the circulation mechanism of lake water are considered. First possibility is an inflow of the river water having heavier density due to high concentration of dissolved components especially metals. If the river water has the heavier density than the lake water, the river water may affect the circulation of lake water by the heavier density flow. Second possibility is the circulation of the lake water by strong wind under the conditions of almost uniform temperature and density of lake water. Considering these points, we study on the circulation mechanism of the lake water based on the physico-chemical characteristics and water quality of the lake water. This study will contribute to predict the circulation variation in the future and the efficiency of the water quality improvement in the lake.
The water samples of Lake Tazawa were collected at five locations in the lake and at some depths at each point. The samplings were carried out between June and October in 2019. Water temperature, pH, EC, Eh, density, specific gravity, quantity of suspended solids, and major dissolved ions were analyzed.
Water temperature was different between shallower and deeper layers and the water temperature in deep layer was almost constant around 4℃ from June to October. So, the thermocline existed through this period. On the other hand, values of pH and concentrations of major dissolved elements of the lake water were similar between all the sampling points and the depths. This result showed the water quality as the whole lake was almost uniform. In addition, the specific gravity and the quantity of suspended solids of lake water and river water of Tama-River were similar. The existence of thermocline and the results of specific gravity and suspended solids of lake water and river water showed that the difference of water density based on the water temperature is much larger than that based on the water quality. Thus, the first possibility was denied. On the other hand, if the shallower water is sufficiently cooled and the water temperature from bottom to surface becomes around 4℃ in winter, the difference of the density of lake water between the shallower and deeper layer will become small. Then, strong winds in this season are considered to cause the turnover of the lake water. The results of this study suggest that the future environment change such as the global warming and climate change may affect the circulation of lake water and the ecosystem of the lake.

Impact of Nishi-Nihon Big Storm in 2018 on nutrient discharge in a Seto Inland Sea Catchment: example in Takahashi River

*Shin-ichi Onodera[1], Mitsuyo Saito[2], Yusuke Tomozawa[1], Toru Takeuchi[3]

1. Graduate School of Integrated and Arts Sciences, Hiroshima University, 2. Okayama University, 3. Fujita Geology Co.

In July 5 to 7 in 2018, the serious disaster by the huge storm event more than 500mm occurred and more than 200 persons dead in a wide area of western Japan. In that time, high turbidity was observed in the wide area of Seto Inland Sea by the satellite image. However, these nutrient flux has not been monitored.

In this research, we aimed to confirm the real situation of high turbidity and nutrient concentration just after this event. We observed those from the river mouth area to 10km offshore of Takahashi River in Okayama Prefecture at three times of 7days, 14 days and 30 days after the disaster. In addition, we monitored groundwater and river water around river mouth area once a week since 2017.

The turbidity in river mouth area of Takahashi River normally was 5 to 8 FTU. On the other hand, it increased drastically more than 1000 FTU just 7 days after the disaster. Especially, high turbidity water of more than 500 FTU expanded to 10km offshore. Though the turbidity decreased on 30 days after, the high turbidity area with around 100 FTU appeared not only at the river mouth but at 8km offshore. These would be by the resuspension from the bottom. The nutrient also indicated same as these.

Ammonium sources in rural coastal aquifer using integrated water quality parameters: chemical, biological, and environmental isotopes

*Anna Fadliah Rusydi[1,5], Mitsuyo Saito[2], Seiichiro Ioka[3], Morihiro Maeda[2], Fujio Hyodo[4], Rizka Maria[5], Shin-ichi Onodera[1]

1. Graduate School of Integrated Arts and Sciences, Hiroshima University, Japan, 2. Graduate School of Environmental and Life Sciences, Okayama University, Japan, 3. Institute of Regional Innovation, Hirosaki University, Japan, 4. Research Core for Interdisciplinary Sciences, Okayama University, 5. Research Center for Geotechnology, Indonesian Institute of Sciences, Indonesia

Ammonium, although, is not regulated in drinking water quality standards, its existence is undesirable because indicated an extinction of domestic waste pollution. In Indonesian coastal aquifer, the dominant presence of ammonium compared to other dissolved nitrogen parameters is not always found. In many cases, the dominant dissolved nitrogen parameter is a nitrate, while ammonium is usually detected in land-use that is heavily impacted by domestic waste, such as densely populated residential and land-fill. Interestingly, in our research area, we detected a dominant existence of ammonium in many types of land-uses, which is not only limited to the area that suspected polluted by domestic waste. Our preliminary results from 46 groundwater samples show ammonium is dominant compared to nitrate at almost samples. Meanwhile, samples from the river (4) and spring water (2), those are taken as a comparison, are dominated by nitrate. Through this research, we analyze the source of ammonium by analyzing major elements, coliform bacteria, and ammonium isotope in order to evaluate coastal aquifer vulnerability towards ammonium contamination.

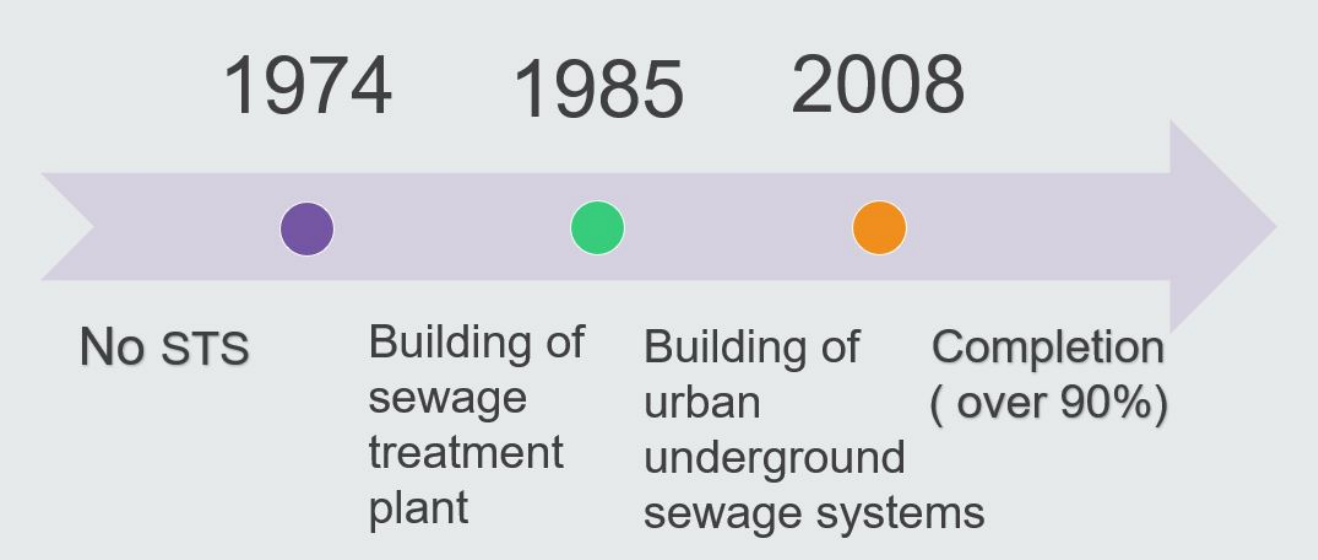
The quantification of the nitrogen discharge in water were most important indicators of the water environment in coastal area because these processes are related to the transport of large nutrient loads. The nitrogen pollution sources of the surface water environment are divided into point source pollution and non-point source pollution according to the different spatial distribution (Niraula et al. 2013; Lee et al. 2010). Nonpoint source nitrogen pollution is a leading contributor to world water quality impairments. (Steffen et al 2015). Sewage treatment system can significantly reducing pollutant emissions by multiple methods.

The construction of sewage treatment systems does not happen overnight, it is divided into two parts: construction of sewage treatment plant and laying of underground pipelines into buildings. Especially for plumbing system, it is a long process. During this period, non-point source pollution from urban areas will be gradually transformed into point sources.



Yamato river is a very important river in west Japan. It has a watershed area of 1067 square kilometers, covering almost half area of Nara prefecture. These have 5 sewage treatment plant in the watershed, 3 of them are located in Osaka Prefecture and others are in Nara Prefecture. These sewage treatment plants were successively constructed and put into use between 1974 and 1985. The progress of pipeline laying varies widely in different cities. As of 2010s, the overall sewage treatment pipeline in the basin covers more than 90% of buildings.

SWAT model could meet this need and has proven to be an effective tool for assessing nonpoint source pollution for a wide range of scales and environmental conditions (Gassman et al. 2007), and it supports inputting point source data according to monthly data (Neitsch et al, 2005). This study used the SWAT model to simulate nitrogen fluxes in the Yamatogawa Basin for more than 50 years, divided into 4 period including 1) no sewage treatment system; 2) sewage treatment plant construction stage; 3) plant completion, pipeline laying stage and 4) full completion stage.

The results show that: 1) SWAT has a very good effect on the nitrogen simulation of mixed watershed with urban and agricultural area. 2) The construction of a sewage treatment plant has a very good effect on the improvement of the river basin environment. As of 2010s, total nitrogen emissions were 9.7 kg/ha, of which point source emissions accounted for 65%.

Characteristic of spatial distribution on nitrate shallow aquifer in a citrus watershed

*Yuta Shimizu[1], Kenji Matsumori[1]

1. Western Region Agricultural Research Center, National Agriculture and Food Research Organization

As aspect of agriculture production, techniques of precise water and fertilizer controlling for individual citrus tree are required to improve quality and quantity of harvest. Citrus orchard dominated watersheds tend to contain abundant nitrate in the shallow aquifer. Using the nitrate-rich groundwater to irrigate and fertigate the tree is effective for both sides of agriculture and environment conservation. The objective of this study aimed to assess spatial distribution of nitrate concentration in a watershed for evaluation the possibility of the groundwater as fertilizer. The target watershed has an area of 0.75 km2 located on Ehime Prefecture. Steep mountains locate the upper stream and an alluvial fan lays between the mountains. The main citrus orchards are cultivated on the fan using groundwater irrigation. A field campaign was conducted on March 2017 to survey groundwater level and nitrate concentration at 91 wells. It was confirmed that shallow groundwater flows mountainous area towards to downstream along the topography based on measured groundwater potential. Mean nitrate concentration was 8.9 mg N/l (Maximum: 26.0 mg N/l, minimum: 0.0 mg N/l). High nitrate concentration was found in central part of the fan while low concentration was found in the area where converted from paddy field on downstream. Especially, very low concentration below detection limit was found near beach that was implies nitrate attenuation by denitrification. However, some hot spots contain high nitrate concentration are expected as fertilizer resource. Evaluation of total nitrate amount in the aquifer and its availability considering with flowing speed is necessary for future work.

Nitrate and Phosphate Contamination of Groundwater in Small and Steep Sedimentary Rock Island

*Sharon Bih Kimbi[1], Shingo Nozaki[1], Shin-ichi Onodera[1], Kunyang Wang[1], Yusuke Tomozawa[1]

1. Graduate School of Integrate Arts and Sciences, Hiroshima University

Over the past years, there has been a constant trend towards greater agricultural intensification and higher agricultural productivity which has been accompanied by a significant increase in the use of inorganic nitrogen and phosphorus in fertilizers. Nitrogen in particular the very soluble nitrate, is vital for life and is found naturally in soil and water however because many crop plants require large quantities of nitrogen to produce high yields, additional nitrogen in the form of fertilizer is applied to crops which easily dissolves into percolating water. Phosphorus on the other hand is less mobile and reaches surface water due to erosion with the bounded soil particles. These different pathways cause a problem with water protection, because elimination of one water pollution source may aggravate another. Phosphates are essential for growth of plants and animals but human activities have altered its natural cycle. Phosphate in excess causes nutrient boost which often equates to excessive algae growth. The present study was carried out in Osaki-Shimojima which is one of the island in the Seto island sea famous for citrus fruit cultivation. The aim of this study was to assess the impact of agriculture, with special attention on nitrate and phosphate contamination of the groundwater quality and to propose mitigative methods for implementing nitrogen-phosphate reduction measures. A total of 49 water samples were collected during the month of October, 2019 and subject to nutrient analysis using the Automatic Nutrient Analyzer. The startling results showed both high nitrate and phosphate concentrations in groundwater. Thus an unfavorable N: P ratio in supplied nutrients were detected. Severe shortage of phosphorus in applied fertilizers maybe one of the major factors causing leaching of nitrogen due to limited possibilities of its consumption by plants.

Phosphorus in groundwater in the coastal area of Mataram, Lombok Island, Indonesia

*Seiichiro Ioka[1], Shin-ichi Onodera[2], Mitsuyo Saito[3], Anna Fadliah Rusydi[2,4], Sachi Wakasa[1]

1. Institute of Regional Innovation, Hirosaki University, Japan, 2. Graduate School of Integrated Arts and Sciences, Hiroshima University, Japan, 3. Graduate School of Environmental and Life Sciences, Okayama University, Japan, 4. Research Center for Geotechnology, Indonesian Institute of Sciences, Indonesia

Several previous studies of phosphorus in groundwater at highly contaminated sites exist. However, although studies on the behavior of phosphorus in pristine aquifers have been increasing, they are still limited. Urban development in Indonesia’ s coastal areas may lead to an increase in groundwater contamination. Mataram City on Lombok Island is a developing area in terms of tourism, and it is important to evaluate the phosphorus in the groundwater prior to the expansion of urban development. Mataram City was therefore selected as the study area for this work and groundwater was sampled at 26 sites.
Our results show that the concentrations of PO_4^{3-} in groundwater analyzed using ion chromatography range from approximately 0.1 to 8.5 mg/L. Fe concentrations in groundwater at 21 sites was lower than 0.1 mg/L. No correlation was found between the Fe and PO_4^{3-} concentrations. In addition, no correlation was found between the DOC (dissolved organic carbon) and PO_4^{3-} concentrations. These results indicate that the DOC and Fe-(hydr) oxides cannot represent the source of P. However, the values of the saturation index of hydroxyapatite for some groundwater samples were close to equilibrium; Therefore, hydroxyapatite may represent the source of P.

Distribution of phosphate oxygen isotope in boring core samples for evaluation of phosphorus cycling in groundwater

*Takuya Ishida[1], Yusuke Tomozawa[2], Xin Liu[3], Jun Qian[3], Mitsuyo Saito[4], Shin-ichi Onodera[2], Noboru Okuda[1], Syuhei Ban[3]

1. Research Institute for Humanity and Nature, 2. Hiroshima Univ., 3. The Univ. of Shiga Pref., 4. Okayama Univ.

Phosphorus (P) input through groundwater discharge plays a significant role in nutrient cycling and primary productivity in the coastal area (Slomp & Cappellen., 2004). Therefore, its biogeochemical cycling in underground environment is important in proper land management and understanding of natural systems. Recently, phosphate oxygen isotope ratio ($\delta^{18}O_{PO4}$) has been used as a promising tool to elucidate the P cycling. Previous studies showed the possibility to evaluate P sources, metabolism by organism in some ecosystems (Paytan & McLaughlin 2011). However, it is not clear whether $\delta^{18}O_{PO4}$ is useful for evaluating the P cycling of in underground environment, because few researches have applied the $\delta^{18}O_{PO4}$ analysis for underground P cycling.
In the present study, we investigated the $\delta^{18}O_{PO4}$ values of boring core samples and groundwater to clarify P cycling in underground.
A boring core (28 m depth) and groundwater (5 m and 28 m depth) were collected at The University of Shiga Prefecture, which is located on coastal area of Lake Biwa, central Japan. Boring core was divided by 1 m and ground to powder using a multi-bead shocker (Yasui Kikai) with tungsten carbide beads. The powdered boring core samples were immersed in 1 M HCl for 16 h to extract the inorganic P. Groundwater samples were filtered through 0.45-μm membrane filters (Advantec). The SRP concentration of each samples was measured using the molybdenum-blue method on a microplate spectrophotometer (Multiskan GO; Thermo Fisher Scientific). For the $\delta^{18}O_{PO4}$ analysis, the extract and groundwater samples were converted to Ag_3PO_4 according to McLaughlin et al. (2004) or Tamburini et al. (2010). The $\delta^{18}O_{PO4}$ values reported relative to the Vienna Standard Mean Ocean Water (VSMOW) of the Ag_3PO_4 samples were measured using a TC/EA-IRMS (thermal conversion elemental analyzer connected to a Delta plus XP via ConFlo III, Thermo Fisher Scientific) at the Research Institute for Humanity and Nature (RIHN).
The soluble reactive P (SRP) concentrations in 5 m and 28 m depth of groundwater were 0.74 and 6.78 μ mol L^{-1}, respectively. Deeper groundwater has much higher SRP concentration than river and lake water (< 0.7 μmol L^{-1}) near The University of Shiga Prefecture. The $\delta^{18}O_{PO4}$ values in 5 m and 28 m depth of groundwater were 15.1 and 17.1‰, respectively. In our poster, we will show the result of distribution of $\delta^{18}O_{PO4}$ in boring core samples and discuss the P cycling in groundwater.

Bulk precipitation and throughfall depositions of atmospheric nitrogen and sulfur in forests surrounding the Tokyo metropolitan area

*Yuko Itoh[1], Masahiro Kobayashi[1], Toru Okamoto[1], Akihiro Imaya[2]

1. Forestry and Forest Products Research Institute, Japan, 2. Japan International Research Center for Agricultural Sciences

Increased atmospheric deposition of nitrogen (N) and sulfur (S) compounds from anthropogenic sources remains a concern in some areas of the world. The impact of increased N emissions on a global scale extends to forest ecosystems as well. N influx into the forested areas distorts the N dynamics in the forest ecosystem. High nitrate concentrations in some stream water have been observed at forest watersheds on the surroundings of the Tokyo metropolitan area. Atmospheric N and S depositions by bulk precipitation (BP) and throughfall (TF) were investigated on 12 (BP) and 15 plots (TF) in forest stands located on the surroundings of the Kanto plain of Tokyo metropolitan area, with intense human activities. In this study, it was observed that throughfall contributes more to N and S influxes than BP. At the majority of the studied sites, nitrogen influx resulting from TF was 2 to 3 times the N influx resulting from BP. The increase in N outflow from watershed surrounding Tokyo metropolis can be attributed to the N influx induced by the forest canopy structure. In contrast, the S influx was higher at sites located far from the Tokyo metropolitan area, which resulted from high annual rainfall and particularly from the influence of seasonal wind, including sea-salt and air pollutants from Asian continent during the winter season. Furthermore, to determine the influences of atmospheric N and S influxes and N saturation, it pertinent to observe the cycling of elements within various forest watersheds, including snowy area.

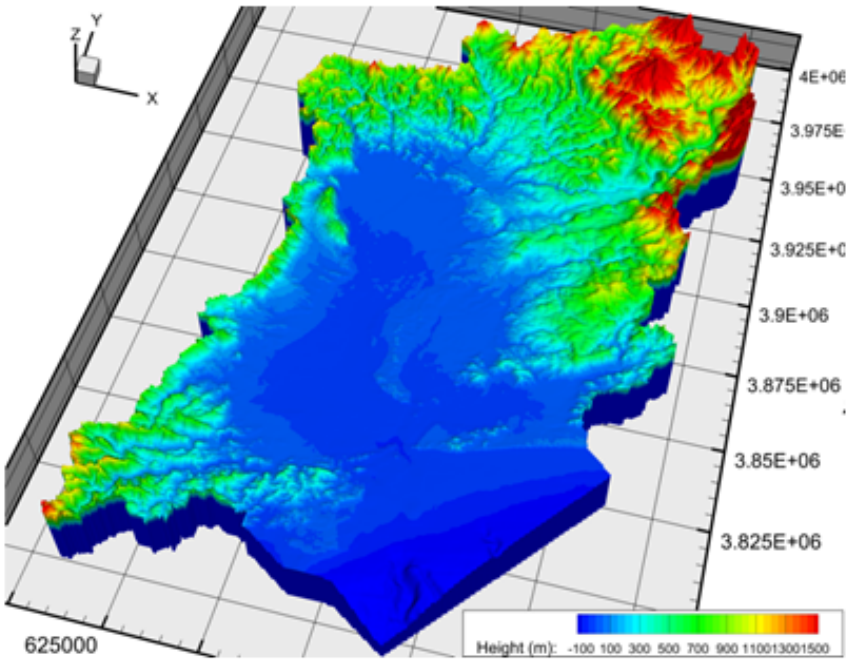
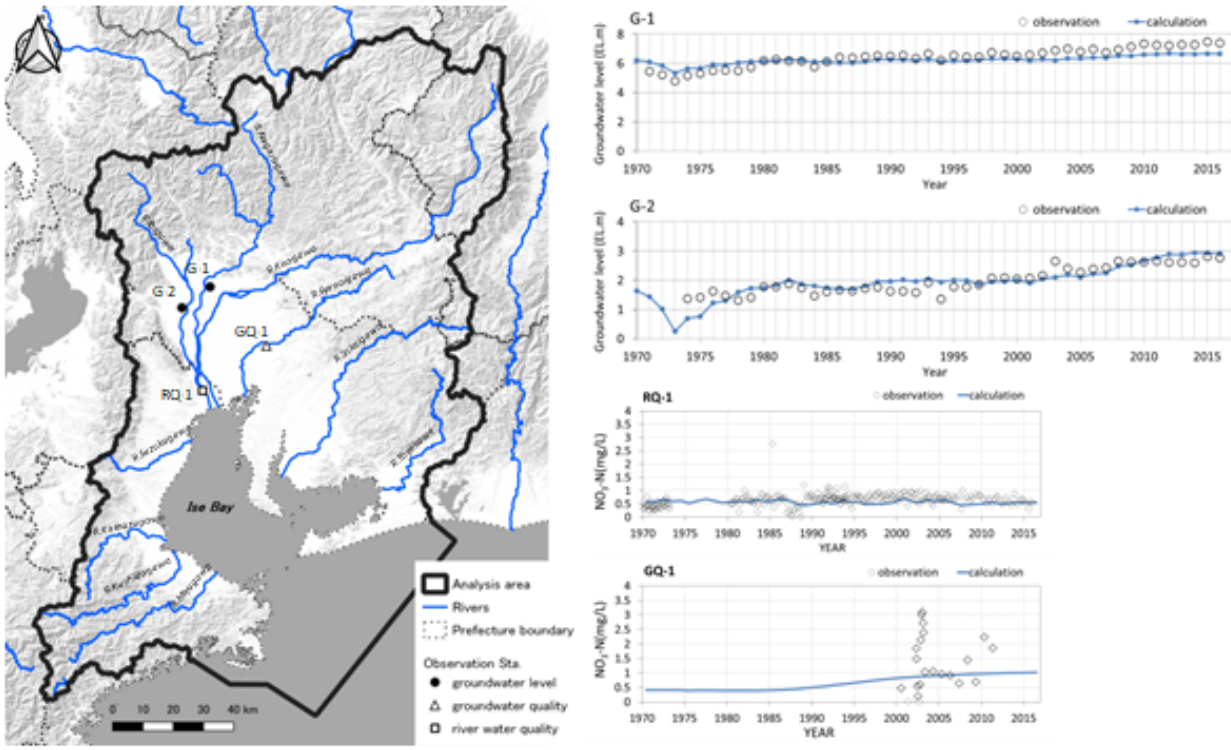
Numerical modeling of nutrient transport in the Ise Bay basin



*Taichi Matsuura[1], Yasuhiro Tawara[1], Susumu Saita[1], Takafumi Yoshida[1], Tetsunori Inoue[2]

1. Geosphere Environmental Technology Corp., 2. Port and Airport Research Institute



Eutrophication is the main cause of the occurrence of red tides in semi-enclosed coastal areas. Studies performing numerical simulations have reproduced the complicated phenomena that caused problems in bays including mid-layer oxygen depletion and the occurrence of discolored tides. The nutrient inflow conditions used in such simulations reflect measured values as closely as possible, however, they are often not temporally and spatially considered in detail. There are limitations on the available measurement data, making accurate simulations difficult to realize. Furthermore, nutrients are transported not only from the surface water but also from the groundwater, and the actual temporal and spatial transport mechanisms are not always understood. The inflow of nutrients in groundwater largely depends on factors such as the geological characteristics of the coastal area, groundwater utilization, and nutrient load in the basin. Models of nutrient transport at watershed scales can therefore be useful tools for elucidating complex mass-transfer phenomena in coastal areas. In this study, we developed a nutrient transport model for marine numerical simulations to track nutrient behavior in Ise Bay by focusing on the actual long-term circumstances of nutrient load and groundwater use in the basin, thereby enabling more accurate reproduction of nutrient load conditions in terrestrial areas.
To calculate the nutrient flow from land to sea in the Ise Bay basin, we constructed a basin model that reflects the hydrological processes and the water usage occurring on the land surfaces, including basin-scale hydrogeological structures. In particular, we incorporated groundwater pumping and nutrient loading processes into models to simulate changes in groundwater levels and nitrogen concentrations from the 1970s until present. During that time, the groundwater level showed a large temporary decrease, from which it gradually recovered, and the initially extremely low nitrogen concentration tended to gradually increase. The constructed model was validated via matching of multiple historical data, including measured river flow, groundwater levels, and water quality factors such as ammonia nitrogen and nitrate nitrogen. The simulation was conducted using the geofluid simulator of GETFLOWS.
The simulation of groundwater levels was successfully reproduced the trend of gradual groundwater level recovery from the 1970s to the 2010s. Furthermore, the simulated ammonium and nitrate nitrogen concentrations in rivers were well-reproduced when compared with measured data. Consequently, we considered that the estimated nutrient loads in the basin using statistical data are temporally and spatially consistent with the actual situation. Regarding observed groundwater concentrations, while responses to seasonal changes have not yet been verified, reproductions of change over time were generally consistent.
The results show that the fluctuation patterns of nitrate nitrogen inflowing from land to sea are highly affected by annual changes in precipitation and are particularly dependent on surface-ground water components. However, there are indications that while groundwater components show small year-round fluctuations, they comprise up to 10% of inflowing surface water. Therefore, we suggest that the nutrient influx should be considered not only from surface water but also from groundwater when evaluating nutrient behavior in semi-enclosed coastal areas. This will lead to a better understanding of marine nutrient transport and more accurate predictions of the effects of countermeasures.

Influence of Material Supply and Human Intervention from Mt. Kusatsu-Shirane Volcano on the Surrounding Water Environment

*Yoshihiro Igari[1], Koji Kodera[2], Kazuki Asami[1]

1. Hosei University Graduate School, 2. Hosei University

I. Introduction

In Japan, a maritime nation, it is important to understand the material balance and water balance between upstream and coastal areas. In order to manage the impact of forests, agricultural land, cities, factories, and other terrestrial ecosystems on the coast within a river basin, it is necessary to understand the entire basin (Mukai 2012). Groundwater stored in volcanic bodies, especially in volcanic areas, has long been used as an important water resource (Yamamoto 1995). On the other hand, acidic rivers around volcanic bodies have a great impact on the ecosystem, water source development, and flood control of the basin. The purpose of this study is to clarify the influence of substances supplied mainly from volcanic bodies on the water quality of rivers, lakes, and precipitation around Mt. Kusatsu-Shirane.

II. Regional Summary

The Kusatsu Shirane Volcano area has a large amount of hot spring water, as typified by the Kusatsu Hot Spring, and hot springs with high temperature and strong acidity can be seen in various places. The acidic water seen in the Agatsuma River basin is caused by acidic hot spring water and acidic sulfur mine wastewater in the surrounding area, and a neutralization project has been carried out for the Yu River basin, where Kusatsu Hot Spring, one of the acidic sources, is the main stream (Oi et al. 1991).

III. Research methods

Field survey items (Temperature, water temperature, EC: conductivity, pH, RpH, flow rate) were measured and sampled at about 45 rivers around Mt. Kusatsu Shirane from May 23 2017 to October 2019. After filtration in the laboratory, some samples were analyzed for dissolved ingredients (TOC, Na^{+}, K^{+}, Ca^{2+}, Mg^{2+}, Cl^{-}, HCO_3^{-}, NO_3^{-}, SO_4^{2-}).

IV. Results and Discussion

In the basin of the Manza River, which is located at the western foot of the mountain, many rivers were affected by the inflow of groundwater with a high proportion of sulfuric acid, but in the mountain stream near the fumarole group, the water quality composition to which chloride was added was observed. Water composition affected by domestic wastewater is also observed.
In the small basins extending north and south at the southern foot of the mountain, the elevation of the headwaters and the distance from the crater are related to the concentration of calcium sulfate-type water quality. If the headwaters of the basin are close to the crater, the water quality of the river will contain many volcanic components, and if the headwaters of the basin are far from the crater, the volcanic components will weaken and the influence of the surrounding fields will appear.
The strongly acidic river (Yu River, Yazawa River, and Osawa River) in the Yu River basin to the east of the mountain is neutralized and flows down through aqueducts to the middle reaches of Shirasuna River and the junction of Shirasuna River and Agatsuma River, but the main stream of the Agatsuma River is strongly affected by this.

V. Conclusion

Research on volcanic bodies with well-developed hydrothermal systems has been taken up in Japan and

©2020. Japan Geoscience Union. All Right Reserved.

overseas, but many studies have focused on specific issues and targets, and few have discussed the water environment of the entire mountain body. By treating not only rivers affected by strong acid drainage but also mountain streams, lakes, and precipitation far from craters, we were able to evaluate natural and human impacts and discuss the target areas in a wide range of fields.

Spatial distributions in groundwater (SGD) and nutrient discharge on tidal flat with the area of around 100m square in a small and steep island, western Japan

*Shingo Nozaki[1], Shin-ichi Onodera[2], Yusuke Tomozawa[2], Mitsuyo Saito[3]

1. Graduate school of integrate arts and sciences,Hiroshima University, 2. Graduate school of integrate arts and sciences,Hiroshima University, 3. Graduate school of Environmental and Life science, Okayama University

Abstract

The purpose of this study was to confirm spatial distribution in groundwater (SGD) and nutrient discharge on tidal flat with the area of around 100m square in a small and steep island. The experimental sites were located on Ikuchi Island in Onomichi City, Hiroshima Prefecture, western Japan. Pore water samples were collected and water levels were monitored at 10 and 17 piezometers on two experimental tidal flats, which is composed of E site (100m x 30m) at the alluvial fan edge of an experimental catchment and W sites at the steep mountain slop foot (300m x 30m), respectively. In addition, rain water samples were collected monthly at seven plots with different elevation from April 2019 in an experimental small and steep catchment with a maximum altitude of 400 meters The stable isotope ratio and nutrient concentration of water samples were analyzed by PICARO and SWAt of Beltech, respectively.

Various groundwater and nutrient discharges were observed at the W and E sites. E site on the catchment foot with a stream had smaller groundwater and nutrient discharge with the pore water of low nutrient concentration and flesh water content as compared at W site. Though experimental Ikuchi Island was small with the altitude of only 400m, we could confirm the elevation effects of stable isotopic ratios in rain waters. However, the rainfall volumes were not clarified to increase with the altitude. These results were only based on the observations for only about six months from April to September 2019, we will show more detail results for more than one year in the presentation, Based on the relationship between the altitude and stable isotopic ratios in rainwater, we could estimate groundwater recharge altitude at some pore waters at W site. It was estimated to be 50m to 300m in altitude. The lower area is covered by the citrus plantation, and high dissolved nitrogen and phosphorus was contained by leaching of fertilizer component. On the other hand, groundwater from the higher area flows longer and deeper path, and high silica was contained. We were able to confirm the difference between groundwater well-rising in tidal flats at low and high tides at the At W test site, the nutrient load was large in the west side.

Estimation of unsteady confined groundwater flow with river water intrusion in coastal alluvial plain during a large flood.

*Yusuke Tomozawa[1], Shin-ichi Onodera[1], Mitsuyo Saito[2], Tohru TAKEUCHI[3], Yutaka MARUYAMA, Koichi Kitaoka[4]

1. Graduate School of Integrated Arts and Sciences Hiroshima University, 2. Graduate School of Environmental and Life Science, Okayama University, 3. Fujita Geology Co., Ltd., 4. Okayama University of Scienece

Several aquifers underlie alluvial plains, and confined groundwater is mainly used intensively. The water potential depression and land subsidence have been caused in the coastal area. On the other hand, confined groundwater is generally recharged in the boundary area (ie. Alluvial fan) between the mountain foot and alluvial plain. The groundwater recharge in alluvial fan mainly and preferentially occurs in the high flow period. This type of groundwater flow is considered to be in the steady to semi-steady state.
In this research, we focused on a small alluvial plain with a little bit slope, we examined to confirm the recharge process and confined groundwater flow, using 10 years monitoring of groundwater level, water chemistry, and oxygen and hydrogen stable isotopic ratios. Our research area was in Okayama alluvial plain, western Japan, buried by the sediment transported from Asahi river, Yoshii river and Takahashi river. We monitored groundwater level and collected water samples at the 6 observation boreholes on the 4 experimental sites.
The component separation of groundwater by stable isotopes of water indicates that the major recharge source is river water in the upper stream section, whereas the contribution of rainwater increases in the lower stream section, and mixing of seawater in to the coastal groundwater with about 20m deep. In addition, large decline of isotopic ratios, chloride and sodium concentration were observed in the confined groundwater in the central part of the plain after an extreme flooding event. This suggests intensive recharge by river water with low isotopic ratios by volume and elevation effect of precipitation during this period.

Establishment and evaluation of a method to reconstruct the past snow fall and winter monsoon intensity based on the inter-annual variabilities of river discharges in Hokkaido, northern Japan

*Airi Maruyama[1], Tomohisa Irino[1]

1. Biogeochemistry Course, Earth System Science, Faculty of Environmental Earth Science, Hokkaido University

Monsoon is the seasonally alternating wind due to heat contrast between continents and ocean by solar radiation (Tada, 2005), and the one of the most characteristic seasonal variation of climate in east Asia. Winter monsoon, which is characterised by cold and dry wind and blows from continents, promotes heavy snowfall along the Japan Sea side of Japanese Islands, while Baiu, where moist tongue characterised by wet wind turning around the north Pacific Ocean, brings seasonal rain front along the Japanese Islands in summer. Although past summer monsoon has been successfully reconstructed in many studies (Ikehara and Itaki, 2005), researches on winter paleoclimate including winter monsoon have not been developed well. In this study, we analyzed the inter-annual variability of river water discharge in Hokkaido, subarctic Japan, to examine how the seasonal precipitation affects the spatio-temporal variability of sediment and water discharge, and tried to utilize it to reconstruct the past variability of winter snowfall from sediment archives.

We collected 10-year water discharge data of 13 class A rivers between 2006-2016 in Hokkaido from Water Information System of Ministry of Land, Infrastructure, Transport and Tourism. Then, we conducted principal component analysis (PCA) using *R*. Missing data was interpolated by the mean values. Out of 13 principle components, we examined PC1, PC2, and PC3 which occupy a large proportion of total variance. Based on the spatial distribution of the principle component loadings and the timings of maximum and minimum of principle component scores, these PCs are characterised like below.

1. PC1 represents average temporal discharge variation in Hokkaido, where the discharge depends on precipitation during summer to autumn and melting of snow in spring

2. PC2 loadings are significantly positive in the Okhotsk Sea side and negative in the Japan Sea side, where timing of maximum score is associated by summer precipitation in the Okhotsk Sea side and minimum score is associated by spring snow melt in the Japan Sea side

3. PC3 loading shows significantly positive in the Okhotsk Sea side and negative in the Pacific side, where timing of maximum score is associated with spring snow melt and minimum score occurs at heavy precipitation in summer and autumn

Considering the timing of maxima and minima in PC2 score, we suggest that the comparison of sediment discharge between the Okhotsk Sea and the Japan Sea may enable us to extract the information of spring snow melt discharge in the Japan Side as well as winter snow fall. However, when magnitude of both PC2 and PC3 scores becomes large, melting snow also depends on temperature that depends on insolation intensity (Chikita. 1994). Therefore, we need to further examine not only precipitation and snowfall but also data of temperature and insolation.

Classification analysis of coastal seaweed beds using UAV and Near-Infrared camera

*Akimitsu Shiraishi[1], Mitsuyo Saito[1], Akira Hama[2], Shin-ichi Onodera[3], Toru Iwata[1]

1. Graduate School of Environmental Science, Okayama University, 2. College of Education, Yokohama National University, 3. Graduate School of Integrated Arts and Sciences, Hiroshima University

Seaweed beds play a role in the coastal sea keeping water quality better and maintain ecosystem itself in shallow waters. However, the coastal environment has been affected by economic development. In Seto Inland Sea separating Honshu from Shikoku and Kyushu of Japan, where water quality has been improved by environmental conservation efforts, and some area appeared to be locally oligotrophic.

Satellite data has been used for remote sensing of seaweed beds, so far, however, it is susceptible to weather and clouds. Furthermore, free satellite data could be used with some problem such as low spatial resolution. Other typical monitoring methods include airborne platforms, grand based surveys and snorkel / scuba surveys. These techniques can suffer from temporal and spatial inconsistency, or are very restricted making it hard to assess seagrass meadows in a structured manner.

This research aims to obtain distribution of shallow seaweed beds by analyzing the combined data of visible and near-infrared images acquired using UAV. The UAVs can reduce effects of clouds and atmosphere. In addition, by conducting surveys at the same location during the daytime in the intertidal zone, the conditions for on-site observations can be made the same. Furthermore use of commercially available UAVs and inexpensive near-infrared cameras also reduce cost of research compared to expensive satellite data and snorkel / scuba surveys. The distribution data of shallow seaweed beds is to be analyzed with ground survey samples and the factors affecting on changes in seagrass bed ecosystems will be revealed.

The study area is Gohonmatsu Beach, Ikuchijima, Onomichi City, Hiroshima Prefecture.

UAV cameras shot about 100 at coasts vertically downward. Next, an ortho mosaic image was created (3.6 cm pixel^{-1}) in Structure from Motion (SfM). The same procedure was used for images from Near-Infrared cameras. Although NDVI were used as first analysis index, NDVI showed negative values for seaweed on the intertidal beach and submerged seagrass. Newly proposed NSGI showed positive value for those ones. Furthermore, we propose SGI1 and SGI2 as a method of seaweed bed classification using the brightness intensity of each band. SGI1 and SGI2 determines the seaweed beds under sea surface and on sandy beach, respectively. By combining these, most seaweed beds in the coastal area could be determined.

Duffy, J.P., Pratt, L., Anderson, K., Land, P.E., Shutler, J.D., 2018. Spatial assessment of intertidal seagrass meadows using optical imaging systems and a lightweight drone. Estuarine, Coastal and Shelf Science. 200, 169-180. https://www.sciencedirect.com/science/article/pii/S0272771417302202

Biogeochemical pathways of critical environmental contaminants (PTTE, POPs) in the rhizospheric soil-plant system

*Hideyuki Inui[1], Vladimir Beskoski[2], Mikael Motelica-Heino[3]

1. Kobe University, 2. University of Belgrade, 3. University of Orléans

Plants have a significant role in the biogeochemical cycling in continental ecosystems namely in the transformation and chemical export of anthropogenic chemicals in the critical zone environments. In particular the rhizosphere soil, which is the few millimeters of soil covering the roots of plants and influenced by their biological activity, is a dynamic system characterized by feedback interactions between soils characteristics, roots processes and dynamics of the associated microbial communities. It is a geochemical micro-environment influenced by plants physiology (roots exudation of compounds such as organic acids etc., respiration, …), microorganism activity (mineralization of organic matter…) and soil characteristics (SOM, pH, texture, WHC, CEC etc). These dynamic small-scale biogeosystems are characterized by feedback interactions between soil characteristics, plant roots and dynamics of the associated microbial communities and play an essential role in the transformation of natural organic matter, nutrients and trace elements. They may also locally influence the ecodynamic of critical environmental contaminants such as potentially toxic trace elements (PTTE) and/or persistent organic contaminants (POPs), either directly (precipitation, complexation, adsorption, degradation, plant uptake) and indirectly (effects of the rhizosphere on pH and redox potential, dissolution of minerals…) in contaminated soils.
The study of rhizosphere-related processes on mobility, availability and toxicity of PTTE and POPs in rhizospheric soils, based, in particular, on the role of the root-mycorrhizae-bacteria associations in their transformation of, is thus a major challenge to understand the ecodynamics of these contaminants in natural or anthropogenic continental biogeosystems. Identifying these feedbacks, positive or negative, for the study of physical-chemical processes, biological and microbial requires to be done at different spatial scales, micro (eg. soil pore –organo/mineral aggregates–microorganism interface), local (biological community or soil unit) to regional (ecosystem in its watershed). This objective will be reached through characterization of rhizosphere microflora, identifying the role of roots exudates, evidencing the influence of these biogeochemical factors on the speciation, transformation, mobility and phytoavailability of PTTE and POPs in rhizospheric soil.
Generic issues to be addressed are:
1) What and how do the structure and dynamics of microbial soil populations control zoning of critical environmental contaminants?
2) Can the foreseen spatio-temporal changes in microbial communities and distribution of these contaminants at a small spatial scale solve their contributions in terms of source and sink on large biogeochemical cycles?
3) What is the role of the rhizosphere on their transformation, mobility and transfer?
4) How can local sources and sinks be upscaled at the watershed and global transfer level?
The specificity of our work is to bring together a diversity of approaches at different spatial scales and in different conditions (laboratory, mesocosm, land) with a holistic integration of components (mineral and organic fractions of soil) and different biological factors (micro-organisms, plants). Results illustrating root-bacteria associations in the mobility, availability and toxicity will be discussed to understand their ecodynamics in soils, study the contribution of rhizospheric microbial communities their (im)mobilization processes, elucidate their transfer from soil to vegetation compartments and more global pathways in the critical zone. Far from being isolated, the different compartments of the critical zone interact according to

Study on water quality composition and its change in Ishigaki Island

*Masato Oda[1], Koji Kodera[1], Atsuki Sato[1]

1. Hosei University, faculty of literature ,Geography

In Ishigaki Island in the Yaeyama Islands, valuable coastal environments such as coral reefs exist, and the impact of land water flowing through the island on the coastal environment is very large. Research has been conducted on the formation of water quality composition by soil, soil and nutrient salts mainly in rivers such as the Nagura River and the Todorogawa River. Our laboratory has been conducting surveys on Ishigaki Island since 2006 –2011 and 2018, and we report a comparison between past research data and recent survey results.
The water quality composition of Ishigaki Island is classified as alkaline earth carbonate type because the dissolved components are overwhelmingly larger than the average river in Japan. In particular, the distribution of the Na-Cl and Ca-HCO3 forms is remarkable. This can be attributed to the geological condition of being a limestone area, sea salt, and agriculture. Nitrogen pollution was significant in upland farming areas and urban areas, and nitrite and ammonia components were detected in some urban areas. It seems that there are areas where wastewater treatment is insufficient.
In the future, it is necessary to collect more samples in cooperation with local citizens' groups, accumulate data through long-term surveys, clarify changes in water quality composition by comparing with past research data, and conduct research on the effects on the surrounding environment.

Keywords: Ishigaki Island, limestone, Nagra River, nitrogen pollution

Effects of sugarcane growth on hydrological elements and sediment yield

*Yang Cao[1], Shin-ichi Onodera[2], Mitsuyo Saito[3], Hide Omae[4], Yoshiko Iizumi[5]

1. Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, 2. Hiroshima University, 3. Okayama University, 4. Tropical Agriculture Research Front (TARF), Japan International Research Center for Agricultural Sciences (JIRCAS), 5. Nihon University

In this work, the effects of sugarcane growth on main hydrological elements and sediment yield were investigated using SWAT model and monitoring data. The growth of sugarcane was controlled by setting tillage and fertilization information in the model. Calibration and validation of the model showed that the reasonable runoff and sediment simulation results were obtained. The results showed that with the growth of sugarcane, the dense roots and branches effectively regulated the runoff during the period of abundant precipitation. Compared with the year 2017 at the initial stage of sugarcane growth, evapotranspiration at the later stage of sugarcane growth in 2018 was lower because of low soil moisture. Reduced evapotranspiration has also led to a significant increase in water yield in the sugarcane region in 2018. In addition, the growth of sugarcane contributed to the reduction of sediment yield in the small basin, with the average sediment yield in sugarcane regions dropping by about 58% in 2018 compared with 2017. The research methods and results proposed in this paper can be used for reference for agricultural management in other small watersheds with abundant rainfall.

Field measurement and numerical simulation of water flux in a forest soil

*Masahiro Kobayashi[1]

1. Forestry and Forest Products Research Institute

To clarify the movement of dissolved substances, such as by nitrogen leaching in forest soil, it is necessary to quantify the water flux. However, measuring water flux in unsaturated soils is not easy. Porous plate tension lysimeters (PPTL), which automatically control the vacuum according to the wetness of the soil, are considered to be one of the suitable methods for this purpose. In this study, the PPTL method was applied to evaluate the seasonal change of water flux in a forest soil. Furthermore, we simulated the observed seasonal water flux by numerical calculation using the experimentally measured soil hydraulic characteristics. In a Japanese cypress forest, a ceramic porous plate was installed in the soil at a depth of 1 m and connected to the vacuum system, and the amount of water flux was measured continuously. Throughfall was measured using a tipping rain gauge and soil water storage was measured using time domain reflectometry sensors. Then, the water balance in the soil layer was determined. The observation period was divided into shorter periods so that the soil water storage at the beginning and end of the period was equal. The average daily water losses (transpiration) in each small period were calculated to be within the range of about 0.2 mm/d in winter to about 3 mm/d in summer. The observed water flux by PPTL was simulated by numerical calculation using water content–potential–hydraulic conductivity relationships determined by laboratory experiments. The numerical simulations were conducted using the HYDRUS1D program. Using the daily water loss by field observation as the value of root water uptake, the water flux for each period was simulated. The simulated temporal change of water flux was comparable to the observed value obtained by PPTL.

Hydrogen and oxygen stable isotopic mapping that allows us to investigate water cycle regimes over Japanese Island

*Shota Nakauchi[1], Takahiro Hosono[1], Kimpei Ichiyanagi[1]

1. Kumamoto University

In the earth surface water cycle, waters fall to the surface ground as precipitation, and then flow through ground and stream waters, and finally flow back to the sea. Oxygen and hydrogen isotopic ratios of water molecular reflect the source mixing and physical processes, i.e., evaporation, in such fluid dynamics. Many studies have applied these tools in revealing processes taken placed in regional watershed systems. Even enormous data have adequately been accumulated by the year 2020, only few researches have summarized and integrated these datasets in regional and continental scales. This study collected these data covering whole Japanese Islands from published literatures, domestic reports and internet websites, for all water regimes including precipitation, groundwater, spring water, and river water to discuss their overall flow systems. As a result, some major findings were obtained. First, it was confirmed that the waters at both higher latitude and the higher altitude showed lower isotopic ratios for precipitation, spring water and river water, that are latitude and altitude effects, except for groundwater which isotopic signatures are formed by involvement of other factors. Spatial distributions of surface and subsurface waters correspond well with that of precipitation. Second, water flow features were examined by characterizing the slope of regression lines on the delta diagram. It was suggested that precipitation fallen on the mountains percolates into ground and seeps mostly from mountain foots as springs that merge to become headwaters in the mountains. Most of downslope aquifer waters more resemble in isotopic compositions to these headwaters rather than mountain waters. The spring waters at lower altitude must be recharged in mountains with lower altitude where these headwaters present. The downslope groundwaters and, to more extent, rivers are most significantly affected by evaporation. Presence of NE-SW trending lower d-excess anomaly belt was suggested in the central part of Japanese Islands, which formation processes should be address in future work.

Estimation of discharge at small forest watersheds in Ibaraki Prefecture by using the SWAT model

*Naohiro Imamura[1], Naoyuki Yamashita[1], Masahiro Kobayashi[1], Takanori Shimizu[1], Shinji Sawano[1], Koji Tamai[1], Shin' ichi Iida[1], Naoki Kabeya[1], Yoshio Tsuboyama[1]

1. Forestry and Forest Products Research Institute

Prediction and evaluation of the impact of forest operations on water and nutrient cycle in forest watershed are required recently. Whereas the SWAT model has been used for estimating discharge at large watersheds consisting of agricultural land, the application of the SWAT model to forest watersheds is expected due to the high versatility of the model. To evaluate the applicability of the SWAT model to small forest watershed, this research used the SWAT model to reproduce daily discharge at small forest watersheds in Ibaraki Prefecture from 2008 through 2011. The watersheds of the Tsukuba and Katsura research sites are 3.79 and 61.7 ha, respectively. In the model calculations, actual observed soil data (soil thickness, hydraulic conductivity, saturated hydraulic conductivity) were used. As a result, the parameters for curve number, canopy maximum water storage, and groundwater had to be calibrated to fit the observed discharge at both sites. In addition, at Tsukuba and Katsura research site, it was necessary to calibrate the average slope aspect and average slope length, respectively. These results indicated that adjusting the gradient parameters was important for applying the SWAT model to the forest watersheds with steep slopes which widely distribute in Japan.

[A-HW33] Prediction of water and sediment dynamics from small to large scales

convener:Yoshiyuki Yokoo(Fukushima University), Yuko Asano(The University of Tokyo)

After the IAHS decade of PUB, challenges have been continued for understanding internal processes and developing models for elevating the predictability of hydrological response for watershed with multiple scales. Simultaneously, changes in the precipitation patterns and intensity as well as increases in associated sediment disasters due to global climate changes brought us challenges for developing tight linkages between water and sediment dynamics in the areas of observation and modeling approaches. For tacking the issues, we have conducted studies for comprehending scale dependency of processes for water and sediment movement from small to large watersheds and explored process representation of numerical models coupled to field-based evidences. Based on these studies, we proposed (1) classification for the behaviors of water and sediment movement from small and large watersheds depending on internal processes, (2) internal hydrologic and geomorphic processes can be included in models. Further discussion needs to be extended for applicability of the approaches.
This session aims to explore updated and current studies for scale dependencies and process representation of hydrologic and geomorphic processes in multiple watersheds. We welcome for topics related to hydrology, geomorphology, and biogeochemistry in small and large watersheds for both field and modeling approaches. Patterns and variability for water and sediment movements within watersheds are also included in the topics.
In this session, we will extend discussion for next step of field and modeling studies toward integrating hydrologic and geomorphologic processes in various landscapes and achieving prediction of ungauged basin in the areas of water and sediment dynamics. Finding through this session may advance our ability for hydrological predictions in any ungauged basins from small to large spatial scales toward sustainable water resources and sediment management.

Quantitative evaluation of sediment dynamics caused by extreme rainfall events in August 2016 in the Pankenushi River, Hokkaido, northern Japan

*Hiromi Akita[1], Shigeru Mizugaki[1], Yasuhiro Murakami[1]

1. Civil Engineering Research Institute for Cold Region

In this study, we conducted satellite image analysis and laser profiler (LP) measurements to clarify the sediment dynamics quantitatively in the Pankenushi River, a headwater catchment of the Saru River, where the landslides and river bank erosion occurred by the extreme rainfall events associated with four typhoons in August 2016. The disturbed areas caused by landslides and river bank erosion across the catchment were extracted using the normalized difference vegetation index (NDVI) calculated from satellite images before and after heavy rain. LP measurements were conducted along the main river channel from the mid- to down-stream areas where the disturbance of the river channel was remarkable, and the topographical changes after the rainfall events were evaluated. The 197 of fresh landslides were found across the catchment, of which 155 (79%) were distributed in the igneous rock area in the upstream area where rainfall of 300 mm or more over 24 hours was concentrated. The depth of landslide scar was estimated as 2 m or less for the 90% of the fresh landslides (N= 57) in the mid- to down-stream area, where the LP measurements was conducted. The volume of eroded and deposited sediment in the landslide scars across the catchment were estimated to be about 470,000 m^3 and 70,000 m^3, respectively, based on the power relationship between the sediment volume and landslide area. In result, about 400,000 m^3 of sediment was found to be supplied from the slope to the river channel by landslides. Along the channel from the mid- to down-stream areas, the sediment volume of erosion and deposition were estimated to be about 1,000,000 m^3 and 330,000 m^3, respectively. The erosion volume along the channel was about 2.0 times greater than that by landslides across the catchment suggesting that not only the landslides but also the bank erosion could play a significant role in sediment supply downstream during and after the extreme rainfall events.

Evaluation of suspended sediment sources at the basin scale: a case study of coastal basin, Hokkaido, northern Japan

*Shigeru Mizugaki[1], Junichi Ohtsuka[1], Yasuhiro Murakami[1], Hiromi Akita[1], Atsushi Tanise[1], Masa-aki Murayama[1]

1. Civil Engineering Research Institute for Cold Region, PWRI

In Japan, coastal erosion has been a problem throughout the country since the 1950s, and comprehensive sediment management of sediment transport through rivers from mountains to coasts is required. Understanding the source of sediment is an important and fundamental issue. In order to understand the connectivity of sediment from the mountainous area to the sea, this study conducted sediment hydrology observations on the Saru River basin in Hokkaido, and fingerprinting sources of suspended sediment using natural radionuclides as tracers. To evaluate the source of suspended sediment quantitatively, the rating curve for each lithological source group was developed. The annual amount of suspended sediment from the Saru River to the sea area was 150,000 t/yr on average from 2011 to 2014, but it was more than 17 times as large as 2.6 million ton in 2016 due to heavy rainfall. The main source areas of suspended sediment were found to be sedimentary rocks and metamorphic rocks, which widely distributed in the middle and lower reaches, during 2011-2014. This result seems to reflect the weathering characteristics of rocks. During the heavy rainfall events in August 2016, the main source areas were metamorphic rocks and sedimentary rocks in the first half, and the accretionary matrix and accretionary basalt blocks in the latter half, which were distributed in the upstream area. These results indicate that the sediment yield and major sediment production sources differ depending on the geological composition and rainfall distribution of the basin.

Dependency of watershed-scale rainwater storage on watershed-area at the occurrence times of slope failures: a preliminary investigation in Japan

*Hikaru Satou[1], Yoshiyuki Yokoo[2], Chris Leong[2]

1. Graduate School of Symbiotic Systems Science, Fukushima University, 2. Faculty of Symbiotic Systems Science, Fukushima University

The authors investigated whether watershed-scale rainwater storage at the occurrence times of slope failures depended on watershed area. If slope failures can be regarded as near surface processes, then rainwater storage that causes slope failures would be independent of watershed area. However, if slope failures are not of near surface processes, slower hydrological processes would influence the slope failures and they would be dependent on watershed area. Towards the aim, we estimated watershed-scale rainwater storage at several watersheds with different watershed areas. We employed a methodology to estimate watershed-scale rainwater storage that was developed in our research group. The result showed that watershed-scale rainwater storage that caused slope failures increased with watershed area. This result suggest that slope failures are not just near surface processes but also slower processes deep in soil that would contribute to slope failures in relatively large watersheds.

Sediment dynamics after the 1973 landslide event in mountain watersheds of Hokkaido, Japan

*Takashi Koi[1], Yasutaka Tanaka[1]

1. Center for Natural Hazards Research, Hokkaido University

When landslide or debris flow occurs due to heavy rainfall in a watershed, sediment movement becomes apparent instantaneously and locally in the form of a landslide disaster. On the other hand, not all of the produced sediment flows out at once, but part of the sediment is temporarily stored in the lower part of slopes or in river channels, and then moves and propagates downstream due to rainfall and other floods. These sediments stored in a watershed will be debris-flowed during the subsequent large-scale flooding, promoting sediment disasters again, and there is concern about effects of abnormal reservoir sedimentation at downstream storage dams. Therefore, to understand sediment dynamics after landslide event is important in terms of watershed management. In this study, we created a multi-period digital surface models (DSM) before and after the occurrence of a sediment production event, and clarified sediment dynamics on a scale of several decades from comparison with time-series hydrological data and vegetation invasion into river channels. Study sites are three mountain watersheds in Kotani’ ishi, Hokkaido, Japan, where multiple landslides occurred due to heavy rainfall event in 1973. The DSM was created by Structure-from-motion (SfM) using archive data of aerial photographs taken during nine periods from 1972 to 2008 and results of a field survey conducted in 2020. As a result of the investigation, although there was no noticeable movement of stored sediment for at least 35 years after the landslides, relatively large-scale sediment movement that caused riparian disturbance during flooding since 2009 has occurred. These results indicate that the constant sediment movement of the stored sediment is not remarkable, but that the sediment may cause large-scale sediment movement even after several decades since the occurrence of landslides.

Keywords: sediment movement, structure-from-motion (SfM), aerial photographs, decadal and longer time scales, landslide event, sediment disaster

Factors controlling concentration of dissolved ^{90}Sr and ^{137}Cs in river water in the Chernobyl exclusion zone.

*Matsushita Koki[1], Yasunori Igarashi[2], Yuichi Onda[1], Yoshifumi Wakiyama[2], Alexei Konoplev[2], Gennady Laptev[3], Sergii Obrizan[4], Volodymyr Demianovych[4], Mark Zheleznyak[2]

1. Tsukuba University, 2. Institute of Environmental Radioactivity at Fukushima University, 3. Ukrainian Hydrometeorological Institute, 4. Chernobyl Ecocentre, State Agency of Ukraine on Exclusion Zone Management

Dynamics of radionuclides, ^{90}Sr and ^{137}Cs, are still of great interest for mitigating radiological risks in the Chernobyl Exclusion Zone (CEZ) and its downstream area. Previous studies showed positive relationship between dissolved ^{90}Sr concentration and water discharge and it suggest that hydrological characteristics affects the ^{90}Sr transfer. However, in practice, the dynamics of radionuclides is closely related not only to hydrological characteristics but also to chemical characteristics and the surrounding environment. For understanding formation of solution concentration in the river water system, several studies attempted to evaluate spatial-temporal variations of factors of interest in a catchment and discussed relationship between catchment characteristics and the behavior of the factors. Such approaches can improve our understanding of radionuclides dynamics. The aim of this study is to clarify the factors controlling dynamics of radionuclides in the river water system in the CEZ and we evaluated spatial-temporal variations in dissolved ^{90}Sr and ^{137}Cs concentration in a small catchment. The study site was in the Sakhan catchment, locating at approximately 7 km northwest from the Chernobyl Nuclear Power Plant. Water samples were taken at main stream, tributaries and water spring points each season. The discharge rate was determined by cross-sectional survey of flow velocity and water level at the same time as water sampling. Each catchment area was made from digital elevation model (DEM) data and mean ^{90}Sr and ^{137}Cs inventory for each sub-catchment was determined by distribution maps of radionuclide. Moreover, the proportion of wetland in dry and wet season was calculated from satellite spectral images. In laboratory, samples were analyzed for dissolved ^{90}Sr and ^{137}Cs, dissolved anions and cations and Si concentration. Discharge rate at the main stream was the highest in snowmelt season and the lowest in summer. The concentration of dissolved ^{90}Sr and ^{137}Cs at the main stream was, as like discharge rate, high in snowmelt season and low in summer. However, the response of dissolved ^{90}Sr concentration to discharge rate was not clear at the spring points and river water in some headwater catchments. We also found that the positive relationship between the area of wetland and dissolved ^{90}Sr and ^{137}Cs concentration in the snowmelt season. Previous studies have showed that “wetlands” and “high water level in the floodplain” can affect high ^{90}Sr discharge. However, the relationship is not clear during the summer. From these results, the tight coupling between hydrological processes and the ^{90}Sr and ^{137}Cs concentration formation processes is suggested, and further study is necessary to elucidate the mechanisms that control the ^{90}Sr and ^{137}Cs concentration in the river water systems.

Explication the effect of thinning on suspended sediment runoff in a cypress and cedar plantation forest by end-member mixing analysis using Fukushima-derived Cs-137, Cs-134 and Pb-210ex

*Motosuke Kinoshita[1], Yuichi Onda[2], Soo Youn Nam[3], Hiroaki Kato[2], Takashi Gomi[3], Chen-wei Chiu[3], Keisuke Taniguchi[4]

1. University of Tsukuba, 2. Center for Research in Isotopes and Environmental Dynamics, University of TSUKUBA, 3. Tokyo University of Agriculture and Technology Institute of Agriculture Division of International Environmental and Agricultural Science, 4. Fukushima Prefectural Centre for Environmental Creation

Skid trail and heavy machinery for forest practice becoming more common for effective forest practices, but these causes soil disturbance in the forest, leading to a sudden increase in the amount of suspended sediment during and post thinning. The discharged sediment can flow into the river and may cause downstream water pollution. To evaluate the effect of thinning on sediment production, sediment fingerprinting techniques can be an effective tool for proper forest practices.

In Tochigi prefecture in Japan, in addition to the Cs-137 by global fallout and Pb-210ex, additional FRN, the Fukushima-derived Cs-137 and Cs-134 on March 2011 are available, but few studies area available for combining use of Fukushima-derived radiocesium and fallout Pb-210ex. Therefore, the objective of this study is to determine the transport of the fine sediment in the forest pre- and post- thinning with using fingerprinting techniques.

The study area is Mt. Karasawa, located 180 km southwest of the Fukushima nuclear power plant in Tochigi prefecture. The fallout inventory of Cs-137 and Cs-134 is 8 kBq/m2(Kato et al, 2012). The study site has two catchments which are called K2(17ha) and K3(9ha) respectively and the observation period was from August 2010 to August 2019. In K2, strip thinning was performed with heavy machines from June to October 2011 while randomly thinning without heavy machines was applied for K3 from January to March 2013.

Soil samples were collected from the slope surface, skid trail and stream bed, which are the possible sources of suspended sediment. The suspended sediment concentration was measured based on the data of the turbidity censor installed in the stream. The particle size distribution and radionuclide concentration of sediment collected from SS sampler and soil samples are also measured.

Hysteresis analysis based on suspended sediment concentration and flow rate and fingerprinting using Fukushima-derived Cs-137, Cs-134, and Pb-210ex, a natural radioactive isotope, was applied to determine the contribution of the slope surface layer and streambed to suspended sediment. By using the difference in the depth distribution of Cs-134 and Cs-137, the production source depth of suspended sediment was estimated.

In the K2 catchment where strip thinning was performed with heavy machinery, suspended sediment concentration during high flow period was rapidly increased up to 333 kg/day during thinning period. It is 30 times more than pre thinning. Then suspended sediment amount decreased down to 503 mg/L after

©2020. Japan Geoscience Union. All Right Reserved.

thinning. On the other hand, in the controlled catchment(K3), no increase in suspended sediment amount was observed during the same period.

By using hysteresis analysis, contribution from forest soil to suspended sediment increase from 0% to about 50% during thinning and that trend had continued by 3 years later of thinning. After that, contribution from stream bed increase and slope decreased.

By using End- Members Mixing analysis, contribution from streambed to suspended sediment are similar to the hysteresis analysis except for the period of midterm of thinning to immediately after thinning. In that period, contribution from the slope also decreased. It is considered to increase the sediment production from skid trails.

Then we focused on the characteristic of the soil from skid trail, which show low Pb-210ex content. In K2 catchment, Pb-210ex in suspended sediment quite decreased during thinning period to 1 month after of thinning. However, Pb-210ex in suspended sediment didn’t change during thinning. It is assumed that contribution from skid trails is very high during and soon after thinning.

Keywords: thinning, Cs-137, suspended sediment, finger printing

[A-HW37] Interdisciplinary approach to support climate change adaptation measures in regional scale

convener:TEBAKARI TAICHI(Toyama Prefectural University), Yadu Pokhrel(Michigan State University), Masashi Kiguchi(University of Tokyo), Sompratana Ritphring(Kasetsart University)

In Japan, the impact of climate change has already become apparent and may become even more serious in the future. For example, there are the following specific damages; crop damage such as mandarin orange edema and white immature grains of rice, health hazards such as the northward distribution of Aedes albopictus and heat stroke patients, meteorological disasters such as increased torrential rain and increased number of strong typhoons, and coral bleaching Ecosystem.
The climate change adaptation law, which was enacted in 2018, clarified the legal position of adaptation measures in Japan, and is a legal for the national, local governments, businesses and citizens to cooperate and cooperate to promote adaptation measures. Based on this law, the Climate Change Adaptation Information Platform (A-PLAT) was established to develop and provide tools to support information provision and adaptation actions, and to collect, organize and provide best practices. AP-PLAT and T -Overseas development such as -PLAT is also progressing. Overseas expansion such as AP-PLAT and T-PLAT are also progressing.
In each research field, it is necessary to promote effective adaptation measures based on reliable and detailed information, and measures based on scientific knowledge of future impacts and strengthening of adaptation in the region are urgently needed.
This proposed session would like to invite presentations on the latest achievements in interdisciplinary fields such as hydrology, agriculture, forestry, weather, and climate that support specific climate change adaptation measures, as well as on the development of new research.

International Interdisciplinary Collaboration Essential to Linking the Changing Antarctic Ice Sheets with Global Coastlines

*Robin Elizabeth Bell[1]

1. Lamont Doherty Earth Observatory of Columbia University

International collaboration together with innovative technology have produced tremendous leaps in our understanding of the Antarctic Ice Sheet. Before the International Geophysical Year we did know how much water was locked in the Antarctic Ice Sheet. Before the launching of the modern suite of international satellites that measure the ice sheet elevation, velocity and mass we had no good constraints on how quickly the ice could change. Before we were collected and shared data on the structure of the ice sheet, the age of the ice and the temperature of the surrounding oceans we did not have good constraints on what might drive rapid change. Now we have the framework of warming oceans can trigger rapid change at grounding lines of marine ice sheets and warming atmospheres may lead to rapid collapse of buttressing ice shelves. Increasingly we are seeing the impact of the changing Antarctic ice along the coastlines around the globe. Our challenge has expanded from discovery of new frontiers to understanding how fast the ice will retreat and how fast the sea levels will rise. The ongoing work at US-UK effort at Thwaites Glacier is an example of internal collaboration targeting a vulnerable, rapidly changing marine outlet glacier. Looking as the Antarctic system as a whole, it is essential that we as the international community work collaboratively to understand the Antarctic ice-ocean-atmosphere-solid earth system. Our recent interdisciplinary work over the Ross Ice Shelf has built a framework for addressing ice sheet stability from a systems framework that enables new discoveries and eventually improved projections of how sea level will change at coastlines from Mumbai to Manhattan.

Development of climate change-related data accumulation system in Thailand

*Masashi Kiguchi[1], Chaiporn Jaikaeo[2], Eiji Ikoma[1]

1. The University of Tokyo, 2. Kasetsart University

Although certain data may be available to researchers, accessing that data in a usable form is not always straightforward, especially for researchers without a programming background. Some data, such as weather observations, are accessible only for a short time. Historical datasets are usually not easy to download due to the large file sizes, which tend to consume an organization's network bandwidth. Although some organizations provide historical data, these are often in a form that is difficult to extract. For example, the Electricity Generating Authority of Thailand (EGAT) allows access to dam-operation data spanning many decades using an interactive web application. Researchers can view the data for a given date, and individual data points can then be copied into a spreadsheet. This procedure can be repeated as many times as needed; however, it is error-prone and time-consuming, especially when a large dataset is required. The Thai Meteorological Department (TMD) and Royal Irrigation Department (RID) use a different approach, by providing Application Programming Interfaces (APIs) that can specify data types and time periods of interest when downloading a dataset. This method saves considerable time and network bandwidth, but still requires a degree of programming knowledge.
To address these shortcomings and facilitate data access for researchers, our project (ADAP-T; Advancing Co-Design of Integrated Strategies with Adaptation to Climate Change in Thailand) has designed a data-sharing architecture. The main servers are responsible for downloading and archiving data in various forms from related organizations. At the time of writing, the ADAP-T project has been archiving weather observations and runoff data from the TMD and RID via their respective APIs. The TMD also publishes hourly QPE (Quantitative precipitation estimation) data, which can also be downloaded and archived. The EGAT, whose dam operation data are required by several groups, does not allow access to raw data, so a web scraping technique must be used. The archived data are then provided to ADAP-T researchers via a unified API, as well as simple comma-separated values (CSV) files. The results produced by different groups are also collated and can be accessed by researchers outside the ADAP-T project, if permitted. Unique results not found on other websites can be visualized in an interactive fashion and viewed by adaptation policymakers and the general public.

Development of future climate scenario based on multi GCMs of CMIP5 and rain gridded data observed by multi-agencies in Thailand

*Masashi Kiguchi[1], Ruthaikarn BUAPHEAN[2], Aphantree YUTTAPHAN[2], Boonlert ARCHEVARAHUPROK[2], Eiji IKOMA[1], Taikan OKI[1,3]

1. The University of Tokyo, 2. Thai Meteorological Department, 3. United Nation University

A bias-corrected future climate scenario is developed using multiple General Circulation Models (GCMs) outputs of CMIP5 (Coupled Model Intercomparison Project Phase 5) and rain gridded data observed by Thai Meteorological Department (TMD), Royal Irrigation Department (RID), and Department of National Parks, Wildlife and Plant Conservation (DNP) in Thailand during the period from 2080 to 2099. This dataset enabled us to conduct a projection considered spread in projections derived from multiple GCMs. Multiple performance-based projections were obtained using the correlation of monsoon rainfall between GCMs and several agencies observations. Because these three agencies (TMD, RID, and DNP) observation network covered mainly plain, area of along river, and mountainous region, respectively, it could avoid underestimating when we use only TMD and RID dataset as usual. Our results highlight the importance of appropriate evaluation for the performance of GCMs, and the impact assessment on climate change.

Interannual variability of timing of monsoon-onset in South East Asia

*Ryosuke Kato[1], Tomohito Yamada[2]

1. Hokkaido university graduate school of engineering, 2. Hokkaido university faculty of engineering

There has been a lot of flooding in recent years in many places around the world because of climate change. In Thailand, in August 2011, there was a record-breaking heavy rainfall and the flood occurred on Chao Phraya river basin. About 800 people died in the flood and more than 9 million people suffered. In addition to human damages, the floods did much damage to agriculture area, industry area and urban area, and the total damage approximated to about 30 billion yen. The seasonal prediction of rainfall plays an important role in operating the dams for controlling the flood.
Especially, the onset of rainy season has an effect on agricultural fields. Rice production is one of the major agricultural practice in Thailand. It contributes 3600 which is about 12% of Thailand’ s GDP. In Thailand, Farmers usually raise two rice crops a year. The first seeding time and the second cultivating time is after the onset of rainy season. So, the onset of rainy season plays an important role in the rice agriculture. In the other agriculture fields, they also need to store adequate water in dams on rainy season to irrigate on dry season for cultivating rice whole year. For irrigating steadily in dry season, the seasonal prediction of rainfall is also utilized in operation of the large dams as dams can store more than 100 billion tons.
In this paper, we first examined the variation in onset of rainy season in Thailand by 37 years for the period 1981-2017. The definition of the monsoon onset date was the first Julian pentad in which monsoonal rainfall exceeds 5 mm/day following the method of Wang and Lin Ho [2002]. This variable is defined by the difference between the pentad mean and the January mean precipitation rates. The quantity is referred to as the relative pentad mean rainfall rate. Here, January mean rainfall represents the winter mean precipitation rate. Thus, the pentad essentially measures the contrast of the rainfall rates between a specific pentad and the corresponding winter.
We defined dates of monsoon onset by climatological pentad mean rainfall during 1981-2000 and compared the climatology with the pentad mean during 2001-2017. The monsoon onset dates in the western part of Thailand have shifted in advance of 10 days earlier. In the contrast, the onset dates in the eastern part of Thailand have shifted delay about 5 days.
To analyze possible factors causing the onset of rainy season, we applied probability density function to the onset dates and classified the earlier onset years and the later onset years. We examined the difference of the wind at 850hpa, 500hpa and 200hpa between earlier’ s year mean and climatology during 1981-2000. We followed the Welchi’ s t-test and took significant difference at 95 % level. On May, western wind from Indian ocean becomes larger at 850hpa and eastern wind along 15N becomes larger than climatology.

Deep learning for seasonal to sub-seasonal rainfall prediction in Chaophraya river basin

*Kiyoharu Hasegawa[1], Shinjiro Kanae[1]

1. Toyko Institute of Technology

In Thailand 1-2 month ahead rainfall prediction is essential for flood mitigation of Chao Phraya river basin. Especially it is needed to decide dam operation for both purpose of preventing drought and flood. Such a seasonal to sub-seasonal scale prediction still remains as difficult problem since numerical prediction contains large uncertainty in this time scale. On the other hand, observed data has been collected for years and statistical analysis skill appeared as the possible solution. One of the most powerful statistical modeling methodology is deep leaning in terms of detecting hidden relationship beneath the complex combination of atmosphere, ocean and land conditions. In the field of rainfall prediction, however the number of observed data is still limited and not enough to train the deep learning model. It requires hundreds of data which enables us to use many variables. To overcome lacks of data, this research applied some data expanding methodology and verified its influence on modeling.

Seasonal precipitation forecast model in wet and dry seasons using global monthly surface temperature by deep learning

*Shingo Zenkoji[1], Taichi Tebakari[1], Kazutoshi Sakakibara[1]

1. Toyama Prefecural University

In recent years, the number of extreme weather events has increased around the world, it has caused disasters such as drought and flood. Water management in Thailand has been very difficult because of conflicting extreme disasters such as drought and flood has occurred continuously in the same area. A typical method of predicting precipitation was a numerical prediction model based on physical equations. However, the accuracy of long-term precipitation prediction using numerical prediction model has not yet reached a level applicable to practical use. In this paper, seasonal forecast of monthly precipitation model in Bangkok, Thailand was made using deep learning and global surface temperature.

The used data were the global monthly surface temperature and monthly precipitation. The analysis period was from January 1958 to August 2017. The training phase was from January 1958 to December 2007, and the test period was from January 2008 to August 2017. Used data within training phase was divided into study data and validation data. Natural observation data had the characteristic that the number of occurrences decreased as the intensity increased. In order to eliminate the variation in precipitation intensity between the training data and the validation data, used data within training phase was rearranged them in the order of precipitation intensity and separated.

In this study, a seasonal precipitation forecast model was developed using convolutional neural network. Convolutional neural network algorithms excel in image processing. First, an ensemble forecast of precipitation was performed using random elements from machine learning. As a result, the forecasted precipitation was underestimated when the precipitation by JRA55 was large, and the forecasted precipitation was overestimated when the precipitation by JRA55 was small. It was difficult to predict monthly precipitation such as the past maximum. The range of predicted precipitation was different depending on whether or not the monthly precipitation by JRA55 exceeds 200 mm. As a cause of this, it was considered that the influence of the monthly surface temperature was different between the low intensity precipitation phenomenon and the high intensity precipitation phenomenon. For this reason, in this paper, as an initial study, the used data was divided into a dry season (November to April) and a rainy season (May to October). Precipitation forecast models in each period was developed.

Case 0 was a precipitation forecast model created using all the data of the training phase regardless of the season, and Case 1 was a precipitation forecast model created by dividing the used data into the dry season and the rainy season.

According to the validation data results, in Case0, the MAE was 55.3 mm and the RMSE was 74.2 mm. In Case 1, the MAE was 56.1 mm and the RMSE was 73.7 mm. Comparing the results of the dry season between Case0 and Case1, MAE was 2.7mm smaller and RMSE was 7mm smaller in Case1 value than in Case0 value. Comparing the results of the rainy season between Case0 and Case1, MAE was 4.5mm bigger and RMSE was 4.9mm bigger in Case1 value than in Case0 value.

According to the test data results, in Case0, the MAE was 49.1 mm and the RMSE was 66.2 mm. In Case 1, the MAE was 54.6 mm and the RMSE was 70.3 mm. Comparing the results of the dry season between

©2020. Japan Geoscience Union. All Right Reserved.

Case0 and Case1, MAE was 3.0mm smaller and RMSE was 3.8mm smaller in Case1 value than in Case0 value. Comparing the results of the rainy season between Case0 and Case1, MAE was 13.8mm bigger and RMSE was 9.1mm bigger in Case1 value than in Case0 value. The prediction accuracy of the dry season was higher, but the prediction accuracy of the rainy season was lower when the models were created for the two seasons-the dry season and the rainy season.

Using weather pattern recognition to classify and predict summertime heavy rainfall occurrence over the Upper Nan river basin, northwestern Thailand

*Ryosuke Kato[1], Dzung Nguyen-Le[2], Tomohito Yamada[2]

1. Hokkaido university graduate school of engineering, 2. Hokkaido university faculty of engineering

In Thailand and the Asian monsoon region in general, water-related disasters have taken many lives and devastated infrastructure such as bridges, roads, buildings, electrical grids and telecommunication. To mitigate damaging effects of such severe events, precise and timely rainfall prediction is crucial. In addition to dynamical approach, various statistical techniques have been proposed to improve the prediction of rainfall. Typically, in the case of statistical rainfall prediction, a perfect prognosis (PP) method in which a statistical relationship is established between a local-scale observed ‘predictand’ (i.e., rainfall) and simultaneously observed large-scale ‘predictors’ (e.g. temperature, humidity, wind or geopotential height) is taken and then applied to predicted ‘predictors’ derived from a global model to yield forecasts of the ‘predictand’. The weather pattern (WP) recognition such as the Self Organizing Map (SOM), developed by Kohonen (1982; 2001), is one of the widely used methods to determine this relationship. Nguyen-Le et al. (2017) recently uses SOM in combination with the K-means clustering to objectively classify the anomalous WPs causing heavy rainfall days over northern Kyushu, southwestern Japan, during the Baiu season. The classification results are then implemented with the PP and analogue method (Lorenz, 1969) to predict the occurrence (yes/no) of heavy rainfall days in the region. The forecast skill of this relative new method ASOM (combination of Analogue forecast and SOM) up to 7-days lead times is significantly improved than that from the traditional method using only the predicted rainfall intensity from an operational global model. Here, a work extending Nguyen-Le et al. (2017) to summertime (May–June, MJ, and July–August–September, JAS) heavy rainfall over the Upper Nan river basin (17.375° –19.375°N, 99.875° –101.125°E) in northwestern Thailand is conducted.
First, it shows that in MJ, intensive rainfall over the Upper Nan is mainly brought by the remarkable enhancement of westerly summer monsoon. Meanwhile, westward-propagating tropical disturbances including tropical cyclones are the primary factors reproduce heavy rainfall over the Upper Nan in JAS. It also suggests that the occurrence time of local heavy rainfall is strongly related to the seasonal transition of summer monsoon in the Indochina Peninsula.
These classification results are then used to predict the occurrence of heavy rainfall days in the studied basin in summer 2008–2017 using prognostic WPs from the operational Japan Meteorological Agency Global Spectral Model (GSM). In general, the forecast skills of ASOM up to 3-day lead times are significantly improved, in which it not only outperforms GSM with same forecast ranges but also its 3-day forecast is better than
1–2-day forecasts from GSM. However, the false alarms ratio is still high, particularly in JAS. In addition to overall results, the differences in the performance of ASOM between years and heavy rainfall-inducing WPs are evaluated. It is shown that it strongly depends on the WPs that bring heavy rainfall events. More specifically, the skill is higher if the WP is limited to one phenomenon such as intensified westerlies or tropical disturbances. In contrast, ASOM has more difficulties to capture the WP imposing the interaction between the monsoon westerlies and the trade easterlies or northeasterly winds. It is also suggested that the performance of ASOM (for the heavy rainfall occurrence) and GSM (for the prognostic WPs) is roughly in phase.

Impact of Rainfall on Urban Traffic Flow based on Probe Vehicle Data in Bangkok

*Tsuyoshi Takano[1], Hiroyoshi Morita[1], Shinichiro Nakamura[2], Miyazaki Hiroyuki[3], Wasan Pattara-atikom[4], Napaporn Piamsa-nga[5]

1. Nippon Engineering Consultants Co., Ltd, 2. Nagoya Univ., 3. Asian Institute of Technology, 4. National Electronics and Computer Technology Center, 5. Kasetsart Univ.

Adverse weather frequently affects the capacities and travel speeds on roadways, which result in worsened traffic congestion and incurred productivity loss. Further, with climate change predicted to increase rainfall in various cities in Southeast Asia, the risk of flood damage in this region is not only anticipated to increase and affect urban function but may also significantly aggravate daily traffic flow. This study highlighted an analysis of the effect of rainfall on urban traffic flow through the use of probe vehicle data and rainfall data in the center of Bangkok, which is known for problems with respect to maintenance of pumps and drainage channels and for many flooded roads after heavy rainfalls.

The probe vehicle data (observed in 2018) used in this study were obtained from open data (historical raw vehicles and mobile probe data in Thailand) provided by the Thai Intelligent Traffic Information Center Foundation. This data consists of Vehicle ID, GPS location collected every minute, time stamp, and speed. The rainfall data are a 5-minute unit data obtained (in 2018) from the Bangkok Metropolitan Flood Control Center.

To explain the relationship that exists between rainfall intensity and travel speed, regression models are developed.

The experimental results demonstrated that the average daily travel speed decreases by 0.02 km/h per 1 mm of daily rainfall. Especially during morning and evening peaks, the average travel speed greatly decreases due to 1-h rainfall (short-term impact) and 6-h rainfall (long-term impact) when compared to the case of no rain. As a result, loss time due to rainfall in 2018 was estimated to be about 4 million hour which is equivalent to 5% of the loss time due to much traffic demand.

Future rainfall forecast data makes it possible to assess the risk of climate change on urban traffic flow.

Investigation of Extreme Flood Changes in the Mekong River Basin Using +4K Climate Simulation

*Sophal Try[1], Shigenobu Tanaka[1], Kenji Tanaka[1], Takahiro Sayama[1], Chantha Oeurng[2]

1. Kyoto University, 2. Institute of Technology of Cambodia

The future changes in frequency and intensity of precipitation will definitely affect the flooding due to climate change leading to the future direction for the development of social infrastructure. The study of flood was done by using the precipitation output from the climate model as input data to the hydrologic model. The uncertainty of climate simulation due to an insufficient number of ensemble members was inadequate to capture the change of the edge of the phenomenon. For this reason, the application of large ensemble data would reduce the uncertainty of climate simulation. This study aims to (1) define the effective duration of precipitation which has the highest correlation to the annual maximum flood in the Lower Mekong Basin (LMB); (2) assess the change of flood severity under climate change impacts using large ensemble dataset from Database for Policy Decision-Making for Future Climate Change (d4PDF). The data is available for 60-year (1950-2010) with 100 ensemble members for historical climate; the future climate simulation (2050-2110) consists of 90 ensemble members which were simulated under 4 K warmer experiment by 6 patterns of sea surface temperature (SST) from CMIP5 models. The flood inundation in the LMB was simulated using a coupling rainfall-runoff and inundation (RRI) model with 2-D diffusive wave approximation. The statistical Kolmogorov-Smirnov (K-S) test of two samples was used to determine the significant difference between the two cumulative distribution function (CDF) for each future SST pattern. The Generalized Extreme Value (GEV) was used for fitting the extreme flood. The results indicated that 90-day precipitation counting backward from the day of peak flooding has a high correlation to peak inundation volume and discharge (both R-sqr = 0.81). The historical simulation of d4PDF was able to catch up the past observed flood events in the LMB in 78 years of the data record (1934-2011) which had good agreement with the ensemble mean. The K-S test revealed the majority of significant difference of discharge simulation from each SST (i.e. 14 out of 15 cases) while the null hypothesis from only one case was accepted at a significant level of 5%. The relative changes of future and past experiments of 1:50, 1:100, and 1:1000 year flood events showed an increase by +25%, +33%, and +40% for peak discharge at Kratie and +19%, +29%, and +36% for inundation extent, respectively. In conclusion, the magnitude of extreme flood in the LMB in the future will definitely be severer than the historical experiment. To reduce its impacts and damages, we need to implement effective water resource management as well as flood mitigation and adaption countermeasures.

Climate change and land use change impact assessment on flood and inundation in a river basin in Sumatra island in Indonesia

*Kodai Yamamoto[1], Takahiro Sayama[2], Apip Apip[3]

1. Graduate School of Engineering, Kyoto University, 2. Disaster Prevention Research Institute, 3. Research Center of Limnology, Indonesian Institute of Sciences

Indonesia will face challenges on flood disaster management and environmental problems due to climate change. Previous IPCC AR5 describes that monsoon-related precipitation will increase in Southeast Asian countries. Combined with precipitation increase, larger urban area will be exposed to coastal floods and river floods in Indonesia (Muis et al. 2015). In addition, deforestation and land use change increase of flood hazards in a tropical catchment (Tarigan 2016). Moreover, tropical peatland area is more likely to have the significant impact due to flood hazards, where large area is developed for agriculture plantation.

One of the challenges of climate communities is to reproduce rainfall spatial and temporal patterns by GCM in many islands in oceans between the Indian and Pacific Oceans, which is known as Maritime Continent. This can attribute to coarse resolution of topography or imperfect representation of local weather in Maritime Continent. Regional Climate Models has high potential to represent the local weather at finer resolution. In addition, there are many studies on rainfall projections but their impact on river discharge is still limited in Indonesia (Ammar et al. 2016; Hero Marhaento et al. 2018). Moreover, very limited studies focus on the impact on inundation phenomena at catchment scale.

The primary objective of this research is to assess the possible climate change impact on flood and inundation in a catchment. This study uses Atmospheric General Circulation Model ver. 3.2 (hereafter AGCM) and Non-Hydrostatic Reginal Climate Model (hereafter NHRCM) developed by Japan Meteorological Research Institute (MRI). NHRCM is a regional climate model, which is dynamically downscaled at less than 5 km resolution with boundary condition of AGCM at 20 km resolution (Sasaki et al. 2008). Bias correction is applied to correct AGCM/NHRCM-simulated rainfall and evaluated based on annual maximum (1) daily and (2) 15 days rainfall. We discuss the impacts of the bias correction on hydrological projections using Rainfall-Runoff-Inundation (RRI) model (Sayama et al. 2010) applied to one of the largest river basin in Sumatra Island in Indonesia under current and future climate conditions. We assess the results according to (1) flow duration curve, (2) annual maximum daily discharge and (3) annual maximum inundation pattern/volume. Finally, future impact on flood is analyzed with the most reliable rainfall datasets of non-/bias corrected AGCM and NHRCM. RCP8.5 was used for the future scenario of climate change. Furthermore, future land use data (land use 2040) and climate change (RCP8.5) was applied to RRI model. The results of RRI model and was compared with the results of climate change ones with only RCP8.5 to clarify which impact is more significant.

AN ASSESSMENT OF RESERVOIR OPERATION POTENTIAL FOR FLOW REGULATION IN THE CHAO PHRAYA RIVER BASIN

*SARITHA PADIYEDATH GOPALAN[1], Naota Hanasaki[1]

1. National Institute for Environmental Studies

The flow regulation of the Chao Phraya River is very crucial due to the frequent flood and drought occurrences. Therefore, it is essential to maintain a lower limit (to stabilize the flow) and an upper limit (for the flood control) of outflow, which can be achieved by building structures such as reservoirs. There are several large and small-sized reservoirs in the basin and many of them are multi-purpose that could be used to regulate the flow in the Chao Phraya River. Hence, this study examines the efficacy of the eight existing reservoirs for regulating the flow in the basin by quantifying the low as well as high flows for the baseline (1990-1999) as well as future (2090-2099) scenarios. The hydrological analysis was performed using the H08 global hydrological model with the reservoir operation module. The effect of the individual reservoir was analyzed at a point downstream to it, and the cumulative impact of all reservoirs was assessed at Nakhon Sawan and Bangkok, two major cities within the Chao Phraya River basin. It was clear from the baseline scenario simulation that the individual reservoir operation considerably reduced high flows with an exceedance probability of 10% (Q_{10}) and improved the low flows with an exceedance probability of 95% (Q_{95}). The Q_{10} was reduced to 1485 m^3/s from 1992 m^3/s, and the Q_{95} was increased to 233 m^3/s from 13 m^3/s at Nakhon Sawan after the cumulative reservoir operation. A similar pattern was observed for Bangkok City with a reduced Q_{10} value of 1837 m^3/s from 2366 m^3/s and an enhanced Q_{95} value of 265 m^3/s from 17 m^3/s. This further reveals that the reservoir operation can regulate the river flow by storing water in the wet season and releasing it in the dry season, and hence it benefits both flood and drought mitigation. Further, the simulated results for the future scenario exhibited an immense increase in the high flows compared with baseline scenario which can be attributed to (i) the climate change that increases precipitation/streamflow in the wet season, and (ii) the increased projection of precipitation by some general circulation models. The reservoir operation was able to reduce the downstream high flows to some extent, whereas as they well maintained the low flows. The results demonstrate that the Chao Phraya River basin is more likely susceptible to floods than the droughts in the near future which can be alleviated by combining structural as well as non-structural measures.

Regional climate change impact on water quality in the lower Chao Phraya River, Thailand

Taichi Tebakari[1], Sanit Wongsa[2], *Horiuchi Yusuke[1]

1. Toyama Prefectural University, 2. King Mongkut's University

River water quality requires a great deal of time, labor, and cost for measurement and analysis, but could be useful background information for returning to the present situation in the event of a quality problem. However, in developing countries and middle-developed countries, environmental water quality standards are still low, and many rivers do not satisfy even those standards. In Thailand, which has been middle-developing country in recent years, the environment of river water has not been significantly improved since 1996 due to socio-economic development, and it is the fact that major rivers are deteriorating. Also, in recent years, the change of river water quality is very complicated due to the construction and operation of many hydrological structures throughout the Chao Phraya River. Bangkok, is located on the coastal lowland, Thailand. At present, most of the tap water used in Bangkok is taken from the Chao Phraya River, which flows on the coastal lowland. This intake is located in the brackish water area of the lower Chao Phraya River. In the dry season, the rise in salinity of rivers and the rise in sea level caused by climate change may affect the intake. The Thai government has identified the Chao Phraya River as a priority area, where salinization is a problem in terms of water quality management.

Therefore, water quality observations were conducted in the lower Chao Phraya River November 2016, March 2017, August, November, April 2018, June and November, and using the results of the Thai government's automatic water quality observations from August 2016 to February 2020, By comparing these data (water level, discharge, air temperature, water temperature, pH, EC, salinity and dissolved oxygen) with each other, the secular variation of the water quality characteristic of saltwater run-up was clarified.

As a result, in the dry season, pH ranged from 7.2 to 8.2 along the river, from neutral to slightly alkaline. The water temperature was found to be between 28 ˚C and 34 ˚C along the river. The DO was very low, less than 3 mg / l from the estuary to 80 km from the estuary in the dry season from November to April. There was no seasonal change in pH, but the seasonal change in water temperature was about 4℃ between the dry season and the rainy season. The water quality along the Chao Phraya River was high salinity, low water temperature and low oxygen. In the rainy season, the water quality along the Chao Phraya River was low salinity, high water temperature and high oxygen state. the increase and decrease of EC were clearly divided according to the water level fluctuation during the rainy and dry seasons. It was found that the saltwater intrusion range was changed by the difference of discharge volume of Chao Phraya Dam during the rainy season and the dry season. During the rainy season, the salinity intrusion was suppressed by the natural discharge from the Chao Phraya Dam. In the dry season in February, the peak of EC increase was observed and the value was high from 80 to 100 km from the estuary. In the dry season of 2016 and 2020, the salinity of the intake water exceeded the standard of raw water in Thailand of 0.5 g / L. Thus, it is thought that the seasonal change is closely related to the inflow of saltwater due to the difference in discharge from the Chao Phraya Dam.

Research on the current thermal energy budget of land surface by continuous observation of near-surface ground temperature in Kanto Plain, Japan

*Osamu Matsubayashi[1], Hideki Hamamoto[2], Sachio Ehara[3]

1. National Institute of Advanced Industrial Science and Technology, 2. Center for Environmental Science in Saitama, 3. Institute for Geothermal Information

We are conducting a study on present-day changes of ground temperature at depths down to 1.0 m from the surface in order to know the physical processes currently occurring on the land surface. In the last few decades there have been many works to obtain by mathematical inversion the past climatic changes based on deep downhole temperature data, which are given as function of depth. But, we think that the relationship between such downhole temperature anomaly signals and the ongoing near-surface processes have not been fully clarified yet. For addressing such an issue we have started a campaign of long-term monitoring of near-surface ground temperature at some locations in the Kanto Plain area, Japan.

Three observation sites are selected in the Kanto Plain: Tsukuba in Ibaraki Prefecture, Toda and Sayama both in Saitama Prefecture. At these sites we have had good records of 1m depth ground temperature (denoted as GT1.0) for more than 4 years, and partly supplementary temperature records at shallower depths such as GT0.3 (those at 0.3 m depth). It is noted that one-year period ground temperature change is the most prominent component at all those sites, and we see longer phase delays and also larger amplitude attenuation of the sinusoidal variation at the deeper part of the same sites, where surface temperature is likely to be the primary driving force. Therefore, to compare with the change of ground temperature we have employed different information, which is time-series of satellite derived land surface temperature for each of the sites. In this study LST (Land Surface Temperature) data from MODIS sensor on Aqua and Terra satellites have been used. The observed LST seasonal change may be controlled by that of solar radiation from above to the particular sites. From the above-mentioned dataset, i.e., MODIS-LST, GT1.0, and GT0.3, we have attempted to estimate the effective thermal properties of the near-surface subsurface layers of the sites, with a result of fairly large variations of thermal properties among our study sites depending on the surface material characteristics.

Good Practices for Climate Change Adaptation in Agricultural Sector, Thailand

*KOSHI YOSHIDA[1]

1. Ibaraki University

Meteorological Uncertainty caused by Global Climate Change would have significant impact on agricultural sector, because agricultural systems are strongly affected by local climate condition. In Thailand, agriculture is major sector which producing 11% of GDP and 40% of employment. Ratio of irrigated agricultural land is 30% and other 70% is rain-fed so that climate change makes agriculture more unstable and also makes crucial damage to the societies and economics in local area. To mitigate these issues, it is desirable to develop and disseminate enhanced adaptation systems including impact assessment tool for drought problem by using water-soil-plant model, mapping technology of shallow ground water or soil salinity, and development of adaptive farming practice. Therefore, in this study, we introduce the good practices of following topics related to agricultural adaptation measures under CC condition in Thailand.

1.Enhancement of Production System Management in Orchid farming
Low water levels in the Chao Phraya River cause seawater intrusion. Salinity, in irrigation water, is one of the major environmental limiting factors for growth and productivity of orchids. Since orchid farmers do not know much about the effect of salinity, they are afraid of using saline water to irrigate mature plants, especially in the flowering stage. Therefore, the objective of this research was to determine the interaction between water salinity level and duration of growth, flower quality and photosynthesis parameters. And new growing material, the cement block and coconut shells were tested.
2.Development of Drought Monitoring Platform in whole Thailand
This research mainly develops drought monitoring model based on satellite data which can provide drought risk map country-wide on a weekly basis. In addition, an algorithm to combine phenological and demographic data will be pursued to generate a drought vulnerability map. Such results can be analyzed with other group’ s results (via Multi-Criteria Analysis) to provide useful information to the government for adaptation and mitigation to Climate Change.
3.Salt Affected Soil Mapping and Future Projection of Soil Salinity Level under Climate Change Condition
In North East Thailand, annual rainfall is about 1200mm and average rice yield is only 2.1 t/ha (rain-fed). In addition, 50% of total land area in this region are classified as salt affected area. Therefore, salt-affected soils are major environmental problems in NE Thailand. In future, climate change may cause negative impact on salt-affected soil problems. In this study, we investigate the climate change impact on salt affected soil, establish more useful salt affected soil maps to propose appropriate cropping system/crop calendar under CC condition.
4.Evaluation of Potential Yield of Shallow Ground Water for Countermeasure in Drought Problem
This research aimed to assess shallow ground water use for agricultural farming, as the countermeasure of severe drought problem. Firstly, we monitored the seasonal fluctuation of shallow ground water level in Dan Chang district, Suphanburi province, based on resistivity mapping data. Then, sugarcane yield estimation model was developed and applied. And numerical simulation was conducted to estimate the potential sugarcane yield by using shallow ground water.
5.Evaluation of Weather-Induced Economic Damage on Agricultural Production
In The Twelfth National Economic and Social Development Plan (2017), the Thai government advised farmers to cultivate cash crops rather than rice to increase farmer income. However, some upland crops

©2020. Japan Geoscience Union. All Right Reserved.

are more sensitive to climate condition than rice, so weather-induced economic damage should be previously evaluated for each crop. Therefore, in this study, weather-induced economic damages of rice and upland crops such as sugar cane and cassava were evaluated in Northeast Thailand.

Furthermore, it is necessary to conduct reliable research to find ways to achieve economic betterment through agriculture under CC condition. Therefore, cost-benefit analysis also should be applied to consider the possible and acceptable ways and planning.

Evaluation of salinity effects on rice production in farmers' fields in Ban Phai, Khon Kaen, Thailand

*YI YANG[1], Rongling Ye[1], Thanyaluck Nontasri[2], Mallika Srisutham[2], Supranee Sritumboon[3], Masayasu Maki[4], KOSHI YOSHIDA[5], Kazuo Oki[6], Koki Homma[1]

1. tohoku university, 2. Khon Kaen Univ., Thailand, 3. LDD, Thailand, 4. Fukushima Univ., 5. Ibaraki Univ., 6. Univ. Tokyo

Northeast Thailand is the major rice producing region in Thailand, but rice yield there is quite low. One of the major causes is salinity, which is derived from underground rock salt and anticipated to increase in the future under climatic change. Salinity lands in Thailand were classified into class 1 (severe) to class 4 (slight) depended on percentage of salt occupation on land surface, but the classification is not associated with crop productivity. Accordingly, field evaluation for assessment of rice production is recommended. This study evaluated salinity condition during rice cropping and its effect on rice growth and yield.

Field investigations were conducted at farmers' fields in Ban Phai district, Khon Kaen provice, Thailand, during September to November in 2017, 2018 and 2019. The fields were classified into class 2 to 4. Leaf area index (LAI) or leaf coverage (LC) was measured every week to evaluate rice growth and rice yield was determined by sampling. Soil EC and moisture were also measured every week and other soil properties suck as organic matter (OM) and exchangeable cations were determined occasionally. Drone images were also taken every week to evaluate spatial variation in rice growth.

Soil EC was significantly higher in severer class, but the clear thresholds between classes were not observed. Difference in precipitation among investigated years (the highest in 2017 and the lowest in 2018) also caused that in average soil EC (the highest in 2018 and lowest in 2017). Although the relation was not consistent, decrease in soil moisture content tended to increase soil EC.

Rice production was also affected by precipitation. The amount of precipitation seemed abundant in 2017, but scarce in 2018. The amount in 2019 was intermediate but some famers gave up planting because the precipitation in the first half of rainy season was quite limited.

The relation between rice yield and soil EC was not obvious, because the yield quite varied even though the EC level was similar. However, the classification of salinity level of USDA based on electrical conductivity of a saturated soil extract (ECe) clearly showed that rice yield was damaged by salinity level. The classification suggested that rice yield was damaged by slightly salinity level of ECe = 2~4 dS/m. The analysis of rice yield in 2018 showed that the primal factor of rice yield was drought and then salinity; that in 2019 showed rice yield was affected by interaction between salinity and OM.
Drone image analysis during dry season for salt occupation and rainy season for rice growth may contribute the evaluation of salinity level for rice production.

Calibration of cultivar parameters of SIMRIW-RS (rice simulation model for remote sensing) for the rice growth monitoring in Thailand

*Koki Homma[1], Mongkol Raksapatcharawong[2], Watcharee Veerakachen[2], Peerapon Prompitakporn[2], Masayasu Maki[3], Kazuo Oki[4]

1. Tohoku University, 2. Kasesart University, 3. Fukushima University, 4. The University of Tokyo

Rice production is one of the most important agriculture in Thailand. Because the production variability caused large impact on the people living, the assessment of disaster impact before harvest is recommended. The authors have been developing a satellite based observation system for the purpose by employing SIMRIW-RS, a rice growth simulation model for remote sensing. SIMRIW-RS would be applied anywhere, but preparation of cultivar parameters is recommended before the application in order to adjust the relation between rice growth and production.

To obtain cultivar parameters, rice growth and production data obtained in a farmer’ s field in Nongchok districe in Bangkok was used. 50 sample points were selected from the field of 6.88-ha. The growth was evaluated in terms of LAI measured by LAI-2200 (Li-Cor Ltd), above ground biomass and grain yield was measured by 1-m^2 harvesting at the maturity.

The phenological parameters for the cultivar were substantially derived from the parameters that the authors previously obtained for a Thai rice cultivar, and adjusted for the growth duration provided as the cultivar information. The parameters for LAI growth was estimated on the basis of average LAI change for the 50 sample points with air temperature. The parameters for production against LAI growth was also estimated on the basis of average above ground biomass and grain yield for the 50 sample points.

LAI growth at each sample points can be calibrated by using the estimated cultivar parameters for the phenological development and LAI growth, and the calibration produces field parameters to explain locational variability for rice growth and production. The field parameters suggest the field has a large variability of soil fertility, most of which were caused by that of chemical fertilizer application. The estimated rice grain yield after the calibration showed a relative consistency with the measured yield, suggesting the estimated parameters would be reasonable.

Farmers' perception of climate change induced drought in the Northeast Thailand

*Miki Nodera[1], Keigo Noda[1], Koshi Yoshida[2], Mallika Srisutham[3]

1. Gifu University, 2. Ibaraki University, 3. Khon Kaen University

Monsoon Asia has two distinct seasons; the rainy season and the dry season. This region has 52% of the total population of the world and future population is anticipated to increase. In this situation, climate change will greatly affect the social economy. There are two directions to control the progress of warming. One is emission reduction measures (mitigation measures) to suppress global warming, and the other is adaptation measures to the adverse effects of global warming. Northeast Thailand has an area and population approximately one-third of Thailand but Gross Regional Product (GRP) is the lowest in the country. In this region soil has low fertility and low water retention capacity and some areas have salt damage. The irrigation rate is the lowest in the country. So this region is vulnerable for climate change. So we have to promote adaptation measures.

We conducted a questionnaire survey in Khon Kaen province, Thailand in order to grasp farmers' condition of basic profile, agricultural management and perception of climate change. Three villages were selected to compare the different availability of agricultural resources in terms of salt damage and irrigation water. After that we analyzed objective data of rainfall monitoring and agricultural statistics in order to validate the results of questionnaire survey.

According to the 72 farmers' questionnaire result, the type of water used mainly differs by village. Many farmers recognized seasons from weather forecast and they decided to plant rice at the same time as last year or when they thought rainy season start. And they thought their farmland is not stable because of water shortage. About perception of climate change, many farmers thought rainfall had decreased and it caused low yield.

Crop calendar is more same in villages without water restrictions. According to the analysis of rainfall and agricultural statistical data, it's difficult to think that rainfall in cultivation period had decreased. In addition planting area, harvested area and production had also increased. So analysis result differed from farmers' perception.

According to the analysis of the relationship between rainfall and production, the timing of rainfall affecting production was different between the 1900s and 2000s. And dry spell which is the period of little rain in the rainy season appears in various timing. So we thought farmers thought rainfall had decreased and yield had decreased because rainfall patterns had changed compared to the past and they could not adapt that pattern. So if we could forecast the rainfall a few months ahead and propose a crop calendar suitable for the rainfall in the year, we thought it would be an adaptation measure.

Research on farmers' awareness of adaptation to climate change and its information collection and sharing in rural area in Thailand

*Kyoko Matsumoto[1], Mallika Srisutham[2], Supranee Sritumboon[3], Sompratana Ritphring[4], Masashi Kiguchi[1], Taikan Oki[5]

1. Institute of Industrial Science, The University of Tokyo, 2. Facutly of Agriculture, Khonkaen University, 3. Land Development Department, 4. Faculty of Engineering, Kasetsart University, 5. Institute for Future Initiatives, The University of Tokyo

This research was conducted to clarify farmers' awareness of adaptation to climate change and its information collection and sharing in rural area in Thailand. Data were collected using face to face questionnaire survey from a total sample of 50 farmers in Khon Kaen province. The questionnaire was developed based on the semi-structured interview which was conducted in Songkhla province to extract components of questionnaire on perception, information collection and sharing of climate change and adaptation using previous studies. The data from questionnaires were collected in 2018. The attributes of respondents were fifties (34.0%) and sixties (30.0%), farmers (100%), Buddhism (100%) and natives of the study area (62.0%) have higher proportions.

It was found that 100% of respondents answered that they perceived local climate change, and 78.0% of respondents answered that their lifestyles were affected by climate change. Nevertheless, 92.0% of respondents answered that "I do not have willingness to adapt to climate change" and "I cannot decide whether I will take adaptation measures or not" from a long-term perspective. The proportion of respondents who perceive that lifestyles have been changed by climate change or natural disaster is high. However, even if the frequency of natural disaster increase, those who have willingness to do adaptation is less than half of respondents. Those who "undecided to take adaptation" have potential to take adaptation by providing appropriate information on adaptation.

Moreover, we found that 96.0% of respondents got climate information from TV. Next to TV, the percentage of respondents are high in the order of local wisdom based on their own experiences (58.0%), neighborhood (54.0%), radio (40.0%), SNS (Social Network Services) (24.0%), public speaker (18.0%) and TMD Smart Simulation (4.0%) which is weather forecast application at current location provided by Thai Meteorological Department (TMD). Regarding reliability of information resources, the highest percentage of "very reliable" and "reliable" information sources are TV (100%) (n=48), radio (100%) (n=20), public speakers (100%) (n=9) and TMD Smart Simulation (100%) (n=2). Next to neighborhood (96.3%) (n=27), SNS (91.7%) (n=12), local wisdom (82.8%) (n=29). Here it can be seen that it is necessary to make climate information spread from various sources.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-CC Cryospheric Sciences & Cold District Environment

[A-CC38] Ice cores and paleoenvironmental modeling

convener:Ayako Abe-Ouchi(Atmosphere and Ocean Research Institute, The University of Tokyo), Ryu Uemura(Nagoya University), Kenji Kawamura(National Institute of Polar Research, Research Organization of Information and Systems), Nozomu Takeuchi(Chiba University)

Analyses of ice cores from polar and mountain regions have contributed to the reconstruction and understanding of the past environmental changes on timescales from years to several hundred thousand years. In this session, we welcome paleoenvironmental studies using ice cores and paleoclimatic modeling. Studies on reconstruction methods, recording processes and new paleoenvironmental proxies, technical aspects of paleo-modeling are also welcomed. Studies with marine sediment cores, terrestrial sediment cores and tree-rings on similar timescales are also important and welcomed, in order to discuss past environmental changes from multidisciplinary viewpoints.

We analyzed the chemical compositions of dust and sea-salt particles in the EPICA Dome C (EDC) ice core during 26–7 kyr BP using an ice-sublimation technique, and compared the results with existing data of the Dome Fuji (DF) ice core. Combined with ion concentration data, our data suggested similar sea-salt fluxes in both cores and significantly lower dust flux in the EDC core. The differences in modal size and aspect ratio of dust particles between the two cores support the dominance of Patagonian source suggested by earlier works. The compositions of calcic dust showed major change at ~17 kyr BP, possibly reflecting a relative increase in dust transported via the upper troposphere. The calcium sulfate fraction was higher in the DF core than in the EDC core after ~17 kyr BP, suggesting that higher Patagonian dust contribution to the DF region. Abundant NaCl particles were found in the DF core in comparison with the EDC core from the LGM to early Holocene, possibly because of the high concentration of terrestrial dust in the DF core that reduced acid availability for sea-salt modification. During the Holocene, the lower NaCl fraction and Cl^-/Na^+ ratio in the EDC coresuggested that most Cl^- was lost to the atmosphere from snow at Dome C, while it was preserved at Dome Fuji as NaCl and solid solution.

Evolution in geometry of firn in ice sheets detected by dielectric anisotropy

*Shuji Fujita[1,2], Kotaro FUKUI[3], Mikihiro Hirabayashi[1], Iizuka Yoshinori[4], Sumito Matoba[4], Atsushi Miyamoto[5], Takeshi Saito[4], Hideaki Motoyama[1,2], Toshitaka Suzuki[6]

Ice in polar ice sheets once experience a state of firn at near-surface depths. Therefore, it is important to understand physical processes of firn formation, metamorphism and deformation for ice core studies. We investigated firn through measurement of tensorial values of the dielectric permittivity at microwave and millimeter-wave frequencies. This method can detect presence and strength of anisotropic structure in the geometry of pore spaces and ice matrix. We applied the method to many firn cores drilled at both ice sheets. We find that firn that have shorter residence time at the near-surface depths does not form strong vertical anisotropy that is caused by vertical movement of moistures. In contrast, firn that have longer residence time at the near-surface depths tend to form vertical anisotropy. When density exceeds more than ~600 kg/m3, a common feature of firn at many polar sites is that there is evolution of vertically elongated features of pore spaces in firn despite growth of vertical compression. We hypothesize an explanation as follows. As firn becomes denser, air within firn escape to upward directions as compared to sinking firn. In firn, porous structure tends to have vertically elongated structure because of this vertical escape movement of air. The observed phenomena of the growth of the vertical dielectric anisotropy can be understood by this vertical movement of the air within firn.

Dielectric anisotropy measurement of Dome Fuji ice core and implications for crystal orientation fabric development

*Tomotaka Saruya[1], Shuji Fujita[1,2]

1. National Institute of Polar Research, 2. The Graduate University for Advanced Studies

Crystal orientation fabric (COF) is one of important factors in the physical properties of ice cores. Deformation and flow of ice-sheet ice are highly controlled by COF development. Generally, orientation of c-axes is measured using ice thin sections and crystal fabric analyzers. For the last decades, several systems of automatic fabric analyzers were invented. However, automatic methods still require making many thin sections of ice, which means that we need much effort and a long time. In addition, numbers of crystal grains within a thin section are of the order of several hundreds. To make bulk ice-core based measurements of the COF possible, we developed a new measurement method for COF of ice cores by measuring tensorial components of the dielectric permittivity of ice core using an open resonator.
Hexagonal ice crystal has physical properties with uniaxial symmetry around the c-axis. The dielectric property also has such a symmetry. High-frequency- limit permittivity in ice is approximately 3.15 under the temperature of Cryosphere of the earth. The difference in permittivity between parallel and perpendicular to the c-axis is approximately 0.037 (Fujita et al., 1993). Based on this anisotropic property of each crystal grain, polycrystalline ice has macroscopic anisotropy of permittivity caused by COF. By measuring the macroscopic dielectric property parallel and perpendicular to the ice core axis, we can estimate the degree of the c-axis cluster around the vertical.
We investigated Dome Fuji Station ice cores drilled at Dome Fuji, the second highest dome summit in East Antarctica. To better understand meaning of the COF with respect to glacial processes, successive measurement was performed with an interval of every 5 m. At each step, 1 m-long ice core was measured continuously with a resolution of about 30 mm. Measurements were done to a depth of 1800 m. We used an open resonator of microwave using frequencies between 15 and 20 GHz. All measurements were conducted under -30C in a cold temperature room. We used thick sections of slab-shaped ice core samples with thickness between 35 and 75 mm, which contains 1000 times volume of ice compared with thin section measurements.
As a result of the successive measurement down to 1800 m, we observed that the dielectric anisotropy increased with increasing depth. This trend is consistent with the c-axis clustering toward the core axis due to the uniaxial compression. In addition to the large-scale trend of increase, we found the small fluctuations of the degree of the c-axis cluster with scales of 10 –100 m. In this presentation, we discuss variations of the dielectric anisotropy along core depths in terms of (i) insolation at the timing of snow deposition and (ii) the other physical and chemical properties.

Development of a numerical ice-sheet model for simulation of summit dynamics

*Fuyuki SAITO[1], Ayako Abe-Ouchi[2,1], Takashi Obase[2]

1. Japan Agency for Marine-Earth Science and Technology, 2. Atmosphere Ocean Research Institute, Univ. of Tokyo

Ice divides are important locations for deep drilling on ice-sheets. Precise computation around a divide requires spatially very high resolution due to the characteristics of ice-flow around the divide. In addition, ice flow pattern is significantly different between an ice divide and the other areas: the flow around the divide requires more stress terms to compute than the other area, which is still a challenging topic due to its heavy cost of computation.
This study presents a recent development of Ice sheet model for Integrated Earth system Studies (IcIES) in particular, for improvement and inclusion of higher-order mechanics.

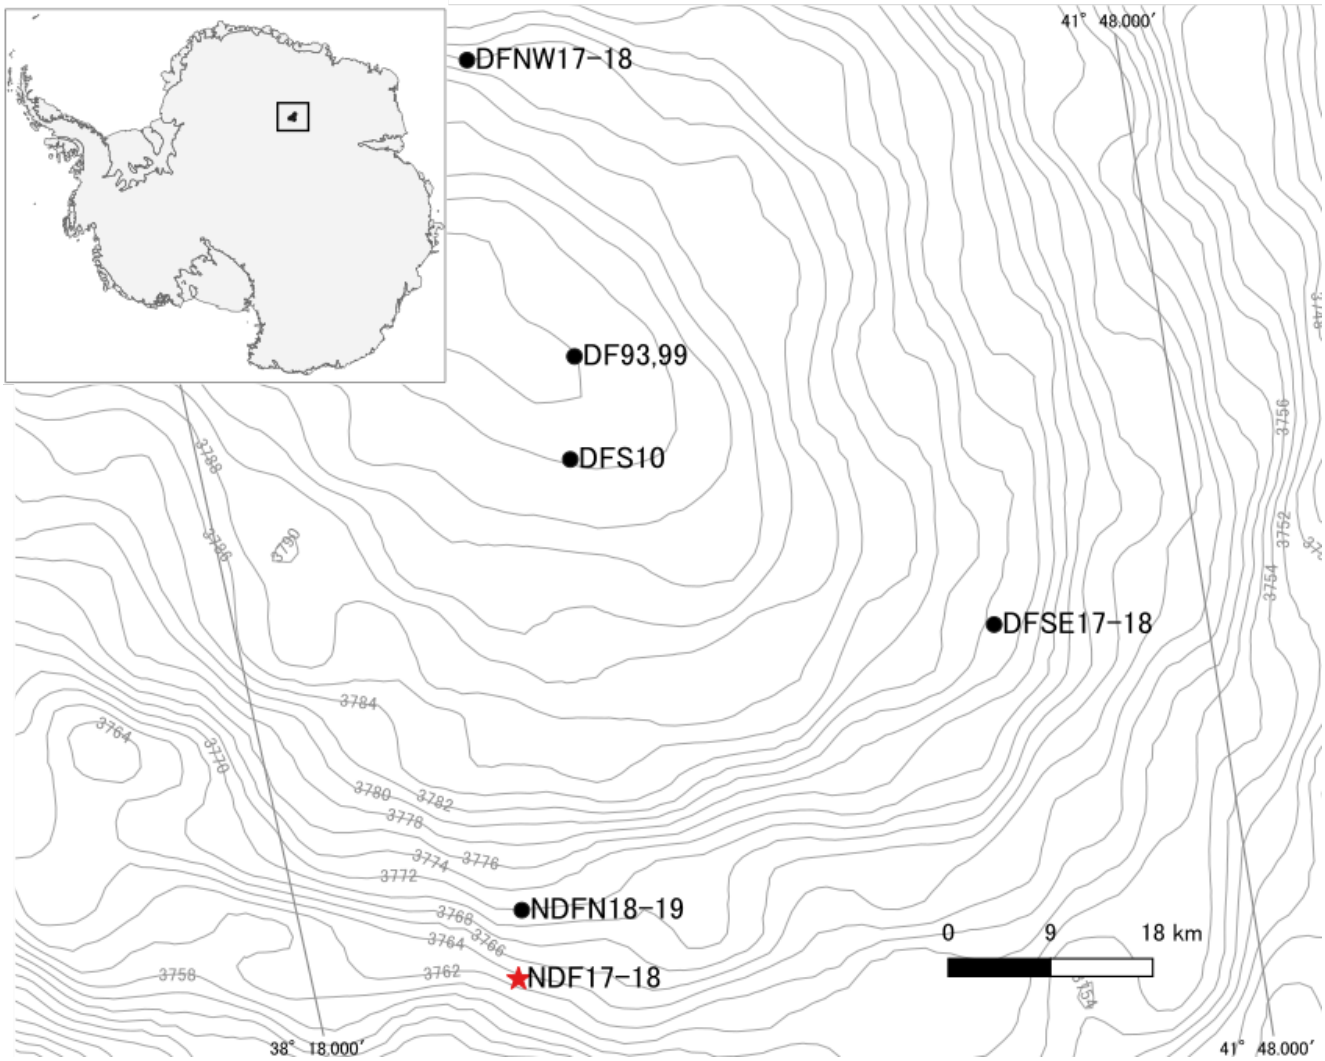
Layering, densification and bubble close-off of firn at a new site near Dome Fuji, East Antarctica

*Ryo Inoue[1], Shuji Fujita[2,1], Kenji Kawamura[2,1,3], Fumio Nakazawa[2,1], Ikumi Oyabu[2]

1. The Graduate University for Advanced Studies, SOKENDAI, 2. National Institute of Polar Research, 3. JAMSTEC



Ice cores provide proxies for chronology and past climatic changes from their ice and gas compositions, and the understanding of firn layering, densification and gas fractionation processes is crucial for better interpretation of the ice-core records. It has been hypothesized that metamorphism and geometric layer structure of firn determines the processes on gas trapping at deep firn, such as the depth range where bubbles are formed, close-off depth and the fractionation of gas components. Fujita et al. (2009; 2016) has reported in detail the layer structure of firn around Dome Fuji, East Antarctica. However, little is understood on the relationships between the geometric layer structure, bubble formation, and gas fractionation. For example, degree of growth of geometric anisotropy differ from one location to another (Fujita et al., 2016), but it is not known as to how such site-dependent difference influences gas trapping process. Another example is poor understanding of the effect of insolation on ice crystal fabric formation and/or water isotope composition. Therefore, it is important to clarify spatial variability of geometric properties of firn and gas trapping process to compare site-dependent variability of ice core signals, especially because a deep drilling of an oldest ice core is planned near Dome Fuji in the near future.

A new shallow ice core was drilled to ~152 m in December 2017 at a site about 54 km south of Dome Fuji station (named NDF, 77°47’ 18S, 39°3’ 15E, 3763 m a.s.l.). Up to now, we have measured multiple physical properties on this ice core; density and geometric anisotropy using a dielectric permittivity tensor measurement, near-infrared reflectance of firn (a proxy for specific surface area) using an optical method, and qualitative measure of permeability using an air-suction system. We also plan to analyze gas component of bubbles at high resolution to quantify gas fractionations in layer-by-layer scale. In the JpGU presentation, we will report the results of the physical properties on the NDF shallow core and compare them with those from the Dome Fuji and Dome Fuji South cores (Fujita et al., 2009; 2016).

Fig. Shallow core sites around Dome Fuji. Numbers after site names indicate the drilling season.

PMIP4/CMIP6 Last Interglacial simulations using different versions of MIROC, with and without vegetation feedback

*Ryouta O'ishi[1], Wing-Le Chan[1], Ayako Abe-Ouchi[1,2,3], Sam Sherriff-Tadano[1], Rumi Ohgaito[3]

1. Atmosphere and Ocean Research Institute, the Universitoy of Tokyo, 2. National Institute of Polar Research, 3. Japan Agency for Marine-Earth Science and Technology

We carry out a Last Interglacial (LIG) experiment, named lig127k and a Tier1 experiment of PMIP4/CMIP6, using three versions of the MIROC model, MIROC4m, MIROC4m-LPJ and MIROC-ES2L. The results are compared with reconstructions from climate proxy data. All models show summer warming over northern high latitude land, reflecting the differences between the distributions of the LIG and present-day solar irradiance. Only MIROC4m-LPJ, which includes dynamical vegetation feedback from the change in vegetation distribution, shows warming signals, even for the annual mean, at northern high latitudes, as shown by proxy data. However, the latest Earth System Model (ESM) of MIROC, MIROC-ES2L, in which there is only a partial vegetation effect through the leaf area index, shows no change or even annual cooling over large parts of the northern hemisphere. Results from the series of experiments show that the inclusion of vegetation feedback is necessary for the reproduction of the strong annual warming over land at northern high latitudes. The LIG experimental results show that the warming predicted by models is still underestimated, even with dynamical vegetation, compared to reconstructions from proxy data, suggesting that further investigation and improvement to the climate feedback mechanism are needed.

Response of convective systems to changes in orbital forcing of the last interglacial

*Minoru Chikira[1], Yohei Yamada[2], Ayako Abe-Ouchi[1], Masaki Satoh[1]

1. The University of Tokyo, Atmosphere and Ocean Research Institute, 2. Japan Agency for Marine-Earth Science and Technology

We ran a number of simulations using a global nonhydrostatic atmospheric model coupled with a slab ocean model for the orbital parameters of the last interglacial. The model used in this work is Nonhydrostatic ICosahedoral Atmospheric Model (NICAM): a framework to resolve cumulus convection when used with a proper resolution. Because of the limit of computational resources, we use NICAM with a horizontal resolution of 56km. The simulations were run with and without cumulus scheme to compare the performance. The integrations were continued for 5 years. The boreal summer climate of the last interglacial shows an enhancement of the monsoon activity. The spatial pattern of the mean-state precipitation is quite similar between the simulations with and without cumulus scheme, while the cumulus scheme tends to moderate the peak precipitation. Since the strength of NICAM is in its representation of variability associated with convective systems, we gave particular focuses on the behaviors of the equatorial waves and tropical cyclones represented by the model. We found that the Madden-Julian oscillation (MJO) is better represented in the present simulation when using the cumulus scheme. We also found that the signal of the MJO is stronger in the last interglacial, which was found both in the coherence-squared and lag-correlation regardless of the use of the cumulus scheme. Although the model does not represent the boreal summer intraseasonal oscillation (BSISO) very well, the lag-correlation shows its greater signal in the last interglacial. In particular, the lag correlation in the simulation of the last interglacial run with the cumulus scheme shows a very clear pattern of the BSISO, comparable to that of the present-day observation. The change in the global genesis frequency of the tropical cyclones was different depending on the use of the cumulus scheme. It decreases without the cumulus scheme, while it increases with the cumulus scheme.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-GE Geological & Soil Environment

[A-GE40] Subsurface Mass Transport and Environmental Assessment

convener:Hirotaka Saito(Department of Ecoregion Science, Tokyo University of Agriculture and Technology), Shoichiro Hamamoto(Department of Biological and Environmental Engineering, The University of Tokyo), Yuki Kojima(Department of Civil Engineering, Gifu University), Yasushi Mori(Graduate School of Environmental and Life Science, Okayama University)

This session covers the topics on fluid flow and mass transport in geological media. Subjects related to laboratory testing, subsurface characterization, theoretical analysis and numerical modeling will be discussed. Presentations on geo-pollution, remediation, geological disposal of hazardous wastes, mass transport in vadose zone, and environmental assessment are especially encouraged.

Environmental Impact Assessment of Open Loop Geothermal Heat Pump System in Gifu City, Central Japan

*Randa Permanda[1], Tomoyuki Ohtani[1]

1. Gifu University

Geothermal heat pumps (GHPs) are most efficient and eco-friendly energy that used for heating and cooling system. In Japan, the number of shallow geothermal installations has increased by year. Open loop GHPs is a type of GHP system which use groundwater as heat source for heating and cooling of building. In fact, there are still no regulations related to thermal use of groundwater and the subsurface in Japan. The aim of this study is to simulate regional and local groundwater flow and heat transport in study area and to assess the environmental impact by extraction and injection of open loop system from the wells into subsurface.

The study area is an alluvial fan of the Nagara River, Gifu city central, Japan. It is bounded by mountain ranges from north to northeast side and plain area remains. The Nagara River flows in the center of the plain. The underground temperature in alluvial fan is influenced by rapid groundwater flow recharged from the river. Rapid groundwater flow has potentiality to spread the environmental impact of GHP system greater than slow groundwater flow. This alluvial fan is composed of sands and gravels and often intercalate thin fine sand and silt layers. Groundwater flow occur mainly in the Quaternary sediments. For assessment of potential energy of open loop GHP system, regional 3D model of groundwater flow with heat transport in study area was developed using FEFLOW program. Model area has size of 13 km (NS), 12 km (EW) and 300 m (depth). Model is constructed first by geological data. In addition, pre-existing hydrogeological data which consist of groundwater table, underground temperature, and temperature of river water data in study area are compiled to construct the simulation model. Boundary condition of groundwater flow system is defined by water table distribution. Bottom of the model is basement rock, treated as impermeable boundary and lateral sides are set as no flow boundaries. For boundary conditions of heat transport, top and bottom of the model are fixed by constant temperature boundaries. In order to study environmental impact of open loop system, local simulation of open loop system was operated. We built local simulation with more fine mesh to create detailed information with wide area 1.2 km (NS), 1 km (EW) and 100 m (depth). Open loop simulation model was consisting of one extraction and injection wells. Both the extraction and injection wells were screened in the first aquifer (gravel layer). The operation mode was applied for heating from January to March, and cooling from July to September. The operation mode of pumping/injection was obtained a time-varying rate with keeping the temperature difference at constant pumping rate 288 m^3/d. The temperature difference of the pumping and injection are contained 3 variant values: 3, 5, 10˚C for heating and cooling periods.

To confirm the results of regional groundwater flow and heat transport simulation, there were comparison groundwater temperature data between calculated results and measured ones at some points. Based on this result, there is reasonably good match between calculated and measured data at southern region of model. Furthermore, the local simulation of open loop GHP system was shown that the distance of thermal discharge from injection activities gets further as variation of temperature difference increase. When the temperature difference between the pumping and injection is 10˚C, temperature changes caused rising groundwater temperatures surrounding injection area up to 37 m in the beginning of winter season and 47 m in the beginning of summer season. Temperature change is defined by a change more than 0.1°C at groundwater temperatures around injection activities. However, variation of temperature changes have impact to rise groundwater temperature less than 300 m from injection well and it is still in allowable range of interference effect from another open loop GHP system according to regulation of

Estimation of correlation between soil organic matter and soil components using neural network

*Masaki Kiyohiro[1], Yasushi Mori[1], Yutaro Yamamoto[1]

1. Okayama University Graduate school of Environmental and Life Science

Soil is the terrestrial largest carbon storage, and, it is key to predict the carbon storage and loss. However, there are many estimation models, and we still cannot understand natural processes. Therefore, instead of predicting the organic matter from the conventional function system, we thought about letting the neural network learn anew and infer the feature value closely related to the soil organic matter.

Deep learning is a type of machine learning and it is also called a neural network. A neural network is composed of a unit called a node or a layer. The node receives a weighted input, outputs the weighted input to a next layer with a specific weight. After passing through all layers, output data can be obtained. The feature of deep learning is that the weight between each node can be selected other than 0 and 1, and other judgment criteria can be selected. Moreover, by preparing a plurality of hidden layers, it is possible to predict more complicated phenomena.

In this study, we conducted an experiment to predict the amount of organic matter in soil, and to estimate the correlation between organic matter and soil constituents using a neural network.

The surface soil data of HWSD (Harmonized World Soil Database) was used as data for learning. The target areas were Europe, Asia and Australia. The input items (features) are 17 items such as particle size distribution and cation exchange capacity.

In addition, feature selection was performed as data preprocessing. Feature selection is a method of automatically selecting important features to create a highly accurate model. In this experiment, the recursive feature elimination method (RFE) was used. Among the estimation models using the features, the one with the highest accuracy was obtained and its performance was evaluated. The model was used to estimate the effect of the selected feature on the amount of organic matter by changing each feature.

Among the features selected by the high-precision model created from the data of the target area, those that matched in three areas were silt content, dry density, cation exchange capacity of soil, and base saturation.

In addition, a model was created again using the features and parameters selected by the model with the highest accuracy, and the effect on organic matter by increasing or decreasing the value of a specific feature by 10% from the average value was determined. As a result, the impact was confirmed in Europe and Australia.

The experimental results suggest that the base model has a positive effect on the European model and a negative effect on the Australian model. In the Asian model, soil organic matter did not change significantly even when each feature was changed.

Prediction of soil organic matter and correlation estimation were performed using neural networks. Four common features were selected in the high-precision model generated from the data of three regions.

©2020. Japan Geoscience Union. All Right Reserved.

However, it was suggested that the effect of selected features on the amount of organic matter differed from region to region.

Fracture domain of granite based on orientation analysis and its relation to water conducting fractures: an example from the “-500m access/research gallery-North” of the Mizunami Underground Research Laboratory

*Koji Shimada[1], Masakazu Niwa[1], Ryuji Takeuchi[1], Kenji Amano[1]

1. Japan Atomic Energy Agency

Groundwater flow in the deep ground composed of crystalline rocks such as granite is largely controlled by the fracture system. Fracture intersections, steps and branches (spray structure) are potential and spatially linear main water conduits (Sugimura et al., 1997). So, it is important to confirm the applicability and sophistication of the geological technique to grasp the distribution of the fracture intersections. A homogenous region characterized by a predominant fracture direction is called a domain, and the domain boundary is a dense zone of the fracture intersections. To make clear spatial distribution of fracture domain, i.e. domain analysis is, therefore, a simple way to depict spatial distribution of fracture intersections. Sophistication of geological technique at the site-scale could be utilized to wide-scale advanced studies such as geological fracture mapping on the kilometer scale and groundwater discharge in relation to geological disposal of HLW.
Domain analysis of granite on the basis of fracture orientation in the 100 m scale by means of structural geologic techniques such as stereographic projection, Strike Versus Traverse Distance (SVTD) diagram (Marshak and Mitra, 1988) and Sequential Linked Median (SLIME) plot (Fisher, 1993) revealed relationship between distribution of water conducting fractures and fracture orientations. This attempt used fracture data taken from the “-500m access/research gallery-North” of the Mizunami Underground Research Laboratory (Kawamoto et al., 2014a, b). Improvement of the SLIME plot based on running median of span 3 shows domain boundary (large kink of fracture trend) and kink in domains of fracture trend (small kink), and their relation to positions of water conducting fractures (Ishibashi et al., 2016, Hayashida et al., 2018, JAEA, 2020), more clearly. Water conducting fractures are concentrated at these kinks of fracture trend. A location of one of the large kinks corresponds to a region of fractures with geochemically high connectivity from deeper parts. Methods to make SLIME plot would also be shown in our presentation.

Effects of Moisture Content on Soil Water and Ion Movements in the Vicinity of Soybean Roots

*Rui Nakasone[1], Shoichiro Hamamoto[1], Naoto Nihei[2], Taku Nishimura[1]

1. Graduate School of Agricultural and Life Sciences, the University of Tokyo, 2. Fukusima University

Radioactive cesium was emitted from the disabled Fukushima Dai-ichi Nuclear Power Plant on March, 2011, and diffused into the environment, including agricultural area in eastern Japan. As one of most effective countermeasure to reduce Cs uptake by crops, additional potassium (K) fertilization at applying basal fertilizer is recommended. It is generally known that with increasing exchangeable K in soils the soil-to-plant transfer factor (TF) of Cs decreases. However, it is also reported that the TF is variable under lower exchangeable K. Further understandings of Cs uptake by roots, governed by mass transport in the vicinity of roots, are required. Soil physical properties such as moisture content affect mass transport in soils, hereunder influencing water and ion uptake by roots.
In this study, using a rhizobox system, soil water and ion movements in the vicinity of soybean roots were investigated for soils with different moisture contents. Sandy soil taken from the agricultural field at Namie-town, Fukushima Prefecture, Japan was repacked to soil box compartment (width:14 cm x height:10 cm x thickness: 3 cm) in rhizobox system. The ^{137}Cs concentration of the soil was around 3000 Bq/kg. Mass water content (w) of the samples was adjusted to either 20% or 28%. The soybean roots which were pre-grown up to root length of around 6 cm were placed on the surface of soil box compartment. The soybean in the rhizobox was grown for around 7 days in the climate controlled room. After the growth, soil box compartment was removed from the rhizobox and sliced at 2.0 mm interval. Mass water content and ion concentration of each sliced sample were measured.
Results showed mass water content in the soil decreased due to root water uptake and more significant decrease was observed at the condition of w = 28%. In addition, mass of K uptake by the roots was higher at w = 28% as compared to the one at w = 20%. Those results indicate water stress at w = 20% reduced water and K uptake by the roots. Mass of ^{137}Cs uptake was higher at w = 20% as compared to w = 28%, likely suggesting the ^{137}Cs was more selectively absorbed due to reduced K uptake under lower moisture condition. The K and ^{133}Cs concentrations at w = 20% increased and decreased near roots (within 5 mm), respectively, while those concentrations at w = 28% maintained almost constant regardless of the distance from the roots in the soil box.

The effect of gas emission from organic matter on the stability of rice terraces structure

*Yasushi Mori[1], Mayuka Kashi[1], Tomoyo Kurozumi[1], Hiroaki Somura[1], Milagros Ong How[2]

1. Graduate School of Environmental and Life Science, Okayama University, 2. Global Harvester

The rice terraces are not only cultural heritage, but also playing a part of natural material circulation. They contributes to the water conservation and organic matter preservation, otherwise inclined slope causes surface flow and organic matter loss. However, in recent years, rice terraces have not been sufficiently preserved, leading to collapse. In the world heritage rice terraces in Banaue, Philippines, drainage channels are not well-organized, and some of the rice terraces are rich in organic matter in the situation where sewage is mixed. Although ponding water was maintained, this water has been kept by clogging of organic matter or small particles rather than hardpan formation.

In this research, we examined how gas emission prevented hard pan formation. Incubation tube experiment was conducted for gas emission and bulk density change, and also soil column experiment was conducted for water content and Eh measurement. Both experiments were conducted by changing organic matter content.

The results showed that methane gas emission was observed only with one week and the methane stayed in the column in bubble shape, not soluble condition. This was supported by the Eh reduction and volumetric water fluctuation. Bulk density of incubation tube decreased by 10-20%, which would result in unstable basement. Volumetric water fluctuation meant the frequent bubble formation and disappearance, causing fluctuation of basement. If this happens in rice terraces, saturated zone would be deeply developed, making unstable rice terraces which has a risk of collapsing. Therefore, we need to tell local people to check hardpan formation, sewage water control and appropriate organic matter application, rather than just confirming ponded water.

Keywords: rice terraces, methane gass, hardpan, organic matter

Effects of Macropore Structures on Agricultural Soil’s Greenhouse Gases Emission

*Thanh Long Bui[1], Yasushi Mori[1]

1. Graduate School of Environmental and Life Science, Okayama University

Agriculture is not only the important economic sector via production of crop and livestock but also a significant contributor of greenhouse gases emission. In 2010, it contributed slightly more than 10% to total anthropogenic emissions of greenhouse gases, which totaled some 49 billion tonCO_2eq *(Francesco Nicola Tubiello, 2019).* Increasing organic matter stocks in soils reduces atmospheric carbon dioxide *(Nadine Jäger et al, 2011)*, but they may promote emissions of nitrous oxide by providing substrates for nitrification and denitrification and by increasing microbial O_2 consumption or may boost methane emission in anaerobic condition.

Both natural and agricultural wetland contribute an estimated 40 to 50% of total methane emission each year *(G. J. Whiting & J. P. Chanton, 1993)*. According to modern agricultural practices in Southeast Asia’s countries and others such as Japan, Korea, etc., rice is grown in flooding paddy field which reliably generate the great deal of methane in anaerobic condition. To hold maximum water in the fields, hardpan was created under paddy field. This meant that the infiltration to deeper layer was decreased. Meanwhile, roots created macropores played pathways’ role to largely and quickly emit greenhouse gases in soil. It may highly emit greenhouse gases to atmosphere than natural wetland. Increasing greenhouse gases emission is in results of the global warming potential, therefore, study of effects of macropores on the generation process and reduction of soil’s greenhouse gases emission was conducted.

In this study, 1st column experiment was set up for granite decomposition soil (Masa soil) and paddy field soil. Furthermore, 2nd column experiment was conducted for paddy field soil in ponding condition to see the difference between with and without drainage (0.4mm-pinhole). Tubular macropore (1.5mm) and manure were applied to both soil texture in two experiments. Then, methane and carbon dioxide were measured by sensors once a week for 1st experiment and every water-adding time for 2nd experiment.

The 1st experiment results showed that high methane and carbon dioxide emission were observed in paddy field soil in ponding condition. In contrast, low concentration of the gases was observed in Masa soil. The methane and carbon dioxide emission of both soil textures increased in the 1st and 2nd week, then decreased in 3rd week. Both experiments indicated that column with manure showed gases emission much higher than without manure. Thus, organic matter is an important impact factor on the methane and carbon dioxide emission of paddy soil in ponding condition. In addition, macropores played as pathways to emit methane and carbon dioxide with higher concentration of the gases in the columns. This is in accordance with the explanation of K. Kusa et al. (2010). However, the 2nd experiment results also pointed that the methane and carbon dioxide gas emission observed at columns with drain were lower than ones without drain.

Interaction between Nano-Bubbles and Colloidal Particles in Saturated Porous Media under Flowing Condition

Takuya Sugimoto[1], *Shoichiro Hamamoto[1], Taku Nishimura[1]

1. Department of Biological and Environmental Engineering, The University of Tokyo

Nano-bubbles (NBs) have a considerable potential for the remediation of soil and groundwater contaminated by organic compounds, especially when used in conjunction with bioremediation technologies. Understanding the transport mechanisms of NBs in soils is essential to optimize NB-based remediation techniques. In natural soils, there are several types of colloids, which are particles with diameters of around 10 nm to 10 mm, in various organic and inorganic sources: silicate clays, iron and alumium oxides, or humic minerals. Deposited colloidal particles on the soil particles likely affect NBs transport. However, interaction between NBs and deposited colloidal particles in saturated porous media under flowing condition is not fully understood.

In this study, one-dimensional column transport experiments using glass beads with 0.1 mm size were conducted, where carboxyl latex (CL) with 500 nm and NBs created by oxygen gas were consecutively injected to the column at the constant flow rate. Effluents were collected at the same time interval. Bubble and particle concentrations in the effluents were measured by a resonant mass measurements. Results showed that NBs retention was enhanced at the condition where CLs were initially deposited in the porous media, suggesting deposited CLs worked as additional deposition sites for NBs. The obtained breakthrough curves of NBs were well simulated by one-dimensional advection-dispersion equation with first-order deposition kinetics.

Numerical Analysis of the Effects of Capillary Barrier under Subsurface Drip Irrigation to Improve Water-use Efficiency

*Koichi Noguchi[1], Hirotaka Saito[1]

1. Tokyo University of Agriculture and Technology

In semi-arid and arid regions, efficient water-use in agriculture is crucial. The installation of the capillary barrier (CB) has been suggested as a promising approach for such a purpose. CB reduces deep drainage by suppressing the downward water movement. The downside of CB is that it may enhance surface evaporation by keeping irrigated water near the surface (Wongkaew *et al.*, 2018). One of the remedies to water loss by evaporation is to use subsurface drip irrigation (SDI) techniques. However, there are few studies on its feasibility in a system with CB. This study aims to evaluate the feasibility of CB under SDI numerically. The effects of the installation depths of the emitter and CB on water use efficiency were also investigated. In this study, the ring-shaped emitter was used because of its high performance and affordability (Saefuddin *et al.* 2019). HYDRUS (2D/3D) (Simunek *et al.*, 2016) was used to simulate water flow and root water uptake (RWU).

The emitter was installed at 10 different depths within the root zone. CB was installed at 5 different depths below the root. Strawberry and spinach were selected as model plants for the long-root and short-root plants because of their distinct root distributions. The installation depths for the emitter and the CB layer were defined relative to the root depth. The objective function (*OF*) was introduced to evaluate water-use efficiency. Uniform soil water pressure of -80 cm was applied to the Tottori Dune sand profile as the initial condition. The potential evaporation rate was set as 7.0 mm d^{-1}. The bottom boundary condition was set as gravity flow. Durner (1994) model was used to account for capillary flow and non-capillary type flow. RWU was simulated by the compensated model (Šimůnek and Hopmans, 2009).

For the long-root plant (strawberry), the peak of the *OF* value was obtained when the emitter was slightly above half the root depth and CB was inserted immediately below the root, which were found to be the optimal depths. This appears to be the result of the trade-off between active RWU near the surface and intense evaporation from the wetted ground surface. Smaller *OF* values were obtained for shallow-root plants when the emitter is near the surface. The water applied at a shallow depth might increase actual evaporation by wetting the upper layer. The best CB depth was found to be far below the root in this study. Installing CB shallowly may lead to an increase in evaporation and the breakage of CB due to the water accumulating upon CB.

Deformation analysis of fill dams due to level 2 earthquakes using PIV

*Mai Masutani[1], Tomotaka Sato[2], Hirotaka Saito[3], Yuji Kohgo[2]

1. Graduate School of Agriculture, Tokyo University of Agriculture and Technology, 2. United Graduate School of Agricultural Science, Tokyo University of Agriculture and Technology, 3. Department of Ecoregion Science, Tokyo University of Agriculture and Technology

A lot of civil engineering structures have been severely damaged by Level 2 earthquakes. An agricultural fill dam in Fukushima prefecture was failed and washed out due to the Great East Japan earthquake in 2011 and a few people were killed in the downstream region. In order to increase the level 2 earthquake resistances, understanding the failure mechanism of fill dams is necessary. The fill dams normally consist of unsaturated and saturated geomaterials. Namely the parts of fill dams above or below the seepage surfaces respectively remain under unsaturated or saturated conditions. Then we should understand the mechanical properties of both saturated and unsaturated geomaterials. Especially it is very important to consider the unsaturated mechanical properties to understand deeply the failure mechanism of fill dams. In unsaturated geomaterials, pore water pressures are normally negative (suction) and the suction effects play important roles. Kohgo et al. (1993) clarified that there were two suction effects: 1) an increase in suction increases effective stresses and 2) suction enhances the internal confinement and an increase in suction increases yield stresses.

In this research we try to investigate the suction effects in the model levels of fill dams. So, several centrifugal shaking model tests were conducted. Two types of model materials: sandy soil and the soil mixed with silty soil named DL clay and No. 6 Silica sand were used. The dimensions of models in prototype were 6 m in height, 31.5 m and 1.5 m in base and crest widths and 12 m in depth after 30g centrifuge acceleration applied. The inclines of both slopes were 1:2.5. Accelerometers, pore water pressure and pore air pressure sensors were installed inside the model. Laser displacement sensors were set above the models. Input sine waves were applied by increasing their acceleration step by step. Before and after each shaking, photographs were taken using a digital camera mounted in front of the embankment model. These photographs were used to calculate inner displacements by using particle image velocimetry (PIV) technology. The displacement data might be used to estimate volumetric and shear strains within the embankments.

It was found that in the sandy model, the crest deformed roundly and vertically. Moreover, slip failures occurred in both slopes. On the other hand, in the mixed soil model, the whole embankment deformed downward but no slide was observed. The displacement vectors obtained from PIV could well reflect the differences of these deformations. The shear strains in the sandy soil model developed near the slops and finally the volumetric strains changed to dilation there while in mixed soil model both shear and volumetric strains developed at the center of the bottom of the embankment.

Applying PIV to deformation analysis in the fill dam model, the strain distribution could be obtained in detail. As a next step, we will try to discuss totally including the behavior of pore water pressures.

An observation of swelling behavior and microstructural change for granulated bentonite mixtures under controlled relative humidity

*Mazhar Nazir[1], Akihiro Matsuno[1], Takeshi Saito[1], Ken Kawamoto[1]

1. Graduate School of Science and Engineering, Saitama University

The granulated bentonite mixtures (GBM) are considered as potential sealing materials in the radioactive waste disposal concepts due to their high swelling capacity, low permeability and good compaction properties. Therefore, it is necessary that the hydro-mechanical behavior of GBM should be thoroughly examined for an efficient design of the repository. This study investigated the swelling behavior and microstructural change of a GBM. OK Bentonite from Kunimine Industries, Japan, was used in this study. First, OK Bentonite grains were sieved and the particle size distribution was adjusted to follow a fuller curve (similar to FE-GBM used by NAGRA, Switzerland). Air-dried GBM samples (RH = 60%, T = 20º C) were packed at dry density 1.2 and 1.3 g/cm^3 in the apparatus and then stored at RH = 95% to observe the swelling behavior and microstructural changes with time (t = 0, 1, 2, 4, 8 weeks). A constant volume rigid cell was used to measure the swelling pressure. The microstructural changes were observed by Microfocus X-ray Computerized Tomography (MFXCT) system. The results provided a quantitative observation of microstructural changes in the GBM under the swelling process at a controlled relative humidity and a better insight to understand the complex hydro-mechanical behavior of the GBM.

Season Effect of the Operation of IPCC Reactor on Solar Photocatalysis of Phenol Wastewater

*Wen-Shiuh Kuo[1], An-Chi Chen[1]

1. National United University, Taiwan

Solar photocatalysis with partial shell-core Ag(0.1%)/P3HT(0.5%)@TiO_2 as catalyst was used to treat phenol wastewater (10 mg/L) in a pilot-scale inclined plate curvature channel (IPCC) reactor. Season effect on the performance of IPCC reactor was investigated. Results showed that the degradation efficiency of phenol in water (180 min) with Ag(0.1%)/P3HT(0.5%)@TiO_2 as photocatalyst were 98.35%, 95.06%, 98.92%, and 99.89% in autumn, winter, spring, and summer (in which UV_{a+b} intensity: 32.85, 27.80, 37.92, 45.86 W/m^2, respectively; VIS intensity: 743.91, 723.05, 822.72, 869.48 W/m^2, respectively), respectively. The degradation efficiency of phenol in water were increased 28.79%, 32.78%, 22.29%, and 5.19%, respectively and phenol degradation rate (k_{phenol}) were increased 2.94 times, 2.73 times, 2.66 times, and 1.98 times, respectively in four season as compared to using TiO_2 as photocatalyst. With the assistance of Fresnel lens (39.5 cm L*39.5 cm W*2 mm T, Fresnel circle width: 0.5 mm, Facet depth: 0.2 mm, Fresnel circles: 395), solar light intensity (UV_{a+b}) were increased approximately 1.86 to 2.34 times and the temperature of wastewater could be raised about 5 ˚C. Hence, the degradation efficiency of phenol wastewater were increased 12.4%, 6.29%, 19.18%, and 2.72% in autumn, winter, spring, and summer season, respectively as compared to that without Fresnel lens. Moreover, the molecules of phenol were more efficiently decomposed into hydroquinone, p-benzoquinone and low-molecular-weight organic acids which were further mineralized into CO_2 and H_2O. The mineralization efficiency of phenol wastewater could reach almost 60% in summer season. Accordingly, it was showed that the Fresnel lens enhanced IPCC reactor would be a promising operation system for solar photocatalysis not only in effectively dealing with a large amount of industrial organic wastewater such as phenols wastewater, but also in the sector of energy conservation in terms of efficient utilization of solar energy for practical application.

Keywords: solar photocatalysis, phenol wastewater, inclined plate curvature channel reactor (IPCC), Fresnel lens

Solar photocatalysis of MeO wastewater with metal@TiO_2 film

*Ting-Yu Zeng[1], Ling-Syuan Tzeng[1], Wen-Shiuh Kuo[1]

1. National United University, Taiwan.

One of advanced oxidation processes (AOPs) - solar photocatalysis with novel Ag@TiO_2 film as catalyst for the treatment of an azo dye (methyl orange (MeO)) wastewater was investigated in this study. Ag@TiO_2 films were prepared successfully by a Dip-coating method and following by a photoreduction method on glass plate. The results of SEM/EDS analysis illustrated that Ag nanoparticles were partially and indeed deposited on the surface of TiO_2 film. The UV-VIS/DRS spectra showed that Ag@TiO_2 film could extend the absorption of TiO_2 film in visible light band, which reduced the defect that TiO_2 film could only absorb ultraviolet light band (λ <387 nm) and made it more efficient to use solar energy. The diagram of XRD analysis showed that Ag@TiO_2 film would not change the basic crystal structure of TiO_2 and the characteristic peak of Ag (2θ : 44.27^0) was observed. Under solar light irradiation (UV_{a+b}: 54.2 W/m^2), the abs@λ_{max} reduction efficiency and MeO molecular degradation efficiency of MeO wastewater (10 mg/L) were more than 90%. Moreover, the results showed that the optimal addition ratio of Ag was 0.5%(w/w) on TiO_2 film and an increase of 1.39 times of the abs@λ 464 nm reduction rate and 1.36 times of MeO degradation rate were achieved for using Ag(0.5%)@TiO_2 film as compared to use TiO_2 film, respectively. Increasing the light irradiation was found to be beneficial to enhance the formation rate of hydroxyl radicals and then promoted the oxidation reaction rate. Increasing the temperature of wastewater from 15 ^{0}C to 25^{0}C could improve the degradation efficiency of MeO which was probably resulted from increasing the frequency of collision between hydroxyl radicals and MeO molecules. However, the enrich effect of wastewater temperature was limited as compared to that of light intensity. In addition, a little lower MeO degradation rate was observed with the reuse of Ag@TiO_2 film. Accordingly, the feasibility of solar photocatalsis using Ag@TiO_2 film for the treatment of dye wastewater was obvious.

Keywords: Solar Photocatalysis, MeO, Ag@TiO2 film

Effects of fine content on mechanical properties of recycled concrete aggregates for unbound road base materials in Vietnam

*Thai Hong Nam[1], Akira Kato[1], Takeshi Saito[1], Ken Kawamoto[1]

1. Graduate School of Science and Engineering, Saitama University

Unbound aggregates crushed from natural rock such as limestone, granite are the most popular materials used to construct the base of the pavements. However, nowadays the resources of natural materials have been increasingly exhausted while the demand for using aggregates in road construction has been increasing due to economic growth and rapid urbanization. Currently, construction and demolition waste (CDW) generated in urban areas in Vietnam is not fully recycled and is used on- and/or off-site for landfilling and ground leveling without the quality control of materials. Besides, some of CDW has been being dumped along a road or river, or in a pond for landing illegally. Therefore, the utilization of CDW for recycling is a crucial issue to reduce the generation amount of CDW and consumption of natural resources.
There were many studies on various factors that affect the mechanical properties of recycled concrete aggregates (RCA). Among of the factors, the fine content influences significantly on the mechanical properties of unbound aggregate road base and subbase. However, the effect of fine content (F in wt.%; typically, with particle size less than 0.075 mm) has not been fully evaluated quantitatively. This study focused on the effect of F on the compaction properties and California Bearing Ratio (CBR) of the RCA base. The samples with the maximum particle size of 25mm, and four different F values, i.e. 0, 5, 10, and 20 %, were prepared and their test results were compared to the current Vietnamese standard. The experimental results showed that the maximum dry density reached highest value with F of 5-10%. Except for the tested sample with F of 20%, the measured CBR values with F of 0, 5, and 10% satisfied the technical requirements of Vietnamese standards, i.e. CBR over 100.

Development of filtering materials for removing heavy metals utilizing industrial by-products

*Akito Ujiie[1], Buddhika Bandara[1], Akihiro Matsuno[1], Takeshi Saitou[1], Ken Kawamoto[1]

1. Saitama university

In developing countries, waste materials including industrial by-products are often dumped directly without any segregation and treatment. The amount of discharge is significantly increasing and segregation and treatment of these materials are essentially needed. From waste materials, harmful substances such as heavy metals can leach, causing soil and groundwater pollutions. To solve these problems, cost effective filter materials for removing harmful heavy metals were developed utilizing industrial by-products. This study also contributes to increase additional values for waste materials. For development of filter materials, AAC (Autoclaved Aerated Concrete) and SS (Steel Slag) were selected and column tests using only AAC and mixture material of AAC and SS were carried out to evaluate their adsorption capacities for Pb^{2+} and Cd^{2+}. As a result, AAC adsorbed almost 100% of Pb^{2+} from the Pb^{2+} solution (100 ppm), but, it did not adsorb Cd^{2+} much from the Cd^{2+} solution (100 ppm). On the other hand, the mixture material of AAC and SS adsorbed almost 100% of each heavy metal (100 ppm). It also adsorbed almost 100% of both Pb^{2+} and Cd^{2+} simultaneously from their mixed solution (Cd: 50 ppm and Pb: 50 ppm). These results suggested that the mixture of AAC and SS can be applied as cost effective filter materials for removing heavy metals.

Effects of Silicic Acid on Arsenite Leaching from Spent Calcium-Based Arsenic Adsorbents

*Hajime Sugita[1], Terumi Oguma[1], Ming Zhang[1], Junko Hara[1], Yoshishige Kawabe[1]

1. National Institute of Advanced Industrial Science and Technology

The spent adsorbents after arsenic removal in arsenic contaminated water itself contain a large amount of arsenic. If they are discarded without appropriate treatment, there is a concern that secondary arsenic pollution may occur due to arsenic leaching from them. In our previous studies, it was suggested silicic acid greatly affects leaching behavior of arsenate from the spent adsorbents. In this study, in order to examine the effects of silicic acid on arsenite leaching from the spent adsorbents, leaching tests with silicic acid solution and 2 kinds of spent calcium-based adsorbent (CaO and $Ca(OH)_2$) were carried out. This study revealed that when the initial silicic acid concentration in solution is high, the leaching of arsenite is also inhibited as in the case of arsenate. This was inferred that when the silicic acid component in the solution reacted with the calcium component eluted from the spent adsorbents to form the calcium silicate species, the arsenite component leached from the spent adsorbents was taken into the products.

The Impact of LSTM Network Structure on Flood Process Simulation and Forecast Period: A Case Study of the Middle Yellow River

*Caihong Hu[1]

1. school of water conservancy science and engineering, zhengzhou university, Zhengzhou city, Henan Province, P.R.China, 450001

Flood forecasting is an important non-engineering measure for flood prevention and disaster reduction. Recently, owing to the breakthrough in the field of computational science, neural network technology based on deep learning have received a growing interest from scientists. The Long Short-Term Memory (LSTM) neural network, one of the most advanced applications of deep learning technology, is applied to rainfall runoff simulation in the hydrological field. Most previous studies focused on verifying the feasibility of LSTM in hydrological forecasting. This paper explores the effects of LSTM network structure on flood process simulation and forecast period by constructing LSTM models with different network structures. The hydrological situation in the middle reaches of the Yellow River has changed significantly in the past 50 years. Jingle station control basin in the upper reaches of the Fenhe River is selected as the case study, which including 98 flood events from 1956 to 2014. The datasets of 1954-2003 was selected as the training sets and the dataset of 2003-2014 was selected as the verified set. The results show that, on the one hand, the prediction effect decreases with the increase of the foresight period. The LSTM simulation effect is the best when the foresight period is 1h. The number of cells and the cycle index are 120 and 200 respectively. The Nash-Sutcliffe efficiency (NSE) coefficient reaches 0.9958, Root Mean Square Error (RMSE) reaches 10.1595, BIAS reaches 0.5575%, and the allowable errors of flood peak forecast and peak time forecast were within 5% and 1h, respectively. At this time, LSTM has a perfect performance in flood forecasting; when the forecast period is 1-6h, the number of cells and the cycle index are 140 and 300 respectively, NSE reaches 0.8857, RMSE reaches 39.0867, BIAS reaches 10.5886%, and the allowable errors of flood peak forecast and peak time forecast are within 10% and 6h, respectively, which meet the allowable errors of flood forecast. When the forecast period exceeds 6h, NSE is lower than 0.8, RMSE is higher than 50, BIAS is higher than 15%, and the forecast error of peak time exceeds the length of a calculation period, and it does not have the ability to forecast floods. On the other hand, as far as the forecast period is selected as 1h, both the number of cells and the cycle index in the network structure are positively correlated with simulation accuracy. At first, when the network structure is simple which has 20 cells and 50 cycles index, the NSE is not higher than 0.5. As the number of cells and cycle index increase at the same time, the simulation accuracy increases rapidly. The NSE stabilizes until the number of neurons and the number of iterations reach 120 and 200, respectively. The reason is that the more cells cause the model more complex which can learn more features of data. By increasing the cycle index, the more the model updates the parameters, the better the simulation effect. In summary, LSTM can be used for short-term flood forecasting in the middle reaches of the Yellow River. It is recommended to use LSTM for flood process simulation when the forecast period is selected as 1h. The effect is best when the number of cells and the cycle index are selected as 120 and 200, respectively.

CHARACTERIZATION OF WATER RETENTION AND HYDRAULIC CONDUCTIVITY PROPERTIES FOR GRADED RECYCLED AGGREGATES BLENDED WITH AUTOCLAVED AERATED CONCRETE GRAINS IN VIETNAM

*Nam Pham Van[1], Akira KATO[1], Akihiro MATSUNO[1], Hoang Giang NGUYEN[2], Van Tuan NGUYEN[2], Takeshi SAITO[1], Ken KAWAMOTO[1,2]

1. Graduate School of Science and Engineering, Saitama University, Japan, 2. National University of Civil Engineering, Vietnam

Permeable pavement systems (PPS) play a crucial role in contribution for reducing surface runoff during heavy rainfall (flood control) and mitigating road surface temperature (reduction in urban heat island).The purpose of this study is to improve water retention capacity for recycled road-base materials blending with autoclave aerated concrete (AAC) grain and to evaluate the effect of mixing proportion of AAC grains on water retention and hydraulic conductivity properties. Graded recycled concrete aggregate (RCA; 0.075-37.5 mm) and fired-clay brick (RCB; 0.075-37.5 mm) made from construction and demolition waste (CDW) masonry which was taken from the CDW dumping site in Vietnam and the graded recycled aggregates were blended with AAC grains (0.106-2 mm) from Vietnam in this study. A comprehensive laboratory evaluation of water retention and hydraulic conductivity characteristics of recycled CDW materials was carried out. The results showed that the mixing of AAC grains contributed highly to increase water retention capacity and hydraulic conductivity for both graded RCA and RCB.

UTILIZATION OF CONSTRUCTION aND DEMOLITION WASTE (CDW) AND INDUSTRIAL BY-PRODUCTS(IBPS) AS LOW-COST LIMING AGENTS FOR NEUTRALIZATION OF SOIL ACIDITY

*Isiri Upeksha Nagasinghe[1], Takeshi Saito[1], Akihiro Matsuno[1], Akira Kato[1], Ken Kawamoto[1]

1. Department of Civil and Environmental Engineering, Graduate School of Science and Engineering, Saitama University, Japan

There are acidic soils widespread all over the world. Soil acidity has a greater potential to adversely impact on soil microorganisms, plant growth, deteriorating soil structure, heavy metal leaching and degradation of infrastructure. Liming has long been identified as a promising method to address the soil acidity. The most common liming agent is $CaCO_3$, which is received from natural resources. If it is possible to use alternative materials having alkaline property, it would preserve natural reserves of $CaCO_3$. Construction and demolition waste (CDW) and industrial by-products (IBPs) show alkaline property. If CDW and IBPs could neutralize the soil acidity, it would be a sustainable solution for the waste to be dumped into landfills too. Therefore, this study was carried out to evaluate the applicability of CDWs and IBPs for neutralization of soil acidity. Volcanic ash soil (VAS), laterite (L) and marine sediment (MS) were used as acidic geomaterials for neutralization. Their pH was 5.5, 4.9 and 4.8, respectively. The selected CDW was recycled concrete (RC) and, autoclaved aerated concrete (AAC) and IBPs were steel slag (SS), and fly ash. Two particle sizes (less than 0.106 mm and 0.106 - 2.00 mm) were used for SS, RC, and AAC. To compare the neutralization capacities of alternatives, typical liming agents of $CaCO_3$, $Ca(OH)_2$, and CaO were also tested. Liming agent was gradually added to each geomaterials until they become neutralized. The best neutralization capacity was shown by finer fraction of SS. 1.8%, 0.4%, and 0.5% weight of the finer SS neutralized VAS, L, and MS, respectively. Neutralization capacity of $CaCO_3$ was very similar to the finer fraction of SS. Thus, it is revealed that there is a potential of applying of CDW and IBPs as alternative liming agents. Nonetheless, it is necessary to evaluate the leaching of harmful chemical components including heavy metals from neutralized soils to soil and groundwater.

Keywords: Acidic soil, neutralization, construction and demolition waste , industrial by-products (IBPs), liming agents

Estimation of Coastal Aquifer Properties Using Multiple-Frequency Ocean Tides

*Ming Zhang[1], Ling Yang[2], Yonghong Hao[2], Zhixue Zhao[2], Tongke Wang[2]

1. Institute for Geo-Resources and Environment, Geological Survey of Japan, AIST, 2. Tianjin Normal University

Determination of the hydraulic properties of coastal aquifer systems has important implications that cover a number of research topics, such as seawater intrusion, submarine groundwater discharge, migration of contaminants, assessment of water resources, and geotechnical engineering. Although many theoretical solutions have been developed over recent decades, most of them assume that an aquifer system extends inland and subjected a single-frequency tidal fluctuation on coastline boundary. In addition, only one hydraulic parameter, i.e., the hydraulic diffusivity, a ratio of transmissivity to storage coefficient, of an aquifer can be obtained in most cases.

Considering more realistic conditions, the solution of groundwater response in a leaky confined coastal aquifer to dual frequency tidal fluctuations has been developed as an example. The solutions for a perfectly confined aquifer and single-frequency tidal fluctuations can be considered as special cases of the newly developed, generalized solution. The transport of ocean tides through a leaky confined aquifer depends on both the hydraulic diffusivity of the aquifer and leakage of semi-impermeable aquitard overlapped on it. Ocean tides could only transport to a limited distance towards inland if the hydraulic diffusivity is low and/or the leakage is large. Cautions should be excised that both earth tides and changes in local atmospheric pressure may induce similar tidal fluctuations in hydraulic head within an inland monitoring well. Both the hydraulic diffusivity and leakage can be identified from the monitored, time-depended fluctuations of hydraulic head detected with reliable accuracies. By incorporating the use of aquifer thickness that can be determined independently from observation of core materials during drilling of a monitoring well, both the transmissivity and storage coefficient of a perfectly confined aquifer or a confined aquifer with small leakage can be simultaneously estimated. The findings obtained from this study may provide a better understanding of using ocean tides for determining the hydraulic properties of coastal aquifer systems and a practical example for examining the applicability and/or limitations of the tidal method.

History of Hydropedology and perspectives

*Kosuke Noborio[1]

1. Meiji University

Hidropedology was first proposed by Professor Henry Lin in 2003. He defined Hidropedology as an intertwined branch of soil science and hydrology that embraces interdisciplinary and multiscale approaches for the study of interactive pedologic and hydrologic processes and properties in the earth’s critical zone. He hosted the First International Hydropedlopgy Conference in 2008 at Pennsylvania State University. In 2012 he edited a book entitled Hydropedology, which was published by Academic Press. He hosted two more International Hydropedology Conferences. The fourth is scheduled to be held in Australia in 2020, but he cannot make it. He passed away on September 26, 2019 at the age of 54. His idea of the interdisciplinarity should be inherited and extended into soil physics as well.

Capture of surface runoff by constructing ditches has been widely practiced. Filling the ditch with sands may be useful to conserve its shape and minimize area for ditch. Through a series of laboratory experiment, we have confirmed the effect of a sand ditch to enhance groundwater recharge. To optimize design such as width, depth, and spacing under various combinations of soil and climate, numerical model may be applied to save time and cost for experiments. The purpose of this study was to incorporate surface runoff process into a numerical model to solve two-dimensional water flow and solute movement, WASH_2D, and demonstrate its performance in a numerical experiment. We employed the Manning equation which presents overland flow velocity as square root of hydraulic gradient, caused by slope of ground surface and/or non-uniform depth of standing water. Results of the numerical experiments matched with experimental results: enhanced downward drainege, enhanced storage by surrounding soil and prevention of run off beyond the sand ditch. The modified WASH_2D is now ready to be applied to optimize design of sand ditches.

Hydraulic properties of clay loam paddy soils in Japan.

*Taku Nishimura[1], Shoichiro Hamamoto[1]

1. Deptartment of Biological and Environmental Engineering, Graduate School of Agricultural and Life Sciences, University of Tokyo

Introduction

Paddy rice is a typical agricultural practice in monsoon Asian countries such as Japan. Historically, paddy fields adopted to wet soil conditions such as low land and high precipitations. Since it was assumed paddy field is ponding during cropping season, unsaturated soil properties such as water retention and unsaturated hydraulic conductivity had not been a topic of science in paddy soils. However, recent agricultural practices i.e. direct seeding and winter sowing of rice may be affected by soil moisture condition of spring before surface water ponding.

Methods and Materials

We choose 11 experimental sites. Four of them are clay loam soil (CL) and rest of five soils were boundary of either clay loam-sandy clay loam (SCL) or clay loam-light clay (LiC). Rest of two soils were still CL but had distinctly more clayey. Soil moisture sensors were varied at a depth of 5 and 10 cm and soil temperature and moisture were monitored. Besides, undisturbed and disturbed soil samples were taken and texture, dry bulk and particle densities, and saturated hydraulic conductivity were measured. For soil water retention, sand box was employed for high matric potential range, 0 to -6 kPa. Evaporation method by Hyprop (Meter Environment, Inc.) was employed for middle range of matric potential such as higher than approximately -40 kPa. Also, water content at -101.3 kPa by pressure plate and at smaller than -200 kPa by psychrometer (WP4, Meter Environment, Inc.) were used as supplementary for low matric potential range. In addition to the measurement, water retention curve of each soil was predicted using soil texture and dry bulk density by Rosetta model (Schaap et al., 1998) and SolphyJ database combined with RETC (Kato and Nishimura, 2016).

Results and Discussion.

Water retention measured by sand box often showed smaller water contents. Still the reason is not clear however, in comparison with porosity it could be underestimation of water retention. Thus, we omitted the results of sand box for further discussion.

Even for the same texture water retention varied a lot. Within the one texture class, LiC and CL soils, water retention curves of soils in both texture class were very different. Natural factor such as soil type and mineralogy, and artificial effect such as tillage practice could affect the hydraulic property.

Distinctly low matric potential, i.e. smaller than -100 kPa, is important to discuss growth of plant. For this matric potential range, water retention predicted by Rosetta model agreed well with the measured water retention curves, even though there was large discrepancy in high matric potential range. SolphyJ combined with RETC could consider information of soil type more than Rosetta model, however, it could not evaluate water retention of the eleven experimental well. So only for assessing draught risk for spring germination, prediction of water retention from dry bulk density and soil texture may be usuful.

©2020. Japan Geoscience Union. All Right Reserved.

As mentioned above, soil texture of the nine experimental sites are very similar. However, small difference in texture could affect soil moisture conditions. According to the soil monitoring data, three experimental sites with soil texture of either SCL or SiCL were suffered from very low soil water matric potential during early spring. This could inhibit sprout of germinated seeds. This trend was rarely observed the other experimental sites with CL and LiC soils.

This study was supported by Research Program on Development of Innovative Technology, BRAIN, NARO (Leader: Hiroyuki, Shimono). We would send deep appreciation to project members who maintained this experiment at 11 study sites and Mr. Baba Toshiki and Ms. Isumi Kyoko of UTokyo.

Soil and Water Management & Crop Nutrition Subprogramme, Joint FAO/IAEA Division of Nuclear Techniques in Food and Agriculture, International Atomic Energy Agency, Vienna, Austria, 4. Institute for Land and Water Management Research, Federal Agency for Water Management Austria, 3252 Petzenkirchen, Austria

General circulation models predict that annual rainfall rates in many countries will decline by the end of the century. Coupled with population growth, there will be stiff competition for water resources. It is therefore important that new and advanced irrigation technology be developed to help mitigate this challenge. Currently, 40% of global food production comes from irrigated areas that account for only 20% of the cultivated land. Regrettably, water use efficiency in many irrigated systems around the globe is less than 50%, as most of the applied water does not go towards plant transpiration. Hence, there is an urgent need for improvement in the efficiency with which irrigation water is applied to secure sufficient water for both humans and the ecosystem. One critical gap is the disconnection between current techniques for measuring soil moisture at plot-scale with water (and fertilizer) decisions often for larger areas. This difference in scale creates uncertainty and thus inefficiency in water resource management. To overcome this pressing challenge, the Joint FAO/IAEA Division of Nuclear Techniques in Food and Agriculture, the University of Nebraska (USA) and the Federal Agency of Water Management (Austria) have helped advance the nuclear technique (Cosmic-Ray Neutron Sensor, CRNS) that measures soil moisture over large area scale, compared with point sensor, by counting naturally occurring low-energy neutrons in the air above the selected area. The neutrons are created by incoming cosmic rays, providing an average soil moisture measurement over a ~10 ha of circle area and a depth of ~30 cm. The CRNS technique is a nuclear technique that does not need a radioactive source, with low power consumption, allowing for either stationary or mobile measurements.

There are 3 types of the devices, stationary which stay in place and can provide reading every one hour, backpack which can move in areas difficult to access and read few minutes, while rovering which is carried by a vehicle at low speeds and measures every minute. The last two are used for two- or three-dimensional heterogeneity mapping to measure the soil water content within the footprint.

The data of CRNS are freely available with about 70 devices in USA, and over 200 in independent networks around the world (mainly in developed countries), with additional data sets from developing countries in recent years.

In this study, we highlighting the research investigated and carried out by the Joint FAO/IAEA Division of the International Atomic Energy Agency using CRNS.

The research conducted at several studied sites in Austria. The Petzenkirchen study which is within the Austrian Institute for Land and Water Management Research, with heterogeneity cropping, employing stationary CRNS, has been established in Dec.2013 and it provides major dataset for this study, although we also used the backpack for short times. It represents a small watershed in a hilly area of northern foot

©2020. Japan Geoscience Union. All Right Reserved.

slopes of the Alps. Also, we used the backpack in Grabenegg (which is 5 km away from Petzenkirchen, and has a homogeneity cropping pattern). Apart from that short-term measurement campaigns were carried out using backpack CRNS in alluvial plain east of Neusiedler See Lake and in mountainous areas of Rauris Municipality, at different heights, in the central part of Austrian Alps. This study describes the results and interpretation of about 7 years of soil moisture data set (2013-2020).

In this study, we will present the calibration and validation of CRNS and illustrate the future research and constraints using this technology. We will also highlight future collaboration possibilities with institutions in Japan.

Relationship between GPS signal and soil volume moisture content / electrical conductivity

*Natsumi Naganuma[1], Shinsuke Aoki[2], Tetsushi Ikegami[3], Kosuke Noborio[4]

1. Graduate School of Agriculture, Meiji University, 2. Institute of Soil, Water, and Environmental SciencesAgricultural Research, The Volcani Center, 3. School of Science and Technology, Meiji University, 4. School of Agriculture, Meiji University

In the field of agriculture, we focused on the development of measurement methods to determine the appropriate irrigation water and fertilizer rates. Since 1980, the TDR water sensor, TDT water sensor and capacitance water sensor have been the mainstream of measurement methods because they enable nondestructive and continuous measurement of soil moisture and electrical conductivity. However, these methods have poor spatial representation. Therefore, we tried to estimate the soil moisture content using electromagnetic waves from a GPS satellite in the same 1GHz frequency band as the TDR water sensor. The purpose of this study was to clarify the relationship between the reflected signal received by an inexpensive GPS receiver and the soil water content and soil electrical conductivity.
We experimented at Kurokawa Farm in Meiji University in Kawasaki City, Kanagawa Prefecture. The experimental period is from November 22, 2018 to December 31, 2019. We calculated amplitude B and the phase of the complex reflection coefficient from the reflected signal and compared with the volumetric water content and soil electrical conductivity.

Reviewing the EC Temperature Calibration Equations and Tracing Two Dimensional Distribution of Soil Nutrients.

*Yuki Sunakawa[1], Satoko Fujita[2], Yuki Ito[3], Shinsuke Aoki[4], Kosuke Noborio[2]

1. Graduate School of Agriculture, Meiji University , 2. School of Agriculture, Meiji University, 3. Gilat Research Center, Agricultural Research Organization, Israel, 4. Institute of Soil, Water, and Environmental Sciences Agricultural Research, The Volcani Center, Israel

It is essential to control soil nutrient balance to gain an identical yield of crops. As an indicator of the amounts of soil nutrients, electrical conductivity (EC) is commonly used. Since EC depends on solution temperature, ECw25, which is EC of the solution whose temperature is 25 ℃, is used as a comparison criterion. To correct EC to ECw25, some calibration equations were developed like USDA Salinity Laboratory’s equation or Heimovaara’s equation. However, less attention has been paid for the accuracy of these equations. Therefore, the first objective of this study was reviewing the accuracy of the USDA Salinity Laboratory’s equation or Heimovaara’s equation. Because there is a linear relationship between EC and each dissolved ion when the ion concentration is low, each ion’s distribution can be traced by estimating ion concentration from EC. The second objective of this study was to determine soil nutrient’s two-dimensional distribution under a drip irrigation system. TDR method was used to measure EC of soil columns, which were put in an incubator. High EC conditions (ECw25 was about 400 mS m-1), and low EC conditions (ECw25 was about 150 mS m-1) were tested. The temperature of the incubator was changed from 10 ℃ to 50 ℃. When EC was high, the two equations corrected the EC well. However, when EC was low, the correction of two equations was not accurate, especially at low temperatures. It might be necessary to use different EC calibration equation depends on EC value and temperature of the solution. We modified Heimovaara’s equation for low EC conditions. From June 8th, 2019 to July 31st, 2019, volumetric water content and EC were measured with the TDR method, and soil temperature was measured with thermocouples in bell pepper grown drip-irrigated field. Soil samples were collected to measure its EC and chemical concentration with EC meter and ion analyzer, respectively. We will report how EC changed and each nutrient transported during the measurement period.

Case study of current status and issues of new entrant apple farmers in Nagano Prefecture

*Takamitsu Kai[1]

1. Meiji University

In Japan's agriculture, the retirement of elderly farmers is expected to increase in the future, so they will be able to use them effectively on degraded farmland and farmland of farmers without successors and become human resources who will support Japan's agriculture in the future The urgent task is to secure new youth farmers and promote their establishment. Under these circumstances, the number of new farmers from 2014 to 2017 was 57,650, 65,030, 60,150 and 55,670.If new farmers under the age of 49 were limited, 21,860, 23,030, 22,050, 20,760 and 20,000 It has been maintaining more than people. The main reasons for this are that the government is promoting a system to support new employment of young people, such as the “employment of farming” and that the number of family-owned (sales farmers) is decreasing, but the number of organization-based entities is increasing. It is also possible that the number of workplaces that can farm as salaried workers has increased. In this study, a new self-employed farmer in the apple orchard in Nagano City, Nagano Prefecture, and a sales farmer aiming for the organic apple JAS certification. The current situation and issues of new farmers will be introduced, based on interviews with selling farmers and analysis results of apple orchard soil.

[A-CG44] Extratropical oceans and atmosphere

convener:Youichi Kamae(Faculty of Life and Environmental Sciences, University of Tsukuba), Toyama Katsuya(Meteorological Research Institute), Hyodae Seo(Woods Hole Oceanographic Institution), Yoshi N(Hokkaido University)

The extratropical ocean had been considered passive to atmospheric variability. Recent studies, however, revealed active roles of the extratropical ocean in modulating the atmosphere. The goal of this session is to deepen our understanding of the air-sea interaction in the extratropics. A wide variety of researches whose topics range from meso-scale to basin-scale interactions, and from daily to global warming timescales are welcomed. Researches on topics related to extratropical air-sea interaction, including cloud, aerosol, and ecosystem, are also welcomed.

Seasonality and Regional Characteristics of Sea-Surface Wind Responses to Mesoscale SST Features assessed by Transfer Functions

*Ryusuke Masunaga[1], Niklas Schneider[1]

1. International Pacific Research Center, University of Hawaii

Satellite observations have revealed that sea-surface temperature (SST) anomalies on a scale of 50–500 km exert significant influence on sea-surface winds. Warm (cold) SST anomalies act to accelerate (decelerate) surface winds. Recently, spectral transfer function approach, where the surface wind response is evaluated using linear regression coefficients on the wavenumber space, has been proposed to investigate the mesoscale air-sea coupling. In the present study, seasonality and regional differences of the wind responses are investigated by adopting the transfer function approach to the Gulf Stream, Kuroshio Extension, Southern Ocean regions based on satellite observations. Although structures of the transfer functions in the wavenumber space exhibit consistent characteristics between the ocean regions, their magnitude is found to be dependent on regions and seasons. When background winds are strong (weak), the mesoscale wind responses tend to be stronger in winter (summer). Furthermore, observed mesoscale wind fields are reasonably reconstructed from the transfer functions and observed SST, especially over the Southern Ocean domain. These results further support the validity of using transfer functions, and suggest that underlying dominant dynamics are ubiquitous over the globe.

Ocean warming patterns and heavy rainfall over East Asia associated with atmospheric rivers

*Youichi Kamae[1], Wei Mei[2]

1. Faculty of Life and Environmental Sciences, University of Tsukuba, 2. University of North Carolina at Chapel Hill

Atmospheric rivers (ARs), narrow moisture transport bands developed over the mid-latitude oceans, have attracted much attention because they often cause natural disasters (flash flood, extreme wind) when they make landfall. Over East Asia, ARs explains 20-90% of heavy rainfall events occurred during warm seasons. On an interannual timescale, substantial fraction of East Asian AR frequency is explained by the Pacific and Indian Ocean SST variability, suggesting the potential predictability of seasonal AR-disaster risk. Recent studies suggested that the global SST rise under the global warming results in more occurrence of ARs due to increased water vapor content. In addition to the thermodynamic effect, change in atmospheric circulation associated with SST warming patterns may also increase AR-disaster risk over specific regions. We examine spatial patterns of change in AR-disaster risk under global warming using ensemble simulations assuming different ocean warming patterns. When we assume warm Indian Ocean during summer, an anomalous subtropical anticyclone over the western North Pacific results in an enhanced moist southwesterly over East Asia and more occurrence of ARs. In addition to the dynamic effect, warm condition over the East China Sea and the western North Pacific are also related to the enhanced AR activity over the western North Pacific. We further evaluate AR-related heavy rainfall using hourly model outputs and effects of ocean warming patterns.

Predictability of 2019 stratospheric sudden warming in the Southern Hemisphere and its impact of surface weather

*Hiroaki Naoe[1], Chiaki Kobayashi[1], Yayoi Harada[1], Yukiko Imada[1], Shuhei Maeda[1], Toshihiko Hirooka[2]

1. Meteorological Research Institute, 2. Kyusyu University

This study analyzes observational features of displacement-type of minor sudden stratospheric warming (SSW) event that occurred in the Southern Hemisphere (SH) in September 2019 (SSW2019-SH). The predictability of SSW is also investigated examining the Japan Meteorological Agency operational 1-month and 6-month ensemble prediction data in comparison with the Japanese 55-year Reanalysis data. SSW events are rare in SH, with only two in recorded times - one in 2002 that is the first major (split-type) event and the other in 1988 classed as a minor warming. SSW2019-SH occurred under El Nino Modoki, westerly quasi-biennial oscillation together with solar minimum, positive Indian Ocean dipole, and phases 3-6 of the Madden-Julian oscillation. This SSW is characterized by the strongest Antarctic warming on record with a temperature increase of 70 K within 2 weeks, the strongest accumulated upward wave activity flux with zonal wavenumber 1 in July-August-September. The vertical profile of geopotential height anomalies averaged over the polar cap region illustrates the downward propagation of SH circulation anomalies from the stratosphere in September to the troposphere in late October. Months of October-December 2019 (the month of September) are marked by anomalously negative values (a positive value) of the southern annular mode (SAM) index. The negative SAM index is characterized by warm polar temperatures, high geopotential height over the polar cap, and weak circumpolar flow along 60˚S. Predictability of sea-level pressure anomalies averaged over 60-90S is usually about 10 days. However, this predictability is a little longer just after signals of such geopotential height anomalies or SAM index descend down from stratosphere to troposphere. Root-mean-square error, anomaly/pattern correlation coefficient between forecast and the reanalysis for diagnostics are investigated to measure the predictability skill of the model.

Acknowledgments
This research was supported by Grant-in-Aid (JP18K03748) for Science Research (KAKENHI) from the Ministry of Education, Culture, Sports, Science, and Technology of Japan.

Interaction between a typhoon moving westward in western Japan and a cold vortex

*Mine Taisei[1], Yoshihiro Tachibana[1]

1. Faculty of Bioresources, Mie University

Typhoon Jongdari (2018) made landfall near Ise, Mie Prefecture and proceed west through Western Japan.
This course of the typhoon was first time ever since records began in 1951.
We hypothesize that the abnormal course was controlled by a cold vortex in the south of Japan.
In this study, we focus on the interaction between the typhoon and the cold vortex, and we investigated whether the cold vortex affected the abnormal course of the typhoon.

On the maintenance mechanisms for the wintertime subtropical high over the South Indian Ocean

*Ayumu Miyamoto[1], Hisashi Nakamura[1], Takafumi Miyasaka[1,2], Yu Kosaka[1], Bunmei Taguchi[3], Kazuaki Nishii[4]

1. Research Center for Advanced Science and Technology, The University of Tokyo, 2. Japan Meteorological Business Support Center, 3. School of Sustainable Design, University of Toyama, 4. Graduate School of Bioresources, Mie University

Over the South Indian Ocean, the subtropical Mascarene high exhibits a distinct seasonality from the other basins. While the high resides over the eastern portion of the basin in summer, the high resides over the western portion of the basin and its strength as a planetary-wave component is maximized in winter. The present study investigates the maintenance mechanisms for the wintertime subtropical high by using an atmospheric dynamical model and an atmospheric general circulation model.

We find that enhanced storm-track activity maintained by the Agulhas sea surface temperature (SST) front is important for the maintenance of the poleward portion of the subtropical high through the convergences of eddy heat and vorticity fluxes and the resultant acceleration of the climatological-mean westerlies on the poleward side of the high, as shown by the dynamical model experiments. The atmospheric general circulation model experiments further indicate that the Agulhas SST front acts to reinforce the high by energizing the storm-track activity.

The dynamical model experiments also reveal the remote influence from the tropics, especially the Asian summer monsoon region. The enhanced deep convection over the Asian summer monsoon region as well as the equatorial eastern Indian Ocean and western Pacific acts not only to shift the subtropical high westward but also to enhance mid-tropospheric subsidence and equatorward surface winds over the central and western portions of the subtropical South Indian Ocean. The induced subsidence acts to stabilize and dry the free troposphere, and the equatorward surface winds yield near-surface cold advection, both of which are favorable for the low-level cloud formation but unfavorable for the development of deep precipitating clouds. The resultant enhanced radiative cooling and reduced deep condensation heating can reinforce the equatorward portion of the subtropical high.

Surface velocity variation of the Kuroshio-Kuroshio Extension system -its relations with local monsoon winds-

*YUXIANG QIAO[1], Hirohiko Nakamura[2], Kako Shinichiro[3], Ayako Nishina[2]

1. The United Graduate School of Agricultural Sciences, Kagoshima University, 2. Faculty of Fisheries, Kagoshima University, 3. Graduate School of Science and Engineering, Kagoshima University

Our previous study focused on the decadal surface velocity variation over the entire Kuroshio-Kuroshio Extension (KE) current system, and found that such a variation is out of phase between the Kuroshio and KE. In another word, Kuroshio is strengthened (weakened) while KE is weakened (strengthened) for a decadal time scale. From our results, the above-mentioned phenomenon is caused by the climate oscillation such as Pacific Decadal Oscillation (PDO) through a remote process. The Sea Surface Height (SSH) anomalies excited by the PDO over the northeastern North Pacific and the area east of Philippines propagate to the Kuroshio-KE area, and then generate an opposite intensity variation between the Kuroshio and KE because of different propagation times. Following the above results, our present study focuses on the interannual surface velocity variation of the Kuroshio-KE system, and its relation with local monsoon. In order to pay attention to interannual modulation of the seasonal change, we investigate the yearly time series of the monthly Kuroshio-KE system velocity. Our preliminary result suggests that the interannual winter velocity variation of the Kuroshio has a significant correlation with the local winter monsoon. However, the interannual time-scale relation between the summer Kuroshio velocity variation and local summer monsoon is unclear.

The potential impact of the 2014-2016 marine heat wave over the North Pacific on the atmosphere

*Kazuaki Nishii[1], Bunmei Taguchi[2], Hisashi Nakamura[3]

1. Graduate School of Bioresources, Mie University, 2. Faculty of Sustainable Design, University of Toyama, 3. Research Center for Advanced Science and Technology, The University of Tokyo

Anomalously warm anomalies of sea surface temperatures (SSTs) had been observed over the North Pacific, which is called the marine heat wave or the “blob”. One of the causes of the blob was weaker than normal wind associated with the anticyclonic circulation anomaly over the eastern North Pacific. We have conducted a series of ensemble experiments by using an atmospheric general circulation model (AGCM) to assess impacts of the blob on the atmospheric circulation. In the AGCM experiments forced by observed SSTs only over the extratropical North Pacific, a tropospheric anticyclonic circulation response is observed in the winter 2013-2014 over the Bering Strait, where an anticyclonic anomaly was actually observed. In the winter 2014-2015, a tropospheric anticyclonic circulation response is observed over western Canada, which is also consistent with the observation.

[A-CG45] Multi-scale ocean-atmosphere interaction in the tropical Indo-Pacific region

convener:Yu Kosaka(Research Center for Advanced Science and Technology, University of Tokyo), Sang-Wook Yeh(Hanyang University), Takanori Horii(Research and Development Center for Global Change (RCGC), Strategic Research and Development Area, Japan Agency for Marine-Earth Science and Technology (JAMSTEC)), Hiroki Tokinaga(Disaster Prevention Research Institute, Kyoto University)

Tropical Indo-Pacific Oceans are home to ocean-atmosphere interaction on a broad range of spatio-temporal scales. Teleconnections induced by the tropical Indo-Pacific variability exert a significant imprint on global climate. Since the 1980s, in-situ and satellite observations, reanalysis products, and advancements in climate modeling have led to depicting various aspects of intraseasonal (e.g., MJO), interannual (e.g., ENSO and IOD) and decadal (e.g., IPO) variability in the tropical Indo-Pacific Oceans and their impacts on tropical (e.g., monsoons) and extratropical (e.g., storm track) climate. Newer studies find an active role of salinity in ocean-atmosphere interaction in the tropical Indian Ocean. Other recent studies highlight the inter-basin coupling between the tropical Pacific and the Indian Ocean in seasonal prediction of the Asian summer monsoon and decadal redistribution of ocean heat content associated with the so-called "hiatus" of global warming. Long term change in the Pacific Walker circulation has been recapturing attention in terms of the pattern effect of warming on climate feedback and sensitivity against radiative forcing as well as ENSO modulations under a warmer climate. A variety of processes are mutually interrelated and shape the climate, its variability, and change. To examine these challenging issues from various perspectives and foster understanding of the role of tropical air-sea interaction in the climate system, this session offers a forum to discuss recent progress in observational, modeling and theoretical studies of multi-scale tropical ocean-atmosphere interaction in the tropical Indo-Pacific Oceans.

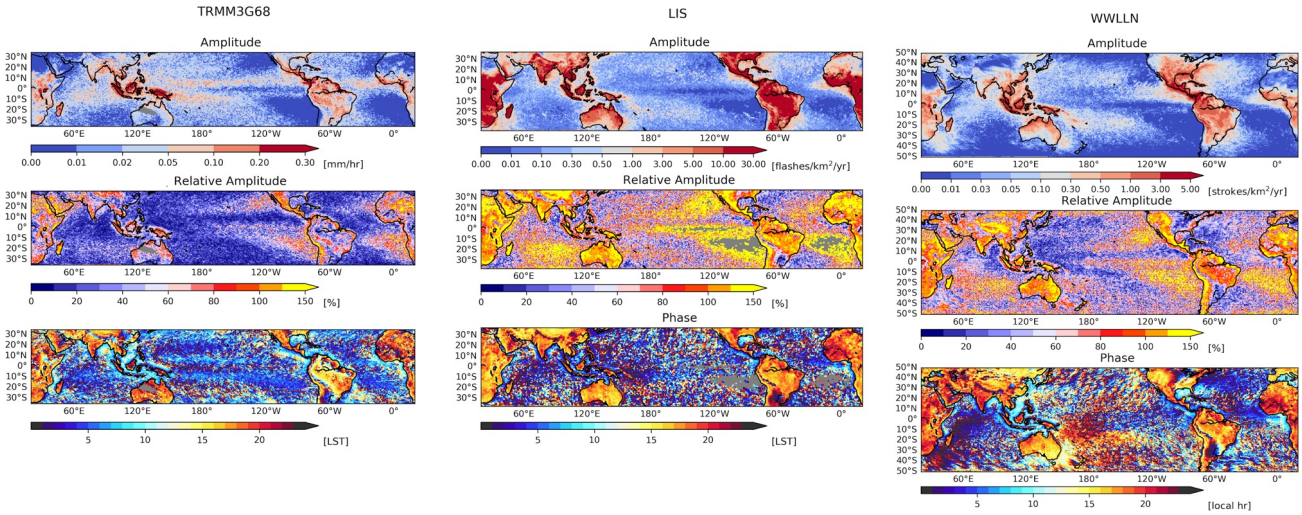
Diurnal cycles of precipitation and lightning in the tropics observed by TRMM3G68, GSMaP, LIS, and WWLLN

*Shoshiro Minobe[1], Jun Hyock Park[1], Katrina S. Virts[2]



1. Graduate School of Science, Hokkaido University, 2. The University of Alabama in Huntsville

The diurnal cycle is a major atmospheric variation in conditions including temperature, wind, precipitation, and lightning. Diurnal precipitation and lightning are closely related because they are both associated with convection, and thus previous studies compared diurnal cycles of these two variables. However, previous diurnal cycle comparisons between precipitation and lightning are conducted as regional studies, and no global comparisons were made. Moreover, previous comparisons used precipitation data derived mainly from infra-red satellite observations, although it is known that IR-based precipitation observations have biases of about three-hour delay. Therefore, the purpose of the present study is to understand the difference and similarity of diurnal cycles of precipitation and lightning over the global tropics.

Diurnal cycles of precipitation and lightning are investigated by analyzing rain rate of TRMM3G68 dataset, consisting of precipitation radar and microwave imager data only, rain rates of Global Satellite Mapping of Precipitation (GSMaP), for which IR data are also used, lightning flash rates observed by TRMM Lightning Imaging Sensor (LIS), and lightning stroke rates of World Wide Lightning Location Network (WWLLN) over the tropics. Diurnal amplitudes relative to averages are generally larger for lightning than for precipitation. Over ocean, relative amplitudes are stronger in the stratocumulus deck region in the southeast Pacific than those over typical ocean regions. The phase of GSMaP is substantially delayed to TRMM3G68 due to the phase-delay problem of IR based estimation. The diurnal peaks tend to occur between 14:00 and 18:00 LST over the continent after spatial averaging with a phase leading order of TRMM3G68, LIS, and WWLLN, and between 0:00 and 7:00 LST over oceanic regions where diurnal cycles are prominent in all datasets. Off-equatorward phase propagations are found in the precipitation in the Pacific and Indian oceans. Over selected coastal regions, all data exhibit consistent oceanward phase propagation with the longest, medium, and shortest phase propagation distances for TRMM3G68 precipitation, WWLLN lightning, and LIS lightning, respectively, with a phase leading order of LIS, WWLLN, and TRMM3G68. The summertime diurnal cycle over the Gulf Stream also exhibits oceanward phase propagation, but with strong amplitude enhancement over the Gulf Stream. Diurnal cycle amplitude is also enhanced over the Kuroshio in the East China Sea in the Baiu-Meiyu rainy season.

Intermodel diversity in the impact of tropical volcanic eruptions on ENSO

*Masamichi Ohba[1]

1. Central Research Institute of Electric Power Industry

Temporary negative radiative forcing caused by sudden super volcanic eruptions (SVEs) in the tropics reduces global surface temperatures and then weakens atmospheric and ocean circulations that can significantly affect interannual-to-interdecadal climate variations. Studies on the relationship between the El Nino-Southern Oscillation (ENSO) and SVEs had been discussed within limited data. However, the last 1000-years SST data reconstructed from the composited proxy suggested significant increase in the probability of the occurrence of El Niño one-year after the SVEs. Our SVE-forced experiment by using an air-sea coupled model (Ohba et al. 2013) also showed that El Niño is also tends to be excited in after the mature of SVEs as similar to findings from reconstructed SST. It is shown that the SVE-forcings can cause westerly wind anomalies in the western Pacific (i.e., weakened Walker circulation), and then El Niño can be excited one year after the SVEs. Similar results and mechanisms have been demonstrated from validation experiments on the other following studies. It is considered that the development of such westerly wind anomalies can be related to the decrease in precipitation on the Indian Ocean to the marine continent due to the SVE cooling that result in the basin-scale east-west gradient of surface temperature. In this study, we evaluate the effect of SVE-induced radiative forcing on ENSO in models using the results of the latest coupled model intercomparison data (CMIP5 and CMIP6) and verifiy the intermodel diversity of the SVE response among the models.

Revisiting the ENSO impact on the Indian Ocean SST based on the combined linear regression

*Lianyi Zhang[1,2,3], Yan DU[1,2], Tomoki Tozuka[3], Shoichiro Kido[3]

1. South China Sea Institute of Oceanology, Chinese Academy of Sciences, 2. University of Chinese Academy of Sciences, Chinese Academy of Sciences, 3. The University of Tokyo

El Niño-Southern Oscillation (ENSO) has great impacts on the Indian Ocean (IO) sea surface temperature (SST). In fact, two major climate modes of the IO that exert strong influences to the IO rim countries, namely the Indian Ocean Basin (IOB) and Indian Ocean Dipole (IOD) modes, are influenced by the ENSO. Based on the combined linear regression, this study quantifies ENSO impacts on these two modes in ENSO concurrent, developing and decaying phases. It is shown that the number of IOB and IOD events decreases by 83% and 25% after adequately removing ENSO influences, respectively. In terms of seasonal march, without ENSO signature, the spring peak of IOB disappears, while the autumn peak of IOD still exists with smaller amplitude. Also, the developing (decaying) phase of ENSO is more influential to the IOD (IOB) development. This implies that merely removing the concurrent ENSO impacts is not sufficient to study the intrinsic SST variability of the IO, and the present method may be useful to study the IO internal variability independent of ENSO.

Assessments of salinity impacts on SST using a linear inverse model

*Shoichiro Kido[1], Tomoki Tozuka[1]

1. Graduate School of Science, The University of Tokyo

The upper ocean salinity undergoes significant variations associated with large-scale climate modes, such as the El-Niño and Southern Oscillation (ENSO) in the tropical Pacific and the Indian Ocean Dipole (IOD) in the tropical Indian Ocean. By changing the density of the seawater, these salinity variations alter the upper ocean stratification and circulation, and thus have the potential to feed back to the climate modes themselves. Indeed, by conducting a series of sensitivity experiments using a regional ocean model, our recent work has demonstrated that surface and subsurface salinity variations associated with the IOD act to damp sea surface temperature (SST) anomalies and serve as a negative feedback to the IOD. However, due to the complex nature of the coupling between temperature and salinity variability, it is not straightforward to clearly identify these salinity impacts only from observational datasets.

To address this issue, here we propose to apply a linear inverse model (LIM), which succinctly describes the evolution of tropical climate variations within a linear framework. We have first determined the linear operator of the LIM based on temperature and salinity anomalies in the tropical Indian Ocean derived from an ocean reanalysis product and carried out a long-term integration of the LIM as a reference experiment. It is found that our LIM reasonably reproduces the amplitude and spatial structure of the observed temperature and salinity anomalies associated with the IOD. Then, we have designed another LIM experiment *without* the coupling between temperature and salinity variations (referred as “T-S decoupled LIM”), by modifying the linear operator of the original LIM. A comparison of outputs from both LIM experiments reveals that the amplitude of the IOD in the T-S decoupled LIM is substantially stronger than that of the reference experiments. This suggests that the interactions between temperature and salinity act to reduce the amplitude of the IOD, consistent with our previous results based on dynamical approaches. Calculations of the growth rates of the IOD-related SST anomalies further confirmed the above idea. Our results imply that the LIM can be a powerful tool for understanding and diagnosing the salinity impacts on SST in a simple manner.

The relationship between the boreal summer intraseasonal oscillation and the Pacific-Japan pattern

*Ayako Seiki[1], Yu Kosaka[2], Satoru Yokoi[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. Research Center for Advanced Science and Technology, The university of Tokyo

Convective activities over the Philippine Sea in boreal summer have been known to be associated with circulation anomalies over the midlatitude western north Pacific (WNP), called the Pacific-Japan (PJ) pattern. In this study, the relationship between the PJ pattern and tropical intraseasonal variability, called the boreal summer intraseasonal oscillation (BSISO), which influences the convective activities over the Philippine Sea is investigated. The monthly PJ indices are not correlated with the amplitude of the BSISO indices, but correlated with the phases of the BSISO indices. This result indicates that the negative (positive) PJ pattern, which is associated with warm (cold) anomalies over the midlatitude East Asia, tended to appear when the strong convective active (suppressed) signals of the BSISO are located over the tropical WNP. In the negative PJ years, convective activities over the tropical WNP drastically develop from the BSISO phase 6 simultaneous with significant increases of the eddy kinetic energy representing synoptic disturbances, compared to the positive PJ years and the other years. The development of the synoptic disturbances over the Philippine Sea might play a key role for exciting the PJ pattern.

The Impact of IOD on rainfall over Spain

*Sourabh Shrivastava[1], Saji Hameed[1]

1. University of Aizu

Previous studies have shown that the Indian Ocean Dipole (IOD) has a significant impact on land temperatures over southern Europe. However, whether IOD influences rainfall over this region and how this impact compares to that of El Nino Southern Oscillation (ENSO) have not been established. Here using the E-OBS gridded rainfall datasets for the period 1958 to 2012, we have analyzed the influence of IOD and ENSO on European rainfall. We find that IOD impacts are predominantly felt over southwestern Europe in a region covering Spain and Portugal during the peak phase of the event. Correlations exceeding 0.4 are observed over the central regions of Spain. We find that ENSO impacts on European rainfall are substantially weaker compared to that of IOD, but occur with a pattern similar to the latter. Partial correlation analysis suggests that the marginal ENSO correlations are a statistical areifact arising from the co-occurrence of a fraction of the El Nino events with positive IOD events. Possible dynamical mechanisms by which IOD impacts rainfall over southwestern Europe will be discussed.

How Large-Scale Circulations Integratedly Influence Precipitation in the Source Region of the Yangtze River,China

*Yiheng Du[1], Dong An[1], Ronny Berndtsson[1]

1. Lund University

Precipitation patterns are highly sensitive to climate change. During recent years, researchers have made significant progress in the understanding of vapor transport by large-scale atmospheric circulation patterns (teleconnections). However, previous research has mainly focused on the influence of individual teleconnection patterns, regardless of joint impact. In our study, the combined influence from large scale circulations on precipitation are examined. Monthly precipitation data at regular grids of 0.5˚ ×0.5˚ derived from observations during June-August 1961-2016 were used to reveal characteristics of large-scale circulations associated with rainy season precipitation over the source region of the Yangtze River (SRYR). A comprehensive analysis of relationships between SST anomalies as well as large-scale circulation including ENSO and PDO and spatiotemporal patterns of rainy season precipitation in SRYR was presented. Our analysis indicated that the leading modes of rainy season precipitation variability can be explained by the variability of SST together with an integrated effect of ENSO and PDO with an explained variance of about 64.2%. It was shown that the influence of ENSO and PDO will enhance/decrease when they are in-/out-of-phase. Negative PDO induces more precipitation in La Niña years than in El Niño years for the SRYR, especially over central and eastern parts of the basin. Positive PDO induces precipitation decrease, and El Niño enhances the decrease. The mechanism behind this pattern is atmospheric circulation affecting the strength of westerlies that transport moisture to the inland areas and as well local convergence conditions. Our results have implications for predicting the rainy season precipitation for coming decades over the SRYR. If the current negative PDO phase continues together with more frequent extreme La Niña events, as suggested in previous research, more abnormal precipitation during rainy season is expected over the SRYR.

Summertime climate anomalies in Asia and the Northwestern Pacific induced by ENSO: Dependence on ENSO's phase transition

*Yu Kosaka[1], Daiki Kado[1]

1. Research Center for Advanced Science and Technology, University of Tokyo

Equatorial Pacific sea surface temperature (SST) anomalies associated with El Niño-Southern Oscillation (ENSO) typically peak in boreal winter and, when composited, dissipate by subsequent boreal summer (June-July-August; hereafter denoted as JJA(1)). Despite the lack of the equatorial Pacific signal, coherent climate anomalies emerge in Asia and the Indo-western Pacific in JJA(1). Studies have identified the so-called capacitor effect of the Indian Ocean for the ENSO's delayed, indirect influence. However, the lack of composited SST anomalies in the equatorial Pacific in JJA(1) does not always apply to individual ENSO events. Specifically, in some events the equatorial Pacific SST anomalies do not disappear in JJA(1) and redevelop toward the subsequent boreal winter (hereafter "multi-year ENSO events"), while in other cases the SST anomalies on average transition to the opposite polarity before JJA(1) ("single-year ENSO events"). We find in a reanalysis dataset and a coupled model pacemaker experiment that the single-year and multi-year ENSOs yield distinct climate anomalies in Asia and the Northwestern Pacific in JJA(1). Our bivariate linear regression analysis shows that the direct teleconnection from the equatorial Pacific interferes differently between single- and multi-year events with the delayed influence through the capacitor effect. The equatorial Pacific SST induces lower-tropospheric circulation anomalies that are spatially orthogonal to those induced by the Indian Ocean capacitor effect, and their different combination leads to the distinct climate anomalies. The distinct influence can explain asymmetry in JJA(1) climate anomalies between El Niño and La Niña. Namely, El Niño tends to decay rapidly while La Niña often persists for two years or more, and this persistence asymmetry is the key to asymmetric climate anomalies between El Niño and La Niña in JJA(1).

[A-CG46] Atmospheric deposition impact on Terrestrial and marine Ecosystems

convener:Eyal Rahav(Israel Oceanographicand Limnological Research), Adina Paytan(University of California Santa Cruz)

Marine and terrestrial ecosystems are frequently subjected to high inputs of wet and dry atmospheric deposition. Aerosol deposition provide dissolved and particulate constituents such as inorganic nutrients and organic matter required for sustaining productivity, as well as toxic metals and other pollutants. In addition, dust also provide a wide array of viable airborne microorganisms such as bacteria, fungi and viruses that, in turn, can also affect productivity and impose strong constraints on global climate changes. These impacts may vary based on the aerosol load, source, trajectory, and its chemical and biological characteristics.

We welcome contributions studying the effects of aerosols on aquatic and terrestrial systems in particular the interactions between aerosols and organisms (i.e., biomass, activity, diversity). Approaches may include in situ observations, laboratory mesocosm/microcosm experiments and modeling.

[ACG46-P01] The hitchhike’s guide to bacterial transport: the role of viable dust-borne microbes deposition into marine environments

*Eyal Rahav[1], Barak Herut[1], Adina Paytan[2] (1.Israel Oceanographic and Limnological Research, Haifa 31080, Israel, 2.Institute of Marine Science, University of California, Santa Cruz, CA, 95064, USA)

The hitchhike’s guide to bacterial transport: the role of viable dust-borne microbes deposition into marine environments

*Eyal Rahav[1], Barak Herut[1], Adina Paytan[2]

1. Israel Oceanographic and Limnological Research, Haifa 31080, Israel, 2. Institute of Marine Science, University of California, Santa Cruz, CA, 95064, USA

Aerosols and dust are regularly transported across the oceans and seas supplying nutrients and trace metals to the surface water. In addition, aerosols may also contain a wide array of different airborne microorganisms (heterotrophic bacteria, virus, cyanobacteria and fungi), that can be easily transported for thousands of kilometers away from their place of origin within a few days. The southeastern Mediterranean Sea (SEMS) and the northern Red Sea (NRS) are ideal marine environments to study the role of aerosols and airborne microbes on surface microbial production for multiple reasons. First, both environments are subjected to relatively high aerosol deposition throughout the year. Secondly, they are oligotrophic environment with low inorganic nutrients and low autotrophic and heterotrophic activity for most months. Thus, any external input of micro/macronutrients, along with airborne microbes, can have a relatively substantial effect upon interaction with the ambient microbial populations; thereby having a potentially large effect on the system’s production and ecological function. Here, we will discuss who are the dominant airborne bacteria that are being transported to the SEMS/NRS during storm events. Further, we will present some of the ecological roles these microorganisms hold (carbon and nitrogen fixation) and how airborne microbes interact with ambient microbial populations. These results demonstrate that dust-borne microorganisms may play a significant role marine environments.

[A-CG47] Global Carbon Cycle Observation and Analysis

convener:Kazuhito Ichii(Chiba University), Prabir Patra(Research Institute for Global Change, JAMSTEC), Forrest M. Hoffman(Oak Ridge National Laboratory), Makoto Saito(National Institute of Environmental Studies)

The Paris Agreement under the United Nations Framework Convention on Climate Change (UNFCCC) is a landmark agreement, which aims at reduction of greenhouse gases (GHGs) emission to keep the global warming below 2 degC. The national commitments and progress should be carefully monitored and verified by international bodies using different but complementary methodologies.

In recent years, many observations and techniques to monitor GHGs budget have expanded. The improvements include observational platforms for monitoring atmospheric GHGs, national or regional emission inventories, top-down models (e.g. atmospheric inverse models), and bottom-up models (e.g. process-based models). However, due to uncertainties in modeling and sparse observation networks, large uncertainties exist in GHG sources/sinks estimations at global and regional scales. These uncertainties lead to large variations in future projections of GHG budgets and climate changes.

The purpose of the session is to discuss state-of-the-art techniques for estimation of GHG (e.g. CO2, CH4, N2O) budgets at global and regional scales. The topic includes natural and anthropogenic processes, various methodologies (e.g. in-situ observation, aircraft monitoring, remote sensing, modeling), and various targets (e.g. atmosphere, terrestrial, and ocean), various spatial and temporal coverage (e.g. regional to global scales and past-present-future). Improved estimates of emissions from land use change, forest fires, and other anthropogenic sources (urban developments and thermal power station etc.) are also of interest. We also welcome discussions for designs and plans for future studies targeting urban and rural scale emission estimations using sophisticated modeling tools and inventories.

The Greenhouse gases Observing SATellite 2 (GOSAT-2) was launched, as the successor of GOSAT, on 29th October 2018 into a sun-synchronous orbit at an altitude of 613 km with 6-day revisit cycle, then the satellite has been operated with normal mode since 1st February 2019. GOSAT-2 is designed to measure atmospheric carbon dioxide (CO_2), methane (CH_4) and carbon monoxide (CO) with two instruments: The Thermal And Near-infrared Sensor for carbon Observation Fourier Transform Spectrometer 2 (TANSO-FTS-2) and the Cloud and Aerosol Imager 2 (TANSO-CAI-2). The GOSAT-2 mission inherits the main objective of the GOSAT that improves our knowledge of spatiotemporal variations of CO_2 and CH_4 in the atmosphere and the process governing their exchange between the atmosphere and the Earth's surface and contributes climate change studies and related environmental policy making. The GOSAT-2 project provides Level 1 radiance spectral products of GOSAT-2 observations for general users and released FTS-2 shortwave infrared (SWIR) Level 2 atmospheric concetration products to the GOSAT series' Research Announcement users. The GOSAT-2 Level 4 products will provide estimates of global surface fluxes on CO_2 and CH_4 based on the FTS-2 SWIR Level 2 products and surface observations. This presentation will introduce detailed features for the GOSTA-2 Level 4 product including the prior information and preliminary results on multi-year global CO_2 flux estimates using GOSAT FTS SWIR Level 2 products, and additional information about the latest GOSAT-2 products.

Toward a long-term global inversion of atmospheric CO_2 for elucidating seasonal and interannual variations of natural carbon fluxes

*Yosuke Niwa[1]

1. National Institute for Environmental Studies

A number of ground-based stations have been performing atmospheric measurements of CO_2 for several decades and have observed notable interannual variations of the growth rate of the atmospheric CO_2, which suggests that the natural CO_2 flux at the earth surface have been varying in conjunction with some climate key parameters (e.g., El Niño Southern Oscillation index). Furthermore, distinct seasonal variations of atmospheric CO_2 observed by those measurements give evidence of dynamic photosynthesis and respiration activities of terrestrial biospheres. However, the mechanisms underlying those natural CO_2 flux variations are not fully understood and that gives significant uncertainties in the global warming prediction by earth system models equipped with carbon cycle feedbacks. An atmospheric observation-based estimate of surface CO_2 fluxes, i.e., so-called top-down analysis, would improve our understanding of the surface CO_2 flux mechanisms. An atmospheric inverse analysis in which a transport model is used to connect surface fluxes with atmospheric mole fractions is a prominent method in that it gives spatiotemporal variations of surface fluxes. In order to give implications of surface flux mechanisms, we should conduct a long-term inverse analysis with a high spatial resolution. In this study, we first use a simple box model that emulates integration of the global atmospheric CO_2 and apply it to a long-term inverse analysis with a variational method. In that experiment, we investigate how surface flux estimation is optimized along iterative calculations. Furthermore, we extend the inverse analysis to a more realistic problem with a sophisticated inverse system name NICAM-TM 4D-Var (Niwa et al., 2017a,b), in which a global three-dimensional model is employed. By using synthetic data with a current observational network, we elucidate uncertainties behind coming inversion results from NICAM-TM 4D-Var with real observations.

European Commission Joint Research Centre, 6. Earth System Research Laboratory, NOAA, 7. University of Helsinki, 8. Max Planck Institute for Biogeochemistry

Greenhouse gas Observing SATellite (GOSAT) detected significant enhancements of column-averaged dry-air mole fraction of methane (XCH_4) in East, South and Southeast Asia in the course of its operation since 2009. The attribution and evaluation of these enhancements will benefit the national mitigation efforts for methane in this area. We compared national inventories submitted to the United Nations Framework Convention on Climate Change (UNFCCC) to top-down emissions estimated at country scale by the global high-resolution (0.1° ×0.1°) inverse model NIES-TM-FLEXPART-VAR (NTFVAR). Long-term GOSAT retrievals and ground-based observations were used in the inversion for the year 2010-2017. Prior fluxes contained adjusted EDGAR v4.3.2 emissions scaled to match the country totals by national reports to theUNFCCC, augmented by biomass burning emissions from the Global Fire Assimilation System (GFASv1.2) and wetland emissions from the Vegetation Integrative Simulator for Trace Gases (VISIT) model. The estimated regional total methane emissions is 163.5 Tg $CH_4\,yr^{-1}$(with an uncertainty of 24.3Tg $CH_4\,yr^{-1}$) from twenty-eight countries included in this study, and 94% are from the top ten emitting-countries China (52.2Tg $CH_4 yr^{-1}$), India (36.7Tg $CH_4\,yr^{-1}$), Indonesia (20.3Tg $CH_4\,yr^{-1}$), Bangladesh (11.3Tg $CH_4\,yr^{-1}$), Pakistan (7.9Tg $CH_4\,yr^{-1}$), Vietnam (6.9Tg $CH_4\,yr^{-1}$), Thailand (6.6Tg $CH_4\,yr^{-1}$), Burma (6.3Tg $CH_4\,yr^{-1}$), Philippines (2.9Tg $CH_4\,yr^{-1}$) and Cambodia (2.6Tg $CH_4\,yr^{-1}$). Among these ten countries, natural methane emissions are dominant in Bangladesh and Cambodia, and anthropogenic emissions are dominant in other counties. Statistically significant increasing trends in anthropogenic emissions are detected in China and Indonesia from 2010 to 2017. Optimized high-resolution anthropogenic fluxes show intensive anthropogenic fluxes in megacity clusters like in eastern China, northern India, western Pakistan and southern Indonesia (Figure 1.Posterior anthropogenic methane fluxes (2010–2017 average, unit: mg $CH_4 m^{-2} day^{-1}$)).

Refinement of a diagnostic terrestrial ecosystem model using AsiaFlux network data toward GCOM-C SGLI GPP/NPP product

*LI JIAWEI[1], Kazuhito Ichii[1], Hideki Kobayashi[2], Wei Yang[1]

1. Chiba University, 2. Japan Agency for Marine-Earch Science and Technology

GCOM-C satellite with SGLI sensor was launched in December 2017. Because of medium resolution(300m) of SGLI sensor, it’ s possible to get more accurate climate change prediction. Furthermore, terrestrial carbon cycle products are significant to create. This presentation will introduce our current work on GCOM-C SGLI terrestrial carbon flux products. We select BESS (Breathing Earth System Simulator) as basic mechanistic terrestrial biosphere model,with some GCOM-C satellite products as inputs and then get estimations of daily gross primary productivity (GPP), net primary productivity (NPP), and net ecosystem exchange (NEE).

For the original BESS model, here are some improvements, including (a) using eddy-covariance observation network data across Asia to optimize model parameters, (b) adding a practical ecosystem respiration module, (c) applying some GCOM-C SGLI land products as inputs. In the beginning, we check the BESS model performance by using existing Asia Flux observation sites (about 50 sites) and select several key parameters by using sensitive analysis. Then, for these parameters, we use a trust-region optimization algorithm to identify their optimized coefficient. Second, a classify method of different land cover is add to improve BESS model accuracy. We think areas with different land covers have their own mechanisms so that optimized coefficients should be different. According to this, we can get a new flux estimation on large scale. Third, we create a semi-empirical respiration model for the BESS model to do more further estimation. So far, we chose Terra and Aqua MODIS data all model inputs. Then, we choose some available input data, such as leaf area index (LAI) and land surface temperature (LST) and switched them from MODIS to SGLI.

In the furture, Our group will still improve the models and calculate GPP, NPP and NEE. Remote sensing data with high spatial resolution (e.g. 300m) and high temporal resolution (e.g. daily) will be helpful to understand terrestrial carbon cycle at global scales. These products will be available as an official SGLI research product soon and updated annually.

In-situ observation of greenhouse-gas flux at proglacial grounds of a glacier –preliminary result for Gulkana Glacier, Alaska-

*Keiko Konya[1], Go Iwahana[3,2], Tetsuo Sueyoshi[4], Tomoaki Morishita[5]

1. Japan Agency for Marine-Earth Science and Technology, 2. Universitry of Alaska, Fairbanks, 3. Hokkaido university, 4. Ninational Institute of Polar Research, 5. Forestry and Forest Products Research Institute

Methane is one of the major greenhouse gases (GHG), and the variation of its concentration in the atmosphere has the potential to bring a significant impact on the global climate and carbon cycle. The methane emission in the Arctic regions, which is largely attributed to the methane production in the seasonally freezing layer, has been considered to be enhanced by thawing of permafrost and to be one of the sources of uncertainty for future climate projection. On the other hand, a notable amount of methane emissions from the proglacial ground surfaces after retreats of glaciers in Greenland and Iceland have been reported (e.g. Lamarche-Gagnon et al., 2019; Burns et al., 2018). Those newly-recognized methane hotspots may exist in other proglacial areas, which could influence on estimation of global methane budget. However, field evidence for the large methane emission is still limited and there is a lack of information about other proglacial areas.
We carried out the field experiments in the Gulkana Glacier in the Alaska Range, United Status. The objective of our study is to measure methane fluxes at the proglacial area of a small mountain glacier to verify if the large emission can be observed as reported in Greenland and Iceland, and expanding the field data towards the evaluation of the generality of previously reported methane emissions. The observation was conducted on 15 and 16 July 2019, one month after the onset of melting of the glacier, at 18 locations in the terminus of the glacier. The in-situ observation was conducted with the chamber method (Morishita et al. 2019). The chambers were set on dry, wet, and inundated ground surfaces to capture differences in the surface conditions. Gas samples were also taken for the isotopic analysis. A small emission was observed at seven locations, most of which were wet surfaces. Stable isotopes in the emitted methane and carbon dioxide imply that the methane was generated by microbial process. Our observed methane emission was small in mid-July and previous studies detected high methane emission at the end of June starting with higher discharge. Therefore, it is plausible that larger methane emission occurs in earlier and warmer melting seasons.

Testing machine-learning methods toward improvement of terrestrial CO2 flux estimations

*Zhiyan Liu[1], Kazuhito Ichii[1]

1. Center for Environmental Remote Sensing Chiba University, Chiba University

Data-driven approach is effective for upscaling observation network data of terrestrial carbon fluxes. In this study, we estimated terrestrial gross primary productivity (GPP) and net ecosystem exchange (NEE) across the globe using machine learning methods –random forest regression (RF) with MODIS collection 6 datasets after previous studies used collection 5 [e.g. Ichii et al. 2017; Tramontana et al. 2016; Kondo et al. 2015]. Furthermore, we introduced lag effects of input parameters (simply input as a new column) on GPP and NEE in RF models and this lag effect include either historical or future (lag within a month) remote sensing based input parameters. Because the ecosystem is a dynamic system, which current status is affected by historical factors and meanwhile will be observed in the future as some other physics or biochemical quantities. Thus, both processes may include the lag effect which mechanism are also different. We also attempt to adopt a deep learning method called RNN (Recurrent Neural Network and its sub-types) in which data flows by each time step and make some comparision. Site-level RF experiments showed that the lagged parameter improved the accuracy of NEE estimation (R^2 0~0.06 increasing for total Koppen climate types). The lagged parameter worked well in site-level anomalies, particularly, lag effect by shortwave solar radiation or land surface temperature in the night. The estimated annual anomaly variations in GPP and NEE showed a good consistency with independent model-based estimations (TRENDY V6). In the future research, the lag-effected will be a more important factor for ecosystem’s prediction and estimation.

[A-CG48] Projection and detection of global environmental change

convener:Michio Kawamiya(Japan Agency for Marine-Earth Science and Technology), Kaoru Tachiiri(Japan Agency for Marine-Earth Science and Technology), Hiroaki Tatebe(Japan Agency for Marine-Earth Science and Technology), V Ramaswamy(NOAA GFDL)

Anthropogenic forcings on global environment are expected to cause intensification of extreme events, sea level rise, ocean acidification and deoxygenation, as well as large-scale ecosystem changes. Earth System modeling groups across the world performed simulations and published projection data toward 6th IPCC assessment report due in 2021. Various new types of studies, such as event attribution and coupling of socio-economic processes and Earth system dynamics, are emerging in the field of global change projections. In addition, observational studies are becoming increasingly more important for grasping changes in the global environment and evaluating model projections. Interactions and collaborations beyond boundaries of conventional scientific disciplines are desired for dealing with the issue of global changes. This session thus aims to deepen our understanding on global change, from both disciplinary and interdisciplinary viewpoints.

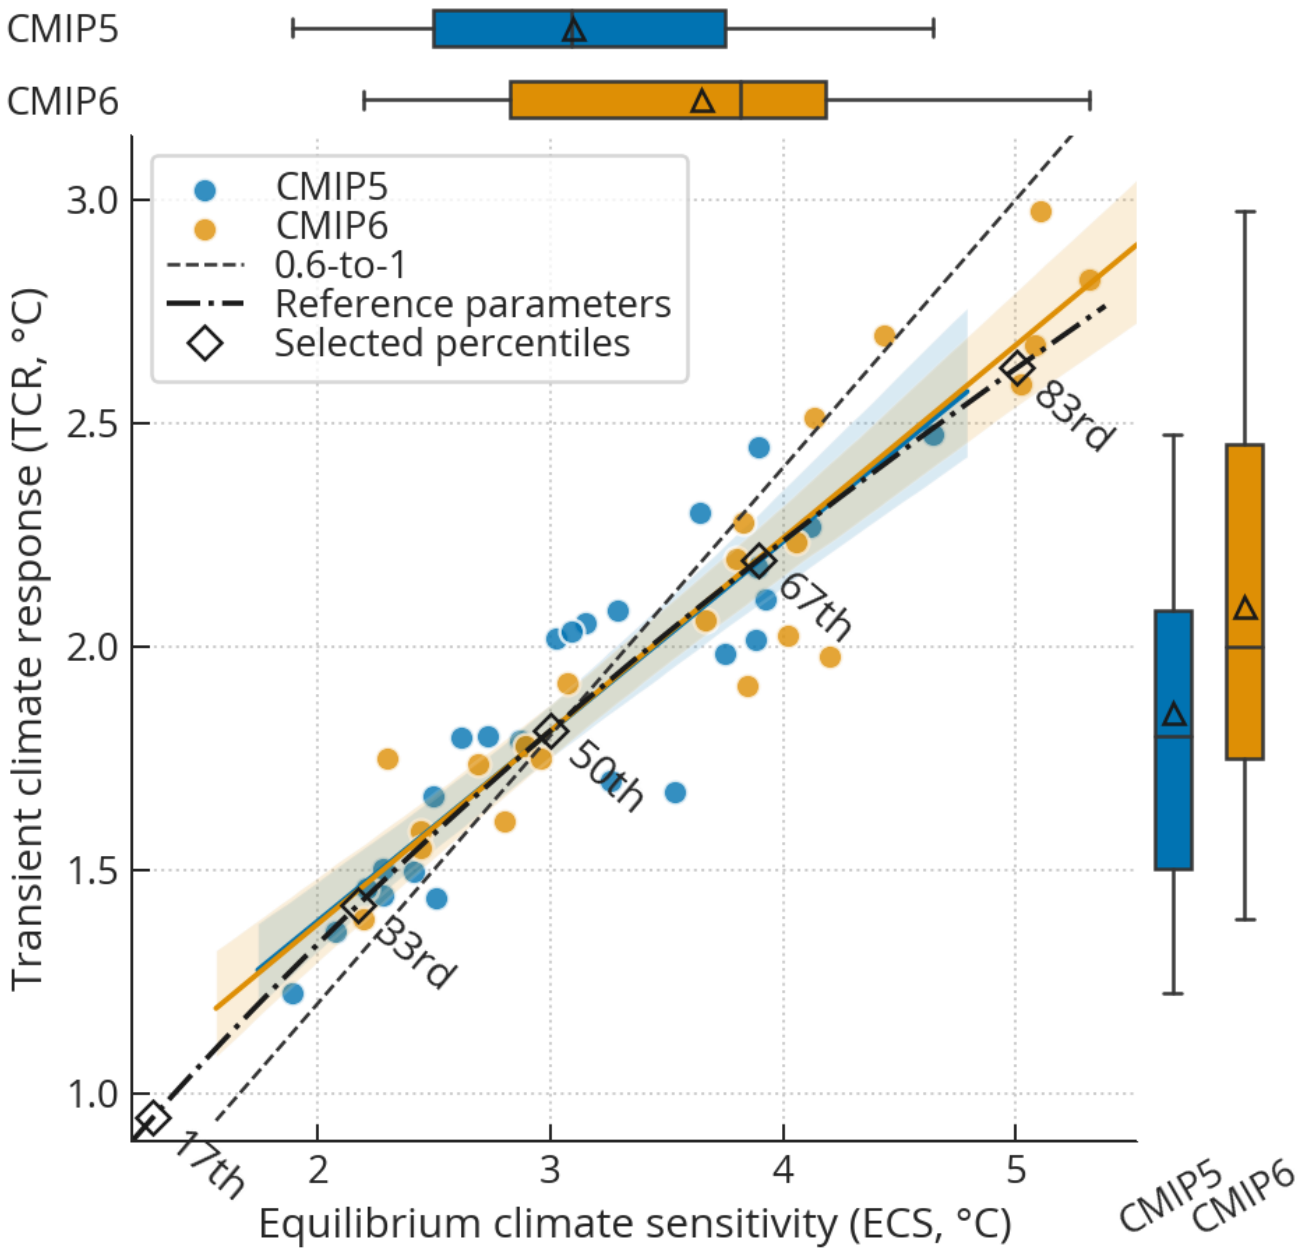
Methodology of probabilistic climate projections for the assessment of climate change mitigation pathways

*Junichi Tsutsui[1]



1. Central Research Institute of Electric Power Industry

Pathways of climate change mitigation are assessed for their consistency with a given temperature goal from probabilistic climate projections that reflect an ensemble of complex climate models and other lines of evidence. The author have been developing a climate model emulator for such probabilistic assessment and here describes and discusses its methodology.
The emulator consists of a thermal response module and a carbon cycle module. These are basically represented by impulse response functions to anthropogenic carbon input that alters the effective radiative forcing of the atmospheric CO_2 and natural processes in the ocean and terrestrial carbon cycle. The parameters of the thermal response module are calibrated for individual complex models from the latest and previous phases of Coupled Model Intercomparison Project (CMIP6 and CMIP5). The parameters of the carbon cycle module are currently fixed to their default values, which are calibrated to historical carbon balance assessed in the Fifth Assessment Report (AR5) of the Intergovernmental Panel on Climate Change and the mean properties of CO_2 increase experiments with CMIP5 Earth system models.
The thermal response parameters are characterized by the two climate sensitivity metrics, equilibrium climate sensitivity (ECS) and transient climate response (TCR). Figure 1 shows the relationship between the TCR and ECS for the individual CMIP models as well as the reference line representing the variation of the models. The reference line is built from principal component analysis for the variation, reflecting that the ratio of TCR to ECS generally decreases with increase in climate sensitivity. The probabilistic projection uses five parameter sets selected along the reference line so that resulting values of transient climate response to cumulative CO_2 emissions (TCRE) match nominal quantiles of 0.17, 0.33, 0.5, 0.67, and 0.83 based on the likely range of the TCRE assessed in the AR5.
Preliminary analysis of the current probabilistic projections compared with other approaches shows similar medians but large variation in ranges. It appears that the current method produces larger ranges than the others constrained by observed temperature changes. This difference implies that the assessed likely range is rather conservative and can be reduced with advanced constrain approaches and emerging observations. Figure 1 also shows that the 66% range of TCR diagnosed from the response parameters is comparable to the AR5-assessed likely range of 1 to 2.5 K despite the fixed carbon cycle parameters. This result implies that the AR5-assessed likely ranges are not necessarily consistent between TCR and TCRE, and that a consistent TCR range can be smaller by the contribution of the carbon-cycle uncertainties to the TCRE range.

Figure 1: Relationship between the TCR and the ECS from the CMIP5 and CMIP6 multi-model ensembles, as of October 2019. The dashed line is drawn to guide a proportional relation with a ratio of 0.6, representing an approximate multi-model mean. The color lines with plumes show regression estimates with a 95% confidence interval. The triangle markers in the marginal box plots indicates means. The dash-dotted line shows a reference line representing the variation of the models, and the five diamond markers along the reference line show reference parameters adjusted to nominal quantiles of 0.17, 0.33, 0.5, 0.67, and 0.83 in terms of the AR5-assessed TCRE range.

Improvement in runoff reproducibility of a land surface model and its implications for the energy-water balances on land

*Kumiko TAKATA[1], Naota Hanasaki[1]

1. Center for Climate Change Adaptation, National Institute for Environmental Studies

Land surface hydrological processes are widely recognized as important elements in climate change studies, and land surface models have been developed by many research groups since the 1980s. MATSIRO (Takata et al., 2003; Nitta et al., 2014) is one of them; it calculates the surface and soil temperatures, evaporation, runoff, soil moisture, etc., based on the energy water balances, taking into account the effects of vegetation such as reflection and absorption of radiation, photosynthesis, transpiration, water uptake from roots, etc. The model has, however, had the strong bias of underestimation in runoff, for many years, compared to observed values. Until today, Hirabayashi et al. (2005) examined and revised the parameter for base runoff, and Yoshimura et al. (2006) improved the algorithms of groundwater level diagnosis. Nevertheless, MATSIRO is still one of the models producing least runoff among others (Haddeland et al., 2011).

We found that the diagnosed groundwater level that was used for calculation of surface runoff (Dunne flow) and base runoff tended to be too deep. Therefore, we tried a simple method to forcibly raise groundwater levels to examine its effect in this study. Specifically, we changed the condition for saturation judgment. In the base experiment (EP.0), a soil layer was judged saturated when soil moisture averaged over a grid cell was almost equal to saturation. In the sensitivity experiments, the condition was relaxed to about 75% (EP.1), 50% (EP.2), 25% (EP.3), and 0% (EP.4) of saturation. A series of numerical experiments was conducted in the Chao Phraya River basin (CP) in Thailand as a case study. The meteorological data from 1981 to 2004 at a horizontal resolution of 5 arc-minutes (i.e., approximately 9 km) (Kotsuki et al., 2013) was used.

The calculated monthly and daily river flow in EP.2 agree well with observation at the Bhumibol Dam (BB) on the Ping River in the northwestern part of CP. The groundwater level in the catchment of BB in EP.2 were much shallower (seasonal range was 1-3 m) than that in EP.0 and EP.1 (5-6 m). The seasonal changes in the vertical profiles of monthly mean soil moisture, and the monthly Bowen ratio were also improved.

The overall behavior of the model was dramatically improved by changing the condition of saturation judgment. The improvements in the Bowen ratio and soil moisture suggests that those impacts will be amplified when the land surface model is couled to the other components of climate models. In the results above, the streamflow and Bowen ratio agreed well with the measurements when the saturation threshold was at about 50% of saturation (EP.2). The good agreement in the experiment with the relaxed threshold implies that there are processes that yield large runoff at a sub-grid scale due to inhomogeneity of land surface, such as macro pore, landscape, land use, etc. An optimum saturation threshold is expected to exist, that simulates such local runoff.

Impact of volcanic eruption on surface climate in VolMIP experiments by MIROC-ES2L

*Manabu Abe[1], Tomohiro Hajima[1]

1. Japan Agency for Marine-Earth Science and Technology

Large-scale volcanic eruptions affect significantly surface climate. Also, uncertainties on the impact of volcanic eruption on the climate have remained. It is important to understand the volcanic impact on the past and future climate changes for improving basic knowledge of climate change. We have conducted the Tir1 experiments of VolMIP endorsed by CMIP6 with MIROC-ES2L. In this study, we summarize the results of VolMIP Tir1 experiments using MIROC-ES2L.

Effect on the Earth system of realizing a 1.5 ˚C warming climate target after overshooting to the 2 ˚C level

*Kaoru Tachiiri[1], Diego Silva Herran[2], Xuanming Su[1], Michio Kawamiya[1]

1. Japan Agency for Marine-Earth Science and Technology, 2. National Institute for Environmental Studies

An Earth system model (ESM) was used to investigate the effect of reaching the target of 1.5 ˚C warming (relative to preindustrial levels) after overshooting to the 2 ˚C level with respect to selected global environment indicators. Two scenarios were compared that diverged after reaching the 2 ˚C level: one stayed at the 2 ˚C level, and the other cooled to the 1.5 ˚C level. Unlike the internationally coordinated model intercomparison projects, the scenarios were developed for a specific climatic model with emissions and land use scenarios consistent with socioeconomic projections from an integrated assessment model. The ESM output resulted in delayed realization of the 1.5 ˚C and 2 ˚C targets expected for 2100. The cumulativeCO2 emissions for 2010–2100 (2300) were 358 (−53) GtCO2 in the 2 ˚C scenario and−337 (−936) GtCO2 in the 1.5 ˚C scenario. We examined the effect of overshooting on commonly used indicators related to surface air temperature, sea surface temperature and total ocean heat uptake. Global vegetation productivity at 2100 showed around a 5%increase in the 2 ˚C scenario without overshooting compared with the 1.5 ˚C scenario with overshooting, considered to be caused by more precipitation and strongerCO2 fertilization. A considerable difference was found between the two scenarios in terms of Arctic sea ice, whereas both scenarios indicated few corals would survive past the 21st century. The difference in steric sea level rise, reflecting total cumulative ocean heat uptake, between the two scenarios was <2 cm in 2100, and around 9 cm in 2300 in the Pacific Island region. A large overshoot may reduce the eventual difference between targets (i.e. 1.5 ˚C in contrast to 2 ˚C), particularly in terms of the indicators related to total ocean heat uptake, and to sensitive biological thresholds.

[A-CG49] Greenhouse Gas Monitoring from Space: Current Capabilities, Challenges, and Future Needs

convener:kurosu thomas p(Jet Propulsion Laboratory, California Institute of Technology), Annmarie Eldering(Jet Propulsion Laboratory), Akihiko Kuze(Japan Aerospace Exploration Agency), Tsuneo Matsunaga(Center for Global Environmental Research and Satellite Observation Center, National Institute for Environmental Studies)

In a circulation letter of their Position Statement on Climate, the AGU writes

"Human-caused climate change is one of the most serious issues of our time. It will cause increasing health, economic, security, and ecological risks, from heat-related deaths and illnesses, hazards such as flooding, water scarcity, wildfire, and extreme weather and impacts to coastal infrastructure, agriculture, fisheries, and global migration."

With the constantly growing threat anthropogenically-induced climate change, global to local monitoring of atmospheric greenhouse gas (GHG) concentrations becomes increasingly important. Over the past decade, space-based GHG sensors have contributed substantially to our understanding of CO2 and CH4 emission sources and natural sinks on global and regional scales. Recent advances in these sensors have now extended these capabilities for studies of more compact sources, including large urban areas. NASAs OCO-3 on the ISS and Japans TANSO-FTS-2 on GOSAT-2 include target mapping modes that continue and extend the observation records of their precursors, and the Canadian commercial GHGSat provides high spatial resolution observations of CO2 and CH4 over selectable locations on the Earth. Sentinel 5P/TROPOMI measures CH4 with a wide swath instrument with daily near-global coverage. Future GHG observing systems are expected to further improve on the bridging of global and local scales, to provide optimized data records as basis for climate change mitigation policies.

We propose a session that focuses on the following aspects of space-based GHG monitoring: (1) capabilities of currently operating sensors measuring greenhouse gases on global to local scales, including OCO-2&3, TANSO-FTS/2, GHGsat, TROPOMI, and TANSAT; (2) identification and quantification of shortfalls in current data records, and requirements for future observation strategies; and (3) future observing systems and how these will address current gaps in GHG monitoring.

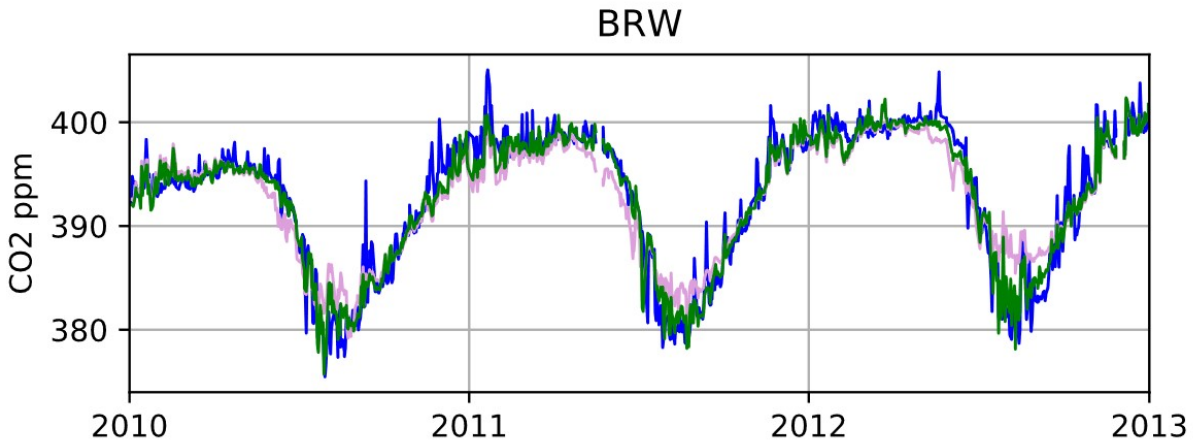
A high-resolution CO_2 inverse modeling using observations from the global ground-based monitoring network and the GOSAT satellite



*Shamil Maksyutov[1], Rajesh Janardanan[1], Tomohiro Oda[2], Makoto Saito[1], Yukio Yoshida[1], Johannes W Kaiser[3], Vinu Valsala[4], Edward Dlugokencky[5], Tsuneo Matsunaga[1]

1. National Institute for Environmental Studies, Tsukuba, Japan, 2. USRA/NASA GSFC, Greenbelt, USA, 3. DWD, Offenbach, Germany, 4. Indian Institute for Tropical Meteorology, Pune, India, 5. Global Monitoring Division, NOAA, Boulder, USA

We present a high-resolution CO_2 flux inversion system designed to estimate surface fluxes from atmospheric CO_2 observational data collected by the GOSAT satellite as well as the global in-situ ground-based observation networks. Our inverse system NTFVAR is based on a coupled transport model combining the FLEXPART Lagrangian Particle Dispersion Model (LPDM) and the NIES-TM global Eulerian transport model. The system solves for flux corrections to the prior fluxes at a 0.1 x 0.1 degree spatial resolution via an iterative optimization procedure using the adjoint of the coupled transport model. We used high-resolution prior fluxes prepared from the ODIAC anthropogenic emissions data product, the GFAS global biomass burning dataset, the OTTM ocean model and the VISIT terrestrial biosphere model. The high-resolution version of VISIT biosphere flux was obtained using a separate VISIT CO_2 flux simulation implemented for each vegetation type identified by a vegetation mosaic map. The prior flux uncertainty for the land and ocean regions was scaled proportionally to monthly mean MODIS-GPP and the ocean flux variability. First, we estimated bi-weekly flux corrections over the period of 2010 to 2012 solely from in-situ CO_2 data by the ObsPack global observation network dataset. The application of the high-resolution atmospheric transport improved the representation of fine-scale anthropogenic CO_2 plumes. A comparison to NOAA’s CarbonTracker optimized simulations shows that our high-resolution model has some advantage at coastal and island observation sites, experiencing a mix of marine and continental air inflow. We also implemented an inversion using the ground-based data and the GOSAT satellite data. The GOSAT Level 2 data (NIES L2 v02.72) were corrected by estimating the deviation of GOSAT L2 data from an optimized simulation with the ObsPack for each latitude band and month. We confirmed the reduction of misfit between the GOSAT observations and the high-resolution model simulations after the inversion.

GOSAT series product validation with TCCON, Sky radiometer and lidar data

*TRIEU THI NGOC TRAN[1], Isamu Morino[1], Osamu Uchino[1], Yukitomo Tsutsumi[1], Tetsu Sakai[2], Tomohiro Nagai[2], Akihiro Yamazaki[2], Hiroshi Okumura[3], Kouhei Arai[3], Ben Liley[4]

1. National Institute for Environmental Studies (NIES), Tsukuba, Japan, 2. Meteorological Research Institute, Japan Meteorological Agency, Tsukuba, Japan, 3. Graduate school of Science and Engineering, Saga University, Saga, Japan, 4. National Institute of Water and Atmospheric Research, Lauder, New Zealand

Data from the Total Carbon Column Observing Network (TCCON) are the primary validation source for the column averaged dry air mole fraction XCO_2 and XCH_4 deduced from GOSAT. In addition, aerosol optical thickness, Angstrom exponent, and single scattering albedo, all obtained from sky radiometer measurements, and vertical profiles of aerosols and thin cirrus clouds from lidar observations are important for fully validating XCO_2 and XCH_4 retrievals.

In this presentation, we investigate influences of aerosols and clouds on GOSAT XCO_2 and XCH_4 data at three TCCON sites: Tsukuba, Saga, and Lauder. At these sites, both sky radiometer and lidar have been also operating. The match up was performed with a ±0.1˚ latitude/longitude rectangular area of each TCCON site and within 30 minutes of the GOSAT overpass time. The results showed that the bias and standard deviation were largest at Lauder (-0.99 ±1.91 [ppm] and -5.33 ±11.13 [ppb] for XCO_2 and XCH_4 , respectively). The bias and standard deviation at Tsukuba and Saga were 0.25 ±1.73 [ppm] and 0.24 ± 1.83 [ppm] for XCO_2 and -0.79 ±9.44 [ppb] and 7.19 ±8.17 [ppb] for XCH_4, respectively.

Both XCO_2 and XCH_4 differences between GOSAT and TCCON at Lauder were negatively correlated with AOT at 500 nm. In contrast, at Saga and Tsukuba the difference of XCO_2 only negatively correlated with AOT at 500 nm. AOT at 500 nm was largest especially in Spring at Saga (0.87) and Tsukuba (0.54). AOT at 500 nm of Lauder was smallest (0.15) among the three sites. The single scattering albedo at 500 nm at Tsukuba varied from 0.75 to 1.0 and from 0.67 to 1.0 at Saga and Lauder. The differences in XCO_2 and XCH_4 between GOSAT and TCCON had no relationship with the Angstrom exponents, which varied site by site. The causes for these findings will be discussed in the presentation. Preliminary results of vertical profiles of aerosols and/or clouds at Lauder will be also shown.

Observations of the Tropical Land Biosphere response to the 2015-2016 El Niño with the Orbiting Carbon Observatory-2 (OCO-2) and Greenhouse gases Observing SATellite (GOSAT)

*David Crisp[1]

1. Jet Propulsion Laboratory, California Institute of Technology

The first two years of the OCO-2 mission were dominated by the record-setting 2015–2016 El Niño. OCO-2 measurements were combined with GOSAT observations and analyzed to yield high spatial resolution estimates of the column-averaged dry air mole fraction, XCO_2, These products clearly resolved reductions in tropical ocean outgassing from net increases in CO_2 emissions from tropical forests. These XCO_2 estimates were combined with OCO-2 and GOSAT solar-induced chlorophyll fluorescence (SIF) measurements to trace the origin of the forest CO_2 emissions to the impacts of drought, temperature stress, and fires. Observations acquired between 2017-2019 documented the atmospheric CO_2 response following this El Niño when, unexpectedly, its XCO_2 and SIF measurements showed that the natural carbon cycle never fully recovered to the state anticipated by most earlier carbon cycle measurements and models. In particular, tropical forests, once thought to be significant CO_2 sinks, continued to be persistent net sources of CO_2 throughout this period. Understanding these results and their implications for the response of the natural carbon cycle to climate change requires longer continuous records of CO_2 and SIF.

Global and local flux estimation of carbon dioxide and methane by GOSAT satellites

*Akihiko Kuze[1], Nobuhiro Kikuchi[1], Hiroshi Suto[1], Kei Shiomi[1], Fumie Kataoka[2]

1. Japan Aerospace Exploration Agency, 2. Remote Sensing Technology Center of Japan

GOSAT and GOSAT-2 have provided long-term radiance spectral data using Fourier transform spectrometer technology since 2009 and 2018, respectively. With the advantage of FTS multiplexing, they can simultaneously measure carbon dioxide (CO_2) and methane (CH_4) absorption bands of reflected solar light with two linear polarizations and thermal emission. Radiance spectra with two polarizations can distinguish between less-polarized reflections from the Earth’ s surface and highly polarized scattering by aerosols and thin clouds. The infrared band can add information to vertical profiles. By combining all these spectra data, partial column densities of the upper (4-12 km) and lower (0–4 km) troposphere can be retrieved, even under thick aerosol regions such as Africa, India, and South Africa. Two-layer vertical information enhances measurements of near-surface emission and uptake and reduces errors in transportation, therefore improving global flux estimation. With two-axis pointing systems, they can target large point sources and mega cities and have enhanced measurements of CO_2 and CH_4. However, local flux estimates by GOSAT may be problematic because of too large a footprint, a lack of proper upwind reference observations, and insufficient wind information. To contribute to the global stocktake of the Paris Agreement, we need a system to observe and estimate local flux from individual source sectors. We will present the status of flux estimation and discuss how to reduce such uncertainties.

[A-CG50] Earth & Environmental Sciences and Artificial Intelligence

convener:Tomohiko Tomita(Faculty of Advanced Science and Technology, Kumamoto University), Shigeki Hosoda(Japan Marine-Earth Science and Technology), Ken-ichi Fukui(Osaka University), Satoshi Ono(Kagoshima University)

In recent years, we have been required to explore various gigantic data leading earth and environmental sciences such as modern meteorology, oceanography, hydrology and so on, to accomplish Society 5.0 and Sustainable Development Goals (SDGs). To examine such environmental big data faithfully, it may be required to use the techniques of artificial intelligence (AI) including spatiotemporal data modeling of AI, prediction and detection by machine learning, techniques of automated data mining, and so forth. At the present, AI is also expected to lead the data-driven science as a bridge connecting science and big data. This session first calls for various studies applying the techniques of AI to global environmental issues and then will discuss them in both natural and information sciences.

A precipitation prediction using an artificial neural network model based on observation time series data

He Zhang[1], Naoki Matsumoto[1], *Tomohiko Tomita[2]

1. Graduate School of Science and Technology, Kumamoto University, 2. Faculty of Advanced Science and Technology, Kumamoto University

In weather prediction, precipitation prediction is one of most difficult but strongly required for society. This work investigated performance of an artificial neural network (ANN) model for the precipitation prediction. In particular, this study examined how training of the ANN model improved the performance of precipitation prediction.

The datasets used in this study are observation time series data compiled by the Japan Meteorological Agency (JMA). The stations are five, i.e., Kumamoto, Fukuoka, Nagasaki, Kagoshima, and Oita located in Kyushu of Japan. The used observation variables are six, that is, hourly precipitation, temperature, pressure, vapor pressure, wind speed, and wind direction. Using these station data, this study diagnosed the performance of the ANN model's few-hour precipitation prediction at Kumamoto. In this study, the ANN prediction model was constructed by a multi-layer perceptron, in which the number of intermediate layers was set to be two for easy experiment and interpretation. Then, a variety of experiments were performed about training of the ANN prediction model. In particular, this work examined how stations and physical variables improved the precipitation prediction. As the evaluation of prediction outputs, this work diagnosed 1) the difference in maximum value, 2) the time lag of appearance of the maximum, and 3) the root mean squared error between and the prediction and real precipitation time series. In addition, a skill score, which was the ratio between the predicted precipitation and the real value larger than 10 mm/h, was used. This skill score has been designed to evaluate the performance of the JMA's physical prediction model for heavy precipitation events.

The results show that 1) Kumamoto's precipitation itself is most crucial for the prediction, 2) the data at western station effectively improve the prediction, and of course, 3) the most recent precipitation data is most valid. In order to improve the prediction at the maximum value in a precipitation event, this study removed the data with no precipitation from the training data as a preprocessing. It was found that this preprocessing effectively improved the maximum precipitation value from 30% to 80% of the real maximum value. The skill score of this ANN prediction model in precipitation, which was estimated for three-hour prediction, was that of JMA's physical prediction model in about 10 years ago. This study is still on going, and the further results will be shown at the conference, e.g., the results of the experiments increasing stations, improving the ANN structure, using other algorithms such as recurrent NN, and so on.

Climate Prediction by Using Periodic Convolutional Recurrent Network

*Ekasit Phermphoonphiphat[1], Tomohiko Tomita[2], Masayuki Numao[1], Ken-ichi Fukui[1]

1. Osaka University, 2. Kumamoto University

Machine learning based prediction methods have been investigated to many climate predictions such as precipitation forecasting, and temperature prediction. However, most machine learning researches on this domain do not consider periodic patterns, which are important for climate data that has strong periodicity. For example, the positive and negative phases of North Atlantic Oscillation (NAO) are repeatedly every year that can indicate seasonal over the Northern Hemisphere. Features from such periodicity may improve prediction accuracy.
In order to consider periodicity, we adopt the periodic convolutional recurrent network (Periodic-CRN) to our research. The idea of this model is to store and load the hidden states that learned by convolutional recurrent network (CRN) as periodic representation. The stored periodic representation is loaded and combined with the current prediction output. The model also has the attention mechanism that is used to weigh multiple periodic representations (e.g., monthly and yearly representation). In this work, we extend the idea of the periodic attention mechanism component to includes nearby time interval (month) representation. The group of nearby periodic representation is considered instead of using only a single periodic time interval. Then we use convolutional long short-term memory (ConvLSTM) as CRN.
We applied the proposed method to upper tropospheric circulations over the Northern Hemisphere and the land surface variable, which are geopotential height at 300 hPa (Z300) and temperature at 2 meter height from the surface (T2M), respectively. These data have a dominant periodic pattern that repeats every year. The proposed method obtained the average root mean square error (RMSE) of Z300 short-term prediction from 2016 to 2018 of 62.48 meters (0.68% compared to average Z300 value). On the other hand, ConvLSTM, convolutional neural network (CNN), and linear regression (LR) obtained average RMSE of 79.24, 113.76, and 125.25 meters, respectively. The proposed method also outperforms in T2M prediction that obtained average RMSE of 1.79 degrees Celsius (˚C) while ConvLSTM, CNN, and LR obtained average RMSE of 2.54, 4.84, and 3.87 ˚C, respectively. The result has shown that the proposed method that considers data’s periodicity can improve prediction accuracy, which is a significant improvement from conventional methods.

K-means clustering of Argo profiles for identifying circulation patterns

*Nozomi Sugiura[1]

1. Japan Agency of Marine-Earth Science and Technology

A k-means clustering of Argo profiles is performed. By using the signature of each data sequence as the coordinate system for feature space, major ocean ciculation patterns are better represented with distinct clusters, than by using conventional Temperature and Salinity coordinate. We will discuss why the signature, which is a key cencept in rough path theory, is relevant to representing a profile. Implications for its usage in data assimilation will also be discussed.

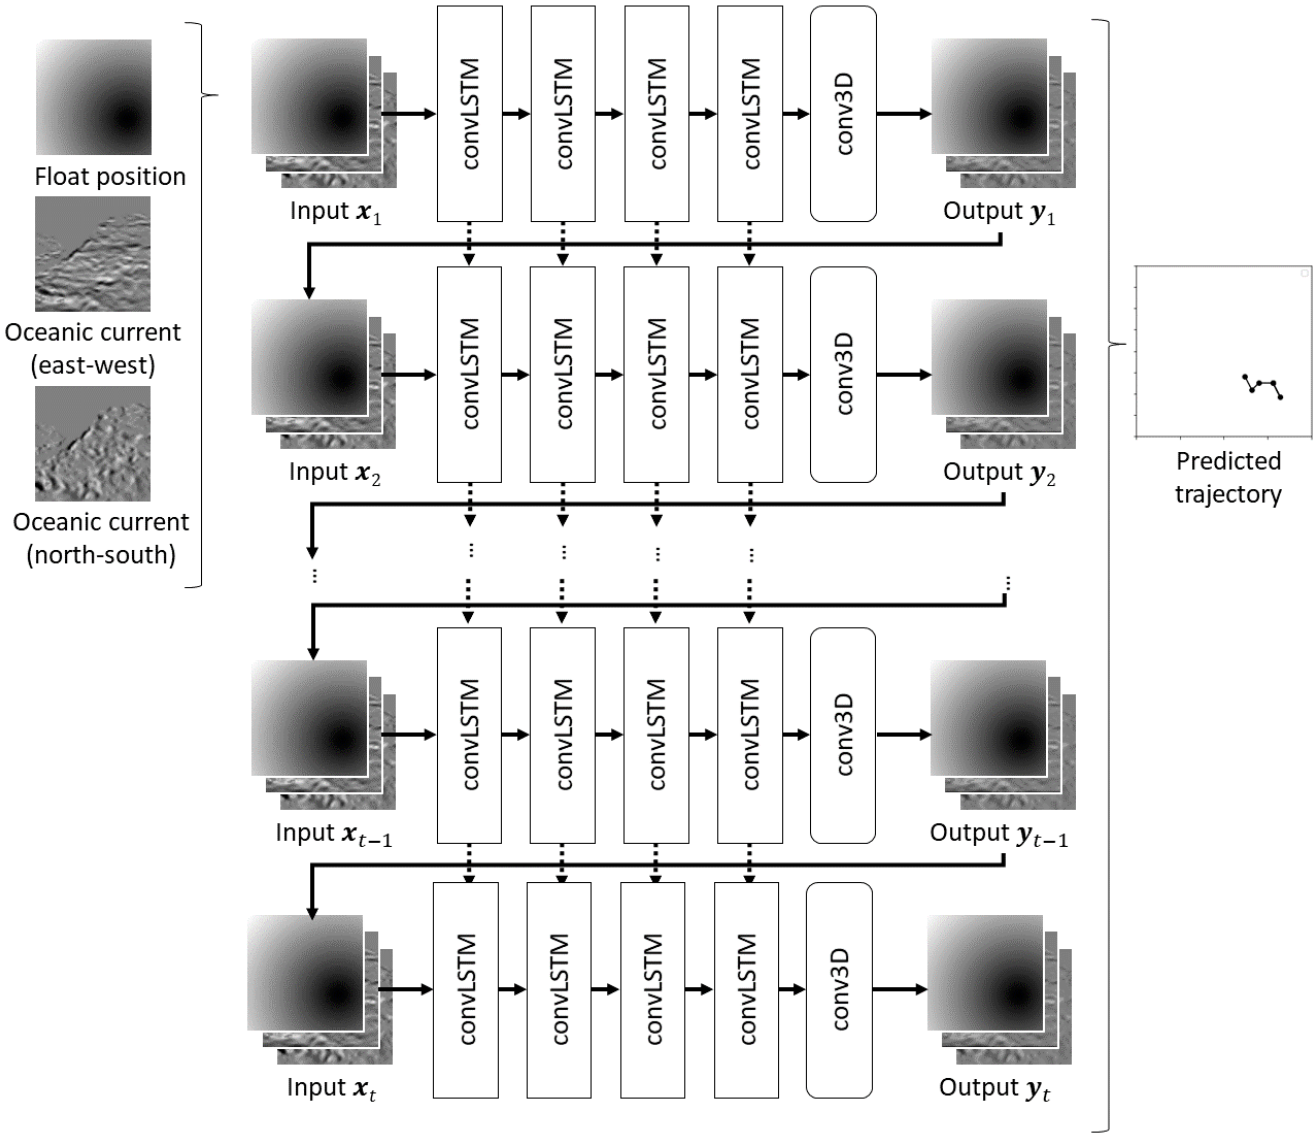
A Preliminary Study on Algo Float Trajectory Prediction using Multimodal Convolutional LSTM

*Serina Higashi[1], Takahiro Kinoshita[1], Shigeki Hosoda[3], Ken-ichi Fukui[2], Satoshi Ono[1]

1. Kagoshima University, 2. Osaka University, 3. Japan Marine-Earth Science and Technology



The ocean is recognized as a driving source of global warming and climate changes. This is because it occupies about 70% of the earth's surface and has a heat capacity more than 1000 times as much as of the atmosphere. The physical state observation inside the ocean is necessary to understand oceanic variability; however, it is difficult by research vessels to conduct long-term ocean monitoring. Therefore, the international Argo project has started since 2000 with the aim of long-term, real-time, and globally-covered ocean monitoring system.

In this program, more than 30 countries operate more than 3,800 Argo Floats, which are autonomous buoys and report observation data in real-time via satellites. A certain country manages each float, and it is necessary to obtain permission if there is a possibility of entering the economic zone of another country. Currently, numerical simulation is performed to predict float trajectory before deploying the float; however, the numerical simulation does not take into account the occurrence of vortices that may affect the movement of the float. Therefore, applications for permissions are being made to all possible countries of which the float may enter the economic zone.

Therefore, this study proposes a machine learning-based method for Argo float trajectory prediction, which allows reducing the number of countries that have to obtain permissions to enter the float. The proposed method adopts convolutional long short term memory (ConvLSTM), which is a recurrent neural network and also has the advantages of a convolutional neural network.

The advantages of the proposed methods are that it performs inductive learning based on past float trajectories, and allows adopting multiple observation data that have different properties such as float positions and ocean current data. The float data consists of the latitude and longitude position and the time when floating on the sea surface every ten days. The ocean current data is based on the monthly average flow velocity in each direction of east, west, north, and south in a range of 0.5 x 0.5 degrees square. To handle both data with different properties in a unified manner, all data is translated into a single image containing multiple channels. In addition, to unify the time resolution, images of ocean current are linearly interpolated.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-CG Complex & General

[A-CG51] Satellite Earth Environment Observation

convener:Riko Oki(Japan Aerospace Exploration Agency), Yoshiaki HONDA(Center for Environmental Remote Sensing, Chiba University), Yukari Takayabu(Atmosphere and Ocean Research Institute, the University of Tokyo), Tsuneo Matsunaga(Center for Global Environmental Research and Satellite Observation Center, National Institute for Environmental Studies)

In recent years, we cannot avoid facing issues on global environmental changes that occur in various spatiotemporal scales. The earth environmental observation data by satellites became the necessary basic data to tackle and solve those issues. Due to the recent advancement in the observation sensor technique and the data processing technique, the satellite observation has been showing rapid progress, and the time is changing from examining the accuracy of the observation sensor data to the advancement of the data application, leading to broaden potential users. In these days application became synergetic, so we comprehensively pick up this topic in the Atmospheric and Hydrospheric Sciences Session of this Union Meeting that enables to comprise the atmospheric, oceanic and land sciences; by combining the intelligence and the knowledge of the party, we propose a session that aims to prompt further studies towards the issues on earth environmental change, the advancement in the data application and future plans of Earth Observation missions.

Australian bushfire captured by AHI/Himawari-8 and SGLI/GCOM-C

*Yukio Kurihara[1], Kazuhisa Tanada[1], Hiroshi Murakami[1], Misako Kachi[1]

1. Japan Aerospace Exploration Agency / Earth Observation Research Center

JAXA in collaboration with JMA provides geophysical parameters retrieved from the data obtained with AHI/Himawari-8. The wildfire product is one of the Himawari-8 products by JAXA. We developed a new wildfire product in 2019, which provides the fire radiative power (FRP) determined by performing the bi-spectral method to 2.3- and 3.9-micron data. About 60 % of the preliminary detected wildfire has agreed with the MOD6 fire products, and the statistical comparison of FRP shows a good agreement between the new product and MOD6.

SGLI is the optical sensor onboard the GCOM-C satellite which JAXA launched in Dec. 2017. SGLI has 11 channels for visible to near-infrared wave range, 6 channels for short-wavelength to thermal infrared wave range, and two polarization channels for visible and near-infrared wavelength. The spatial resolution is switchable between 250 m and 1 km except for some channels which have the 1 km of the resolution. SGLI observes land and the seas near land with the 250 m resolution and open ocean with the 1 km resolution.

The newly developed Himawari-8 wildfire product and SGLI have captured the Australian bushfire from September 2019 to early 2020. The fire radiative energy (FRE) and the burned biomass emission have been calculated based on retrieved FRPs. And a cumulative total of the burned area has been calculated from the fire fractions determined for FRP and compared the area estimated based on NDVI calculated with the SGLI data obtained with the 250 m resolution.

Detecting the Kuroshio-induced island vortices observed from GCOM-C and Himawari-8 data

*Po-Chun Hsu[1], Chung-Ru Ho[1]

1. Department of Marine Environmental Informatics , National Taiwan Ocean University

When the Kuroshio passes Green Island, a small island located southeast of Taiwan, well-organized vortices were formed by the interaction between the current and the island. Previous researches have used high-resolution satellite imagery, acoustic Doppler current profiler data, cruise observations, and numerical models to analyze the Green Island wakes, however, there are still many bottlenecks and questions to be resolved. To more understand the spatial structure of island wake and vortex trajectory, the sea surface temperature (SST) and chlorophyll-a (Chl-a) concentration derived from Himawari-8 and the second generation global imager (SGLI) of global change observation mission (GCOM-C) were used in this study. Based on the GCOM-C data, the horizontal SST and Chl-a variations in observed lines, the fronts of SST and Chl-a between the wake and the Kuroshio, the distance between two consecutive vortices, and different structures of SST and Chl-a in the same vortex have been investigated. Based on the Himawari-8 data, totals of 101 vortex cases from July 2015 to December 2019 have been calculated. The average vortex propagation speed was 0.95 m/s, and more than half of the vortices have propagation speed between 0.8-1.2 m/s. The average incoming surface current speed of Green Island was 1.15 m/s which was calculated by the maximum cross-correlation (MCC) method. In total of 38 cases of two continuous vortices, the average vortex shedding period was 14.8 hours, and the results agreed to the ideal Strouhal-Reynolds number fitting curve relation. Our results suggested that the size of Green island and the horizontal eddy viscosity are suitable selected 5 to 6 km and the 100 m^2s^{-1}, respectively.

Variability of groundwater storage in Northern India using the GRACE

*Amit K Singh[1], M Saravanan[2], Swetabh Patel[3]

1. School of Environmental Sciences, Jawaharlal Nehru University,New Delhi, 2. College of Health Science,Mekelle University, Ethiopia, 3. Department of Agronomy,Iowa State University USA

Groundwater is the vital and largest source of freshwater in India. Changing climate, anthropogenic activities and rising population have affected groundwater storage. Intensive exploitation of groundwater resources leads to depletion and scarcity of water which significantly affects the ecosystem and economic developments. In this work, we quantified the long-term spatiotemporal changes in the climate and groundwater storage in the northern region of India where significant depletion of the groundwater has been observed in recent years. For the monitoring and measuring groundwater changes in the region, observed well data and the satellite data from NASA’ s Gravity Recovery and Climate Experiment (GRACE) have been used for the period 2002 to 2016. The results were well-validated in correspondence with the observed and satellite data. The rainfall was highly variable during the study period and the satellite data reflects the occurrence of water loss in the region, The GRACE satellite showed a decline with the rate of 2.14 cm/year in the groundwater storage. This loss was influenced by the rise in temperatures and marked drought years which led to the anthropogenic withdrawals of groundwater for sustaining the agricultural crops. The information from the GRACE can be used for the various applications in groundwater studies which will be imperative to formulate the policies to achieve the goals of sustainable agricultural production and groundwater resources management.

The characteristics of precipitation and anvil cloud detected by GPM/DPR

*Koichi Toyoshima[1], Hitoshi Hirose[2], Atsushi Higuchi[1]

1. Center for Environmental Remote Sensing, Chiba University, 2. JAXA EORC

The anvil cloud spreads thinly in the upper troposphere with deep convection. The upper clouds play an important role in the radiation budget of the earth, and in order to understand the characteristics of upper cloud using GPM. GPM dual frequency precipitation radar (DPR) is expected to detect a weak signal due to the anvil cloud because it has improved sensitivity compared to the PR of TRMM era. The purpose is to detect anvil clouds by GPM precipitation radar and clarify regional characteristics.
The data for this study is GPM/Ku and Ka band radar standard product version 6, the parameter is flag anvil, ZfactorCorrected, nearSurfaceRain. The study time period is March 2014 to December 2019.
From the results of the vertical structure using CFAD, signals (14 to 18 dBZ) weaker than 18 dBZ, which was the detection limit of TRMM/PR, were detected. In the central African continent where convection is active, the relative proportion of anvil clouds without rainfall is higher than that with anvil clouds with rainfall, suggesting that the anvil cloud is widespread. In the western Pacific Ocean, where the convective activity is high, the echo of mode is weaker and the altitude tends to be lower than that of the land in Africa. In the eastern Pacific Ocean where the short rainfall system is dominant, although the sample size was small, the echo intensity and mode were as high as the western Pacific Ocean. In the sea area, echoes are observed below 16 dBZ and below 5 km.
We also investigated the relationship between the echo top height and rainfall rate of adjacent rainfall samples and the anvil cloud profile. While there is a correspondence between the convection echo top height and the anvil cloud ice particle height, the anvil cloud profile does not depend on the intensity of adjacent rain samples.
In the presentation, we will introduce the evaluation of estimated precipitation products by Himawari-8 for precipitation that covered by anvil cloud.

Improvement for infrared rainfall estimation algorithm of GSMaP using machine learning

*Hitoshi Hirose[1], Takuji Kubota[1], Atsushi Higuchi[2], Koichi Toyoshima[2], Shoichi Shige[3], Tomoo Ushio[4], Tomoaki Mega[4]

1. Japan Aerospace Exploration Agency, 2. Center for Environmental Remote Sensing, Chiba university, 3. Department of Science, Kyoto University, 4. Department of Engineering, Osaka University

The Global Satellite Mapping of Precipitation (GSMaP) produce global precipitation data with one hour temporal resolution by using microwave radiometer (MWR) on board low-Earth-orbit satellites and Infrared (IR) radiometer on board geostationary meteorological satellites (GEOs). In the GSMaP, the rainfall observed by a MWR is propagating along with the moving vector calculated by GEO IR observations for the interpolation of the gaps in MWR observation coverage. Since the GSMaP rainfall rate complemented with IR algorithms is based on the assumption that deeper clouds are more likely to produce heavy rainfall, conspicuous underestimation of rainfall occurred for heavy precipitation from low-level cloud. Observation bands available for GEO have dramatically increased from the conventional about 3 to 9 after latest GEO called Himawari-8 was launched in October 2014. By using the Himawari-8 IR multi-channel observations, we created high-frequency precipitation data, called Himawari Rainfall Estimation Algorithm (HRA; Hirose et al. 2019). We used Random Forest (RF) machine learning method to make the HRA and used Ku-band precipitation radar (KuPR) observation of the Global Precipitation Measurement Mission (GPM) core satellite as truth of rain.

Hirose et al. (2019) verified the accuracy of HRA in the mid-latitudes of the Northern Hemisphere using radar-AMeDAS rain rate and showed that HRA has higher estimation accuracy for heavy rainfall caused by clouds with relatively low cloud-top height than GSMaP with only single IR band. In particular, the three water vapor bands, which became available for the first time on Himawari-8, has greatly contributed to the improvement for the estimation accuracy of the heavy rain. In this presentation, we show the results of global accuracy verification using ground-based radar network in the tropics. The HRA showed the same estimation accuracy in the tropics as the GSMaP MWR observation. In addition, GSMaP tended to overestimate rainfall over sea where rainfall was complemented by using only a single IR band, but HRA did not show such overestimation with IR multiband. The effectiveness of IR multi-band observation was confirmed even in the tropical region. We will also present the results of an attempt to improve estimation accuracy of the GSMaP cloud movement vector with single IR band by using machine learning approach.

Sensitivity experiment of aerosol models in aerosol retrieval algorithm and comparison with ground-based observation using GOSAT/CAI and GOSAT-2/CAI-2 data

*Makiko Hashimoto[1], Hideaki Takenaka[1], Chong Shi[1], Teruyuki Nakajima[1]

1. Japan Aerospace Explortion Agency

Aerosol particles in the atmosphere has an impact not only for the Earth’s radiation budget and changing the Earth’s climate, but also on human health. These aerosol particles are often generated by human activity and are transported to other regions. Satellite remote sensing is an effective way to monitor the atmospheric aerosols in wide area including a source region like an urban area.

Greenhouse gases Observing Satellite-2 (GOSAT-2) that is a successor of GOSAT was launched on October 29th, 2019. GOSAT- 2 has Cloud and Aerosol Imager called CAI-2. CAI-2 performs two-directional observation in forward and backward directions and makes an observation at ten bands composed of seven wavelengths at 340, 380, 443, 550, 674, 869 and 1630 nm. The spatial resolution (IFOV) is 920 m at a wavelength of 1630 nm and 460 m at the other wavelengths. CAI-2 is characterized by having two ultraviolet (UV) bands at 340 and 380 nm. UV band has sensitivity for light absorption of dust particles and light absorption particles such as BC and OC.

We have developed aerosol retrieval algorithm called MWPM (Multiple wavelengths and pixels method) (Hashimoto and Nakajima, 2017). The method simultaneously retrieves fine and coarse mode AOT and single scattering albedo by using several wavelengths and spatial difference of surface reflectance. The method is useful for aerosol retrieval over spatially inhomogeneous surface region like an urban area. The algorithm is applied to CAI-2 aerosol retrieval, and aerosol optical properties such as AOT of fine and coarse particles, Ångström exponent (AE), and BC volume fraction are derived.
In this algorithm, we assume aerosol models for fine and coarse mode aerosols. However, aerosol particle size and these light absorption properties are different in different regions. It is important to know a bias occurred by assumed aerosol models when we validate the aerosol products by ground-based observations and modify the algorithm, so we have investigated the impact on the products by assumed aerosol models, such as aerosol size distribution, complex refractive indices, aerosol height etc.. We show the result of the sensitivity test and discuss aerosol models in the algorithm using a comparison result between aerosol properties from GOSAT CAI/GOSAT-2 CAI-2 and that from ground- based observation such as AERONET and SKYNET.

High resolution Motion Vector for the GSMaP MVK

*Tomoaki Mega[1], Tomoo Ushio[1]

1. Osaka Univ.

The Global Satellite Mapping of precipitation (GSMaP) is global precipitation map with 0.1 gridded every one hour. The GSMaP motion vector with Kalman filter (MVK) precipitation estimated by passive microwave radiometer on low-earth orbit. Although the observation area of the sensors does not cover all earth in an hour. Thus the GSMaP MVK fill the no observation area from previous and feature observation by the Kalman filter with cloud motion vector. The motion vector is estimated from brightness temperature of IR on geosynchronous observation satellites. We are developing high resolution technique for the GSMaP MVK. The observation area of radiometers becomes narrower in a shorter time interval. So the filling region of the high temporal and spatial resolution GSMaP MVK is wider than the current GSMaP MVK. The motion vector for the high-temporal-and-spatial resolution GSMaP MVK must be higher-spatial and temporal resolution by the current motion vector. The resent geosynchronous orbit weather satellite has a high spatial and temporal resolution microwave sounder. The atmospheric motion vector (AMV) is estimation from the sounder. The AMV is high resolution and include altitude information. We will apply the AMV for the high resolution GSMaP MVK. The AMV is, however, not gridded data. The GSMaP MVK algorithm requires motion vector as gridded data. Therefor we develop a technique to calculate motion vector for the high-resolution GSMaP MVK from the AMV. In my presentation, we introduce technique of high-resolution motion vector form the AMV.

Validation of GSMaP toward practical hydrological use over Vietnam: basin-scale validation and estimation of accuracy with time lapse from microwave observation

*Masato I. Nodzu[1], Jun Matsumoto[1,2], Thanh Ngo-Duc[3], Long Trinh-Tuan[3], Tri Truong-Duc[4]

1. Tokyo Metropolitan University, 2. Japan Agency for Marine-Earth Science and Technology, 3. University of Science and Technology of Hanoi, Vietnam Academy of Science and Technology, 4. Ministry of Natural Resources and Environment, Vietnam

1. Introduction

Satellite observation is a promising tool to grasp the horizontal distribution of precipitation intensity over mountainous regions where it is difficult to put gauge stations and surface weather radars are obstructed by orographic clutters. GSMaP has been developed based on passive microwave observation from the TRMM and GPM satellites with the aid of infrared observation and improved with some modification methods. However, the performance of GSMaP is still poor in one-to-one comparison in the scales of 0.1-degree-grid and one hour, i.e. at its highest resolution. Generally such precipitation data has tendency to perform better in lower resolution. It is useful to show a higher limit of resolution and expectant accuracy in a precipitation dataset. For example, in the use for flood warning, the highest resolution is not necessarily needed depending on features of a river basin like topography and expansion of the upstream region. In this study, we investigate the dependence of the GSMaP performance on scale of regional mean. We also examine the relationship between the performance of hourly precipitation and time lag from the microwave radiometer (MWR) observation.

2. Data and methods

The GSMaP version used in this analysis is the semi-standard product, RNL version 6 from 2006 to 2010.

The horizontal resolution dependency is assessed by daily regional mean precipitation in different regions within the Thu Bon River basin, compared with the VnGP data. The regions are A, B, C and D in order of areas. The parameters used for assessment are biases, root mean square difference (RMSD), probability of detection (POD) and false alarm ratio (FAR). The POD and FAR are determined for heavy precipitation over the 95th percentile of hourly precipitation in the VnGP. The analysis period is months from April to October in 5 years from 2006 to 2010.

We examine the relationship between the GSMaP performance and time lag from the MWR observation for hours with precipitation exceeding 1 mm/hour in gauge observation from April to September in 2010. The GSMaP data are compared with gauge precipitation data observed at 6 stations within northern Vietnam. Besides biases and RMSD, we also define GGR as the ratio of GSMaP precipitation to gauge observation. The GGR in the best skill is 1.0. The closer to 1.0 the GGR value is, the better performance we obtain. The performance is measured with the ratio of cases with GGR from 0.5 to 2.0 to all the cases.

3. Results and discussions

The daily regional mean of the GSMaP precipitation is compared with that of the VnGP over the upstream basin of the Thu Bon River in central Vietnam, over four different regions. Against our expectation, the GSMaP performance shows a small dependence on the difference of regions (Fig. 1). The RMSD normalized by the total precipitation shows smaller values for the regional mean over the larger areas, except the region A. The smallest bias is seen in the largest region D. However, it is difficult to be

©2020. Japan Geoscience Union. All Right Reserved.

convinced that GSMaP could reproduce the closer values to the VnGP in the larger-area region, because the biases are scattered in the positive and negative values over the smaller region. The POD and FAR show worse values in regional mean over the larger-area regions. In this analysis, only the larger-area regions (C, D) include highlands over 800 m above sea level. This variety of orographic features in the regions may affect impartiality in the comparison analysis.

The ratio of cases with GGR from 0.5 to 2.0 to all the cases is correlated with the time lag from the MWR observation (Fig. 2). At almost all the grids with gauge stations, the higher this ratio, the smaller time lag. A smaller RMSD between GSMaP and the gauge precipitation is roughly related with a smaller time lag from the MWR observation. However, exceptions to this tendency are not negligible. It is difficult to find correlation between the bias normalized by the total precipitation and the lag time. In the present study, we limited the analysis to time with precipitation exceeding 1 mm/hour. On the other hand, GSMaP sometimes shows zero precipitation under this limitation. Therefore, it is challenging for using a simple RMSD to sufficiently estimate the difference of the both data. This problem also applies to the bias analysis.

Cloud and aerosol discrimination algorithm for EarthCARE/ATLID lidar

*Eiji Oikawa[1], Hajime Okamoto[1], Tomoaki Nishizawa[2], Kaori Sato[1], Rei Kudo[3]

1. Research Institute for Applied Mechanics, Kyushu University, 2. National Institute for Environmental Studies, 3. Meteorological Research Institute, Japan Meteorological Agency

The EarthCARE satellite with the high spectral resolution lidar (HSRL) at 355 nm will be launched in 2022. The cloud mask algorithm at 532 nm had been developed for the CALIPSO satellite retrieval (Hagihara et al., 2010). We have been working on development of the cloud mask algorithm for the EarthCARE lidar retrieval at 355 nm. In this study, we perform data analysis of the observation data of the NASA airborne HSRL (Burton et al., 2015; 2018) and AD-Net Raman lidar (Nishizawa et al., 2017) to determine the threshold values of attenuated and particle backscatter coefficients (β'_{th} and β_{th}) at 355 nm for the discrimination of clouds and aerosols. The color ratio (ratio of the backscatter coefficients between 2 wavelengths) at 355 and 532 nm, which is measured by the HSRL observations, is used to discriminate aerosols and clouds, because the wavelength dependence of backscatter coefficient for aerosols is larger than that for clouds. In the analysis of HSRL airborne observations, we defined the particles, which have attenuated and particle color ratios smaller than 1 below 6.5 km altitude, as aerosols. From these results, the threshold values of β at 355 nm for discrimination of clouds and aerosols are estimated as $\beta'_{th,355}$ = 4.5-5.7×10^{-6} [$m^{-1}sr^{-1}$] and $\beta_{th,355}$ = 2.2-5.7×10^{-6} [$m^{-1}sr^{-1}$]. In addition, we perform the test of EarthCARE lidar retrieval using these new threshold values and the simulated data of the global atmospheric model NICAM (Sato et al., 2014) and J-sim (Hashino et al., 2013).

Climate and air pollution impact on wheat crop over Eastern Indo Gangetic Plains of India

*geetika sonkar[1]

1. Banaras Hindu University

Rapid urbanization and economic development in India has led to an increase in the air pollution which in turn may affect the ecosystem such as crop production. The present study is aimed to analyze the long term variability of climate variables (Temperature maximum (TMAX), Temperature minimum (TMIN), Rainfall (RAIN) & Solar radiation (SRAD)) from 1986 to 2015 and satellite retrieved aerosol optical depths (AOD) from 2001 to 2015 during the wheat season over the Eastern Indo Gangetic plains of India. The study focuses on to examine the possible implications of aerosols loading on the wheat crop yield (rabi season). A decreasing trend in TMAX and TMIN was noted in the crop growing season. The long term variation in the SRAD had a significant influence in declining the solar radiation over the region. The statistical (regression) model suggests that there is an influence of aerosols on climatic parameters which indirectly had affected the wheat yield. For every unit increase in AOD, a decrease in TMAX, TMIN and SRAD was recorded. The influence of aerosols on wheat crop yield had declined the yield by 2%. The present analysis may be crucial in terms of establishing the potential impact of changing climate and air quality on regional food security and therefore, must need to be considered in policy decisions.

ABSTRACT

Rapid urbanization and economic development in India has led to an increase in the air pollution which in turn may affect the ecosystem such as crop production. The present study is aimed to analyze the long term variability of climate variables (Temperature maximum (TMAX), Temperature minimum (TMIN), Rainfall (RAIN) & Solar radiation (SRAD)) from 1986 to 2015 and satellite retrieved aerosol optical depths (AOD) from 2001 to 2015 during the wheat season over the Eastern Indo Gangetic plains of India. The study focuses on to examine the possible implications of aerosols loading on the wheat crop yield (rabi season). A decreasing trend in TMAX and TMIN was noted in the crop growing season. The long term variation in the SRAD had a significant influence in declining the solar radiation over the region. The statistical (regression) model suggests that there is an influence of aerosols on climatic parameters which indirectly had affected the wheat yield. For every unit increase in AOD, a decrease in TMAX, TMIN and SRAD was recorded. The influence of aerosols on wheat crop yield had declined the yield by 2%. The present analysis may be crucial in terms of establishing the potential impact of changing climate and air quality on regional food security and therefore, must need to be considered in policy decisions.

Orverview of Earth Clouds, Aerosols and Radiation Explorer (EarthCARE) projects

*Takahashi Chikako[1], Riko Oki[1], Takuji Kubota[1], Maki Kikuchi[1], Yuichiro Hagihara[1], Mayumi YOSHIDA[1]

1. Japan Aerospace Exploration Agency

Earth Clouds, Aerosols and Radiation Explorer (EarthCARE) have been developing in cooperation between Japan and Europe. The EarthCARE will be equipped with four sensors, which are the Cloud Profiling Radar (CPR), the Atmospheric Lidar (ATLID), the Multi-Spectral Imager (MSI), and the Broad-Band Radiometer (BBR). The EarthCARE is expected to contribute to improving the accuracy of climate change projections by continuously data collection for improving numerical climate models, such as cloud and aerosol distributions and radiation balance energy, through global observation using the four sensors.
The Japan Aerospace Exploration Agency (JAXA) have been developing the Cloud Profiling Radar (CPR) in cooperation with the National Institute of Information and Communications Technology (NICT). The CPR is the first satellite-borne Doppler radar on the W-band (94 GHz), and we can observe not only the vertical structure of clouds, but also the ascending and descending velocity of clouds.
In addition, the observation data product of each sensor mounted on EarthCARE is planned to be created and offered to the user, and the analysis of the observation data and the application research using the observation data are planned. In this poster session the current status of the EarthCARE mission will be introduced.

Sources of countercurrent in northeastern Taiwan

*Chen-Chen Ho[1], Po-Chun Hsu[1], Ching-Yuan Lu[1], Chung-Ru Ho[1]

1. Department of Marine Environmental Informatics, National Taiwan Ocean University

A current along the coast of northeastern Taiwan has been reported by previous studies. Because it flows direction opposite to that of the Kuroshio, it is called a countercurrent. To know sources of the countercurrent, sea surface temperature data from Himawari-8, wind field data from WindSat, flow field data from The Copernicus Marine Environment Monitoring Service (CMEMS), outputs of the hybrid coordinate ocean model (HYCOM), cruise observations, and drifter data were analyzed. The field measurements by ship-board Acoustic Doppler Current Profiler (ADCP) during the cruise R/V Ocean Researcher II on November 13, 2019 showed that the countercurrent has an average speed of 0.18 m/s (ranges from 0.11 m/s to 0.25 m/s). This speed is consistent with the observation of drifters which originate from the Taiwan Strait Current. Satellite wind observations suggested that the countercurrent is forced by the summer monsoon from the Taiwan Strait. Satellite observations and model outputs also suggested that the cold dome near the northeast of Taiwan might be the other source of the countercurrent.

An improved procedure for estimation of propagation distance of tweek atmospherics

*Masafumi Kanno[1], Hiroyo Ohya[2], Kazuo Shiokawa[3], Hiroyuki Nakata[2], Toshiaki Takano[2]

1. Graduate School of Science and Engineering, Chiba University, 2. Graduate School of Engineering, Chiba University, 3. Institute for Space-Earth Environmental Research, Nagoya University

Tweek atmospherics are very low frequency (VLF) / extremely low frequency (ELF) waves radiated from lightning discharge and propagate in the Earth-ionosphere waveguide for a long distance over 1000 - 12000 km. The tweeks have frequency dispersion that the frequency rapidly falls down from 10 kHz to 2 kHz during several tens of milliseconds. The occurrence rate of the tweeks are 50-60 per minute during nighttime in Japan [Ohya et al., JGR, 2015]. By analyzing tweeks, location of lightning in wide area and their reflection height in the D-region ionosphere can be estimated. However, it is difficult to estimate the horizontal propagation distance of tweeks with high accuracy, because of the rapid frequency variation of tweeks in frequency-time spectra and overlapping multiple tweeks. The accuracy of the lightning location estimated from tweek atmospherics has been estimated as less than 60 km in Europe [Santolik and Kolmasova, Sci. Rep, 2017]. The accuracy of lightning location for the lightning discharges of world-wide lightning location (WWLLN) data is less than 10 km [Rodger et al., 2004]. So far, the reflection height and the horizontal propagation distance of tweeks have been estimated by curve fitting on tweek dynamic spectra by the maximum entropy method (MEM). In this study, we improved our procedure to estimate the tweek propagation distances. The new procedure is based on conversion of non-linear dispersion equation to a linear equation. The linear equation would be more useful for estimating the propagation distance, even if attenuation around the cut-off frequency is significant. As a result of evaluation by pseudo-tweeks which have propagation distances in the range of 2000 –10000 km, the error of the propagation distance was estimated to be 6.7% by the new procedure and 13.8% by the previous method. In particular, the new procedure showed a great improvement for tweeks with propagation distances of less than 6000 km. In this presentation, we show the new procedure for tweek propagation distance in detail and discuss its accuracy.

Current status of the calibration for the GPM DPR

*Takeshi Masaki[1], Toshio Iguchi[2], Kaya Kanemaru[3], Kinji Furukawa[4], Naofumi Yoshida[1], Takuji Kubota[5], Riko Oki[5]

1. Remote Sensing Technology Center of Japan , 2. Earth System Science Interdisciplinary Center, University of Maryland, 3. National Institute of Information and Communications Technology, 4. Satellite Applications and Operations Center, Japan Aerospace Exploration Agency, 5. Earth Observation Research Center, Japan Aerospace Exploration Agency

The Global Precipitation Measurement (GPM) mission is an international collaboration mission between the United States and Japan to observe global precipitation using a GPM Core Observatory satellite and some collaborating satellites. The GPM Core Observatory, which was successfully launched in 2014, carries the Dual-frequency Precipitation Radar (DPR) and the GPM microwave imager (GMI).The mission requires that the DPR, which is composed of the Ku-band precipitation radar (KuPR) and the Ka-band precipitation radar (KaPR), be calibrated within ±1 dB because the estimation of precipitation rate depends significantly on the calibration. The calibration method basically follows the method that was used to calibrate the Precipitation Radar (PR) onboard the Tropical Rainfall Measuring Mission (TRMM) satellite. However, both the hardware and data processing method for calibration are improved by taking advantage of the lessons learned from the PR’s calibration. For instance, as to the estimation of radar’s antenna pattern, the effective beamwidths were determined by assuming an antenna pattern created by the Taylor distribution that was used to design the antennas instead of assuming a Gaussian antenna pattern. Four-year calibration including these improvements provides the new precise parameters of DPR’s calibration, and the analysis of calibration data shows that the DPR’s performance is very stable and that the error in the calibration accuracy is within ±1 dB. The new parameters increased the KuPR’s radar reflectivity factor (Z) by about 1.3 dB and that of the KaPR by about 1.2 dB from the pre-calibrated Z values, and the minimum detectable radar reflectivities were 16.41 dBZ, 20.12 dBZ, and 14.66 dBZ for KuPR, matched beam of KaPR and high-sensitivity beam of KaPR, respectively. The calibration methods were applied to the re-examination of the PR’s calibration. After applying the new calibration methods to both DPR and PR, normalized radar cross sections ($\sigma 0$) from the DPR and PR agree with each other.

Observing Simulation System Experiment for Future Small Precipitation Radar Constellation: Impact on GSMaP Accuracy

*Yamaji Moeka[1], Takuji Kubota[1]

1. Japan Aerospace Exploration Agency (JAXA)

Satellite observation is a unique and effective tool to cover a large area homogeneously in a short time. Its advantage is obvious when it observes geophysical parameters varying both in temporally and horizontally, like precipitation. One of the important global precipitation observation missions from space is the Global Precipitation Measurement (GPM) Mission, which is composed of the GPM core satellite and multi constellation satellites carrying passive microwave (PMW) instruments. GPM core satellite carries the Dual-frequency Precipitation Radar (DPR) and GPM Microwave Imager (GMI). DPR consists of the Ku-band Precipitation Radar (KuPR) and the Ka-band Precipitation Radar (KaPR), aiming to observe global precipitation with high accuracy under the GPM mission. GPM core satellite carries both active and passive sensors and is in non-sun-synchronous orbit, therefore, GPM core satellite can be a calibrator of PMW sensors onboard multi constellation satellites in sun-synchronous orbit. The constellation satellites can contribute to extending coverage and increasing frequency. Thus, GPM mission achieves high accurate and high frequent global precipitation measurement.

The Japan Aerospace Exploration Agency (JAXA) has developed the multi-satellite precipitation product called Global Satellite Mapping of Precipitation (GSMaP) with the GPM core and constellation satellites. GSMaP has been developed by using combined data from PMW sensors in low Earth orbit and infrared (IR) radiometers in geostationary Earth orbit, and provides hourly global (60˚S - 60˚N) precipitation map by 0.1 x 0.1 degrees latitude/longitude. As advanced knowledge given by previous studies have been implemented to the algorithms, the accuracy of GSMaP has been improved. Such kind of precipitation product with high spatiotemporal frequency leads to wider applications over societal benefit areas, such as weather forecasts, flood predictions, agricultural monitoring and so on. Especially over the tropical Asian countries, GSMaP has been used as an infrastructure in operational agencies for meteorology and disaster management. Hence, it is strongly desired to keep the GSMaP maintained and improved by updating the algorithms.

As one of the future precipitation observation missions discussed in JAXA, there is a concept of small spaceborne precipitation radar (PR) constellation in the Tropics. The PR can obtain quantitative precipitation measurements over the land as well as over the ocean. It is well-known that there are still large uncertainties of rainfall estimates over the land using the PMW because over-land PMW algorithms basically use only scattering signals due to high and variable emissivity of the land surface. Current GPM/DPR dataset is used as a database to calculate look-up tables for retrieving rainfall from PMW sensors, because the observation frequency is insufficient to retrieve rainfall directly from DPR. If the future PR constellation is realized, the frequency of the PR data with high accuracy can increase, which leads to improve the quality of the GSMaP.

The aim of this study is to quantify the contribution of the future PR constellation to the improvement of future GSMaP. We perform an Observing System Simulation Experiment (OSSE) for the future PR constellation. Also the pseudo PR data obtained from the experiment is input to the actual GSMaP processing system to evaluate the impact on the accuracy of GSMaP.

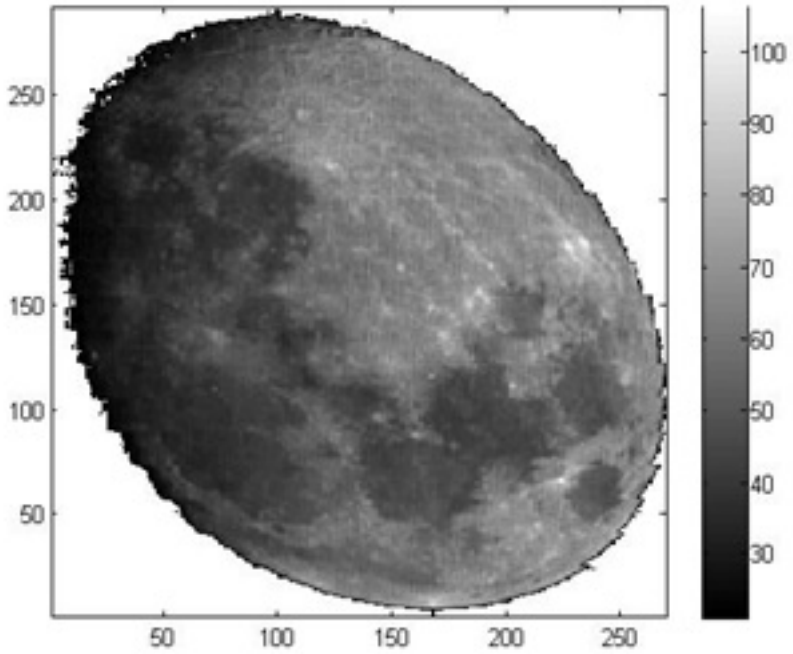
Calibration of INSAT-3D meteorological satellite imager visible channel using Moon



*Shailesh Parihar[1], A.K. Mitra, R. Bhatla[1]

1. Banaras Hindu University, Varanasi, India

INSAT-3D is India’s meteorological geostationary satellite an exclusive next generation mission designed for enhanced meteorological observations having 6 channel imager and 18 channel sounder. INSAT-3D Spacecraft was dedicated to Nation at National Satellite Meteorological Center (NSMC) indigenously designed developed INSAT-3D Meteorological Data Processing System (IMDPS), commissioned at India Meteorological Department (IMD) New Delhi on January 15, 2014. The Moon is being observed from INSAT-3D regularly in the of full-disk operational image of earth with rectangular field of regard in IMDPS New Delhi. INSAT-3D measurements of lunar surface observed in Visible (0.55 - 0.75 μm), Short Wave Infrared 1.55 - 1.70 μm, Mid Wave Infrared (3.80 - 4.00 μm), Water Vapor (WV) 6.50 - 7.10 μm, Thermal Infrared (TIR) 1 & 2, 10.3 - 11.3 μm & 11.5 - 12.5 μm wavelength regions. The visible and infrared wavelengths region provide a new and intriguing methodology of distinguish in sensitivities of Earth observing radiometers. The Moon has been widely used for calibration of earth-observation missions across international community due to its temporal stability absence of any intervening medium such as atmosphere and its spectral resemblance to ground targets. As a preliminary step, attempt has been made to calibrate the VIS channel of INSAT-3D imager using Moon as a calibration source. For the requirements, a GIRO (RObotic Lunar Observatory, ROLO) model has been installed in National Satellite Meteorological Centre, INSAT-3D Meteorological Data Processing System, India Meteorological Department and New Delhi for output irradiance of Moon. Further, this irradiance is compared with INSAT-3D-measured Moon irradiance during July 2015 to June 2016. The preliminarily result shows INSAT-3D is overestimating against the GIRO model output irradiance. However, the pattern found consistency during the period, and no degradation can be estimated with this short span of time and found useful to generate the coefficients.

[E] Poster | A (Atmospheric and Hydrospheric Sciences)：A-CG Complex & General

[A-CG52] Large Ensemble Modeling Approaches as Tools for Climate and Impacts Research

convener:Rodgers Keith Bradley(IBS Center for Climate Physics), Shoshiro Minobe(Graduate School of Science, Hokkaido University), Hideo Shiogama(Center for Global Environmental Research, National Institute for Environmental Studies), Ryo Mizuta(Meteorological Research Institute)

Large ensemble model simulations are now integral tools for evaluating climate variability, climate change, and associated impacts. The range of tools applied encompasses Earth System Models (ESMs), Coupled General Circulation Models (CGCMs), Atmospheric General Circulation Models (AGCMs), Ocean General Circulation Models (OGCMs), and Regional Climate Models (RCMs), with the number of ensemble members typically spanning ten to several tens to one hundred. In addition to their utility in identifying emergent forced trends, they are also proving to be of great value in the study of extreme events and how extreme events evolve under anthropogenic perturbations. Furthermore, large ensembles of AGCMs nd OGCMs can prove invaluable as complements to fully coupled models in providing insights into scales and drivers of variability and trends, as well as climate feedbacks.
This session welcomes studies using the full range of large ensemble modeling tools. This includes studies of emergent trends and extreme events, and more generally studies that facilitate interpretation of observations as well as projections of future changes. Abstracts are particularly welcomed that address novel and emergent topics, including but not limited to compound events, biogeochemistry, and observing system design.

Increase in Rain-on-Snow events in Japan as projected by large ensemble of regional climate simulations

*Masamichi Ohba[1], Hiroaki Kawase[2]

1. Central Research Institute of Electric Power Industry, 2. Meteorological Research Institute

The phenomenon of rainfall on snow is called a rain-on-snow (ROS) event that can cause severe snowmelt hazards such as river flooding, snow avalanches, full-scale avalanches, slope failure, landslides that have significant impacts on various sectors (ecosystem, water resources, risk management and flood forecast). This study investigated the influence of climate change on the frequency of ROS events during the winter season in Japan. Climate projections obtained from the database for Policy Decision-making for Future climate change (d4PDF) is used to investigate the climate change impacts. The projected future climate in the regional model simulations showed increase in the ROS events over Japan Alps (mountainous regions in central Japan) and Hokkaido (northern part of Japan) where the region will record still large snow amount in the future.
Self-organizing maps (SOMs) was applied using the surface atmospheric circulation to determine the dominant snowmelt related weather patterns (WPs). The SOMs showed that some WPs had a significant effect on the cause of ROS events. Additionally, the difference in the impacts of climate change between WPs was evaluated to understand the future changes in runoff and snowmelt associated with ROS events. The SOM analysis results suggest that the increase of ROS events in the future climate is attributed to the changes in dominant ROS-related WP (from cyclonic-type to cold-surge-type) corresponding with the variations in the freezing point line (region of the atmospheric layer at temperatures near 0 ˚C i.e., rain-snow transition layer). These findings can help inform water hazard/resource-management requirements to withstand regional climate change.

Projected changes in extreme precipitation in a 60-km AGCM large ensemble and their dependence on return periods

*Ryo Mizuta[1], Hirokazu Endo[1]

1. Meteorological Research Institute

The dependence of projected changes in extreme precipitation on the return period, as well as on the temporal and spatial scales, is investigated using a large ensemble climate simulation with a 60-km resolution global atmospheric model. The rate of increase is noticeably larger for longer return values in most parts of the world. While thermodynamic contribution to this increase generally follows the Clausius–Clapeyron relationship for all return periods, dynamic contribution determines the dependence on the return periods. While the dependence on the temporal scales of precipitation has similar characteristics, that on spatial scales is not large. Composites for days with the 100-year return value show that upward motion is enhanced in the middle and upper troposphere, and is accompanied by the enhanced horizontal water vapor convergence below, suggesting that an increase in latent heat release due to the water vapor increase plays a significant role in the dynamic contribution.

Detection and Analysis of Tropical Cyclones in the d4pdf Mega-ensemble Projection

*Adrean Webb[1], Tomoya Shimura[1], Nobuhito Mori[1]

1. Kyoto University, Disaster Prevention Research Institute, Coastal Disaster Research

Tropical cyclones (TCs) play an important role in the climate system and are a major source of natural hazards worldwide, such as those due to heavy precipitation, river flooding, and storm surges. TC-related hazards are sensitive to properties of the storm path and while climate models can provide data to accurately model these events, samples are inadequate for analysis of extreme events on climatological time scales. The climate dataset d4PDF, Database for Policy Decision Making for Future Climate Change, was created to overcome this low-occurrence frequency limitation and contains hundreds of thousands of simulated TCs under present and future +4 K warming conditions (11,400 years), making it possible to estimate 100 year or longer return values.

Here, a tropical cyclone track dataset has been created for the d4PDF dataset. The detection method uses pressure difference, wind speed, and SST threshold parameters and is tuned to optimize annual TC count and cyclogenesis locations. Tuning and validation of the method is conducted using 30-year IBTrACS observation and JRA-55 reanalysis data. We will present an overview of the detection method, validation, and performance, and analyze properties of the TC tracks, such as projected changes in occurrence frequency, and cyclogenesis and dissipation locations.

Keywords: tropical cyclone tracks, d4PDF, climate ensemble, IBTrACS, JRA-55

ESM-projected global change in the indices of extreme weather using the TR3S method of bias-correction

*Martin Gomez-Garcia[1], Akiko Matsumura[1], Daikichi Ogawada[1]

1. Nippon Koei Co., Ltd. Research and Development Center

To responsibly support the decision–making processes, the climate–modeling community has been discussing about the conceptual requirements that bias–correction methods should fulfill to avoid altering the relevant information of future climate that is provided by Earth System Models (ESM). Bearing in mind these discussions, a recently proposed method of bias–correction, based on TRend–preserving Synthetic Samples of Stable Distributions (TR3S), decomposes the atmospheric variables into three temporal elements that represent the climate mean state, the interannual variability, and the daily variability. This decomposition is aimed at correcting the biases at one time scale without affecting the projected climate trend or the distributional properties at other time scales. The novelty of this approach is, nevertheless, marked by the adjustment of interannual and daily variability that is made in a way that the ESM–projected changes in the scale, the symmetry, and the frequency of extremes can be measured and applied to the probability distribution of the observed data. The TR3S method differentiates from common quantile –mapping –type methods in that the quantiles (of variability) are corrected considering the change in several distributional properties instead of only the change in that particular quantile. In this work, we corrected the biases in the global surface temperature and precipitation generated by several ESMs using the TR3S method and present the projected changes of a few indices of extremes using an online Atlas of interactive maps. Furthermore, the TR3S method allowed us to document the spatial patterns of the biases in the distributional properties (i.e., scale, symmetry, and frequency of extremes) of daily and interannual variability of each ESM. We hope that this new analytical framework of model biases can be used by modelers to identify ways in which the ESM parameterizations could be improved and by end–users to support the climate change impact assessments.

Droughts, fires and fire emissions of CO_2 and $PM_{2.5}$ in equatorial Asia due to historical and future climate changes

*Hideo Shiogama[1]

1. Center for Global Environmental Research, National Institute for Environmental Studies

In 2015, El Niño contributed to severe droughts in equatorial Asia (EA). The severe droughts enhanced fire activities in the dry season (June-November), leading to massive fire emissions of CO_2 and aerosols. Based on large event attribution ensembles of the MIROC5 atmospheric global climate model, we suggest that historical anthropogenic warming increased the chances of meteorological droughts exceeding the 2015 observations in the EA area. We also investigate changes in drought in future climate simulations, in which prescribed sea surface temperature data have the same spatial patterns as the 2015 El Niño with long-term warming trends. Large probability increases in stronger droughts than the 2015 event are projected when events like the 2015 El Niño occur in the 1.5˚C and 2.0˚C warmed climate ensembles according to the Paris Agreement goals. Further drying is projected in the 3.0˚C ensemble according to the current mitigation policies of nations.

We combine these experiments and empirical functions among precipitation, burned area, and fire emissions of CO_2 and fine (<2.5 micrometers) particulate matter ($PM_{2.5}$). Increases in the chances of burned areas and the emissions of CO_2 and $PM_{2.5}$ exceeding the 2015 observations due to past anthropogenic climate change are not significant. In contrast, there are significant increases in the burned area and CO_2 and $PM_{2.5}$ emissions even if the 1.5˚C and 2.0˚C goals are achieved. If global warming reaches 3.0˚C, as is expected from the current mitigation policies of nations, the chances of burned area, CO_2 and $PM_{2.5}$ emissions exceeding the 2015 observed values become approximately 100%, at least in the single model ensembles.

We also compare changes in fire CO_2 emissions due to climate changes and the land-use CO_2 emission scenarios of five shared socioeconomic pathways, where the effects of climate change on fire are not considered. There are two main implications. First, in a national policy context, future EA climate policy will need to consider these climate change effects regarding both mitigation and adaptation aspects. Second, the consideration of fire increases would change global CO_2 emissions and the mitigation strategy, which suggests that future climate change mitigation studies should consider these factors.

Future change in phytoplankton phenology simulated by large ensemble experiment

*Ryohei Yamaguchi[1], Keith Rodgers[1,2], Karl J Stein[1,2], Axel Timmermann[1,2], John P Dunne[3], Richard D Slater[4], Sarah Schlunegger[4]

1. IBS Center for Climate Physics, 2. Pusan National University, 3. NOAA Geophysical Fluid Dynamics Laboratory, 4. Princeton University

While future changes in annual mean ocean biogeochemical properties (Net Primary Production, Export Production, Chlorophyll concentration etc.) has been studied, there are still only few descriptions and estimates of changes in the seasonal cycle itself. Changes in phytoplankton bloom phenology (initiation and peak timing) should have significant impacts on higher trophic levels, even on fisheries, and on the oceanic carbon cycle, since it is one of largest biogeochemical seasonal signal and could characterize the seasonal biological activity. However, it is challenging to estimate the forced long-term phenological changes as they are embedded in natural variability. In present study, we use a 30-member ensemble simulated by Geophysical Fluid Dynamics Laboratory Earth System Model 2 (GFDL-ESM2M) to deconvolve the forced signal from intrinsic variability in bloom phenology. Using daily mean surface chlorophyll concentrations, we detect the bloom timing shift precisely and estimate the emergence time-scale under a historical/RCP8.5 pathway over 1990-2100.
Over global scales, bloom initiation reveals large structured shifts over the 21st century, with large emergent shifts towards earlier blooms (~few days/decade) north of 30°N, and zonal heterogeneity of the sign of the shift over the Southern Ocean. On the other hand, bloom peak timing is expected to shift more than the initiation, indicating the bloom duration will also change significantly by the end of this century. As the results from budget analysis and the taylor decomposition, a range of variables are considered for attribution of the changes, including not only growth rate (that is, temperature, light, and nutrient) but also loss rate (grazing pressure as a function of temperature and biomass).

Seasonality Constraints on the rate of Pteropod Habitat Compression under 21st Century Climate Change

*Keith Bradley Rodgers[1,2], Sarah Schlunegger[3], Richard Slater[3], Burke Hales[4]

1. IBS Center for Climate Physics, 2. Pusan National University, 3. AOS Program, Princeton University, 4. Oregon State University

Under anthropogenic climate change, ocean acidificaiton is expected to pose mounting threats to ocean ecosystems. Here we consider habitat compression for the case of Pteropods over the North Pacific and Southern Ocean using a large ensemble suite with an Earth system model (GFDL's ESM2M considered for RCP8.5, RCP4.5, and RCP2.6 concentration pathways). Given that pteropods are vertically migrating and that their habitat is tied to the depth of the ocean's well-lit euphotic zone, our analysis of acidification is considered at both the surface and the euphotic zone depth. Our main finding is that the transition time between saturation and undersaturation is controlled by the ratio of the seasonal cycle amplitude to the rate of the secular trend of acidification. This is significanly more rapid at the euphotic zone base than at the sea surface, due to differenes in the amplitude of the seasonal cycle. The implications for adapataion will be considered.

[A-CG53] Terrestrial monitoring using new-generation geostationary satellites

convener:Yuhei Yamamoto(Center for Environmental Remote Sensing, Chiba University), Yunyue Yu(NOAA National Environmental Satellite, Data, and Information Service), Tomoaki Miura(Univ Hawaii), Kazuhito Ichii(Chiba University)

The third-generation geostationary satellites, such as Himawari 8/9, GOES-16/17, Fengyun-4, and GeoKompsat-2A are recently launched, and earth observation is in a new phase. These sensors are equipped with new spectral bands suitable for terrestrial monitoring used in polar-orbiting satellite sensors, enabling detailed land observations such as land surface temperature, surface albedo, and land cover and vegetation dynamics. Furthermore, by utilizing the advantages of hypertemporal (e.g. 10 min) and moderate spatial resolution, various new land dynamics can be observable. By combining these satellites and polar-orbiting satellites/sensors such as Terra/MODIS and GCOM-C/SGLI, a new generation monitoring data covering Asia, Oceania and North and South America will become possible. This would allow for a consistent comparison of a variety of phenomena across continents. To this end, there are many issues to be discussed, such as the standardization of the estimation algorithms of physical quantities, calibration and verification using GEO-(LEO)-GEO satellites, and application of these new datasets to various phenomena.
In this session, we will discuss the retrieval algorithms of land surface parameters, inter-satellite calibration, validation efforts using in-situ data, and novel applications to various phenomena. Studies on atmospheric parameters in relation to land surface phenomena, such as cloud cover are aerosol, are highly welcomed.

1. Center for Environmental Remote Sensing, Chiba University, 2. JAXA EORC

GSMaP is a useful global precipitation product provided 1 hour resolution.
GSMaP estimates the precipitation by IR observation of the geostationary satellite to interpolate a gap of the microwave radiometer (MWR).
However, there is difference in the precision between MWR and IR data source.
This difference is due to the correction of rainfall intensity using only cloud top temperature (altitude) information. This difference is due to the fact that cirrus clouds without rainfall are detected as raining areas, and difficulty to detect and estimate warm rain.
In October 2014, the third generation Himawari-8 geostationary meteorological satellite was launched, and the infrared multi-band observations are available in the Asian monsoon region. Using Himawari-8 and GPM KuPR data as training data, we created a precipitation product estimated by Random Forest machine learning. The purpose of this study is to improve the accuracy of estimating heavy rainfall caused by warm clouds that are difficult to estimate with a single IR band observation.

Development and application of land surface products using Himawari-8 AHI

*Kazuhito Ichii[1], Yuhei Yamamoto[1], Kodai Hayashi[1]

1. Chiba University

New generation geostationary satellites provide very high temporal earth observation with multiple visible, near-infrared, and shortwave-infrared wavelength regions. Thus, these datasets can provide us unexpectedly hyper-temporal resolution to monitor land surface. However, since geostationary satellite data are provided with top-of-atmosphere status, complex data pre-processing such as atmospheric correction, cloud masking are required.
Our group is trying to provide a new datasets for surface reflectance and surface temperatures based on Himawari-8 AHI. Our atmospheric corrected reflectance was calculated based on 6S code and we found that estimated reflectance were similar to those of polar orbiting satellites and sensors, such as Terra/MODIS and GCOM-C/SGLI. Cloud masks and land surface temperatures were generated by Yamamoto et al. (2018) algorithm. We will show our current status of data-processing and potential applications to understant land surface and vegetation dynamics.

Monitoring seasonal variations in vegetation activities over Southeast Asia using Himawari-8

*Kodai Hayashi[1], Kazuhito Ichii[1], Yuhei Yamamoto[1]

1. Chiba University

Tropical forests distributed widely in Southeast Asia play an essential role in maintaining rich ecosystems, energy and water cycles, and flood control. In Southeast Asia, the spatial and temporal distributions of land cover, plant phenology, and biomass are changing rapidly due to human activities and climate change. For example, areas of tropical forests are still decreasing due to human activities. The resulting carbon emissions are one of the significant contributors to atmospheric CO2 increase and climate change. Besides, the magnitude and frequency of environmental fluctuation by anomalous climate are increasing. Especially in tropical regions, droughts occur due to prolonged periods without rainfall, and floods occur due to extreme increases in rainfall. As a result, large-scale forest fires and severe water stress occur, and forest degradation is progressing.

Therefore, monitoring changes in terrestrial ecosystems in Southeast Asia is indispensable and also provides useful information for the conservation of rich ecosystems and the capability of flood control. In particular, it is essential to conduct extensive and continuous monitoring without any defect using satellite data.

However, in Southeast Asia, severe cloud covers exist throughout the year. Moreover, in the rainy season, it is covered with clouds over a broader area and more continuously. Therefore, it is often impossible to obtain the cloud-free data even once a month when using sensor data mounted on medium spatial resolution polar-orbiting satellites such as MODIS, AVHRR, and SGLI.

New geostationary satellites, such as Himawari-8/AHI (H8-AHI), are expected to observe land surface better due to its high observation frequency (every 10 minutes). In this study, we quantified how much more cloud-free observations can be obtained, and how detailed can we understand rainforest phenology using H8-AHI data in Southeast Asia, compared to polar-orbiting satellite data, Terra and Aqua / MODIS. First, we confirmed that the cloud detection rate is similar between H8-AHI and MODIS cloud masks. Then, we found that H8-AHI observation substantially increased cloud-free observation compared with those of MODIS on a monthly scale. Finally, we compared resulting cloud-free vegetation index time-series between AHI and MODIS, and only H8-AHI successfully tracks seasonal plant phenology over tropical forests.

Analysis of the spatial variations in the phenology of deciduous broadleaf forests in Japan with Himawari-8 NDVI hyper-temporal signatures

*Tomoaki Miura[1], Shin Nagai[2]

1. University of Hawaii at Manoa, 2. JAMSTEC

A new generation of geostationary satellite sensors, including Himawari-8 Advanced Himawari Imager (AHI), have been launched during the last decade. These sensors are equipped with a red and near-infrared bands and can image an Earth’ s hemisphere at 10 min intervals, providing the potential to generate high-temporal resolution vegetation index (VI) time series data even in cloud-prone areas and seasons. In this study, we assessed how AHI NDVI “hyper-temporal” signatures varied for deciduous broadleaf forests (DBFs) along a temperature, elevation, and latitudinal gradients in Japan. AHI 10-min data of Japan were obtained for a three-year period of 2016-2018 and reduced into daily NDVI time series. The warmth index (WI) and coldness index (CI), temperature-driven indices, were also obtained from mean monthly temperature. A land cover map derived from ALOS data was used to identify DBF areas along the transects. AHI NDVI hyper-temporal signatures, consisting of a large number of observations, had one growth cycle/season per year, but were different along temperature, elevation, and latitudinal gradients. The start of growth season (SGS) metric derived from AHI NDVI was positively, but weakly correlated with the latitude (r = .47) and elevation (r = .47). In contrast, the AHI NDVI-derived end of growth season (EGS) metric significantly correlated to the latitude (r = .73), but not to the elevation (r = .07). The highest correlations were obtained with the temperature-derived WI and CI for these metrices (r = .86 between the SGS and WI, and r = .75 between the EGS and CI). These results indicate that Himawari-8 hyper-temporal data were useful for regional-scale analysis of vegetation growing season.

Bank erosion owing to tidal currents and its impact on village distribution in the Sittaung River estuary, Myanmar

*Naoko Nagumo[1], Daisuke Harada[1], Tanjir Saif Ahmed[1,2], Shinji Egashira[1]

1. International Centre for Water Hazard and Risk Management, Public Works Research Institute, 2. National Graduate Institute for Policy Studies

The Sittaung River is one of the large rivers in Myanmar, draining an area of about 36,000 km^2. It forms a tide-dominated estuary in its mouth, where dynamic river bank erosion and consequent bank-line changes occur under the influence of river flow and tidal currents enhanced by tidal bores. As the river line retreats inland, serious problems, such as the disappearance of settlements and farmland, have resulted; therefore, we have started research in collaboration with Directorate of Water Resources and Improvement of River Systems (DWIR) to understand the mechanism of the active river bank erosion and plan appropriate prevention measures. Our analyses have so far revealed that the main stream has been shifting its course at least since the 1920s, exhibiting a periodicity, which seems to be induced by meander deformation and channel bifurcation resulting from bank collapses and supplies of very fine sediment in the river reach and estuary areas. The interrelating phenomena among bank erosion, sediment transport, channel-bar formation and deformation, and associated cyclic mainstream shifts have threatened the livelihoods of local people along the bank line. However, our analyses on the historical distribution of local villages also found that the outer edge of the past bank lines indicates a boundary of the safety zone from active bank erosion. We employed a depth-averaged 2-D numerical model to evaluate the sediment transport and associated bed evolution by tidal currents, and the computed results well reproduced the channel bifurcation and channel closing that are responsible for channel bar development.

Grain size and OSL dating of river bank dune deposits: an example from the Kiso River, central Japan

*Kazuaki Hori[1], Kohei Ohata[1], Yuji Ishii[2,3]

1. Nagoya Univ., 2. JSPS, 3. AIST

River bank dunes are common along the left side bank of the Kiso River. Existing studies have reported the distribution of dunes and the grain size of dune surface deposits. However, the vertical change of grain size of dune deposits is poorly known. Additionally, the age of dune formation is unknown because organic matter suitable for radiocarbon dating is uncommon in the dune sand. This study used a sand auger to dig the dunes up to a depth of 6 m, took the dune deposits, and performed the grain size analysis and optically stimulated luminescence (OSL) dating of the deposits. Grain size analysis of sand deposits shows that median grain size is 0.20–0.45 mm and vertical variation in grain size is relatively small. The size is similar to the present river bed sand. Ages from feldspar infrared-stimulated luminescence (IRSL) at 50˚C are 0.2–0.7 ka, and the youngest age of 0.2 ka indicate that residual doses are negligible. In contrast, post-IR IRSL measurements at 150˚C yielded 0.5–2.7 ka, which are significantly older than those from IRSL at 50˚C because of incomplete bleaching. IRSL ages suggest that the dunes have formed since approximately 600–700 years ago. The beginning of dune formation may be related to anthropogenic influence in the drainage basin.

Topographic development process of bedrock river: model experiment

*Yuta Takase[1], Noritaka Endo[1]

1. Kanazawa University

Understanding the evolution of channel topography helps to reproduce past landscape and predict future landscape. Since bedrock rivers are less well studied than alluvial rivers, further study of bedrock river topography is needed. Although the relationship between bedrock erodible and topographical features has been often discussed, both clear relationships are not understood in natural rivers, as various factors change irregularly.

In this study, we investigate the some relationships between complex and various factors through a single channel model experiment that can control the factors that affect the river topography. In addition, we observe the temporal change of the topography and aim to clarify the development process of river. The main controlling factors in this study are topographic uplift and bedrock erodible. The analysis targets are channel width, riverbed gradient, sinuosity, and erosion rate.

The experimental correlation diagram of each factor showed the same distribution as the natural river topography. High erosion rates are showed by steep river beds. The erosion rate tended to be low on the topography with high sinuosity. These distribution trends were showed during the uplift. In this experiment in which the uplift event lasted longer, the sinuosity tended to be lower than in the experiment in which the uplift event was short. On the other hand, the bed slope did not change significantly due to the uplift. Bed slope may not have a strong dependence on uplift event.

In the future, we will continue experiments that combined other bedrock and uplift patterns to study the effects of both.

Patterns of slopes and geological structure in the Atsuma River catchment, Hokkaido

*Takahisa Furuichi[1,2], Seiji Yanai[3], Tomoya Hayakawa[4]

1. Miyagi University of Education, 2. University of the Sunshine Coast, 3. Ishikawa Prefectural University, 4. Nippon Koei, Co. Ltd.

The M6.7 Hokkaido Eastern Iburi Earthquake on 6 September 2018 induced numerous shallow landslides in the Atsuma River catchment and surrounding areas. The induced shallow landslides show several features in shape. One type has planar slipe-surfaces mostly on gentler slopes, while another has V-shaped slipe-surfaces generally on steeper slopes. It was anticipated that these slip features were fundamentally controlled by the geological structure because the Atsuma area lies in the E-W compressed geological setup. Folds, anticlines, synclines and domes have developed as the basement structure of the area, which may have formed gentle, planar slopes along the dip of the basement and steep, V-shaped slopes perpendicular to the dip angle, i.e. a cuesta landform.

However, field evidence indicates that V-shaped slip-surfaces formed along the dip of the basement and planar slip-surfaces developed on slopes perpendicular to the dip of the basement. This landform might be recognized as a ‘reverse cuesta’. We discuss possible mechanisms of the formation of this unanticipated, surprising feature developed in the Atsuma area.

Keywords: shape of slope, fold, dome, cuesta, sedimentary rock

Radiocarbon-based Chronology of Valley Head Deposits: A Case Study of Landslide Scars in Hofu, Yamaguchi Prefecture

Takatoshi Kawano[1], *Tsuyoshi Hattanji[2], Takahisa Furuichi[3], Shoji Doshida[4], Yasushi Tanaka[5]

1. Graduate School of Life and Environmental Sciences, University of Tsukuba, 2. Faculty of Life and Environmental Sciences, University of Tsukuba, 3. Miyagi University of Education, 4. National Research Institute of Fire and Disaster, 5. Komazawa University

Heavy rainfall on July 21, 2009 caused a lot of shallow landslides in Tsurugigawa river basin, Hofu, Yamaguchi prefecture. Most of the shallow landslides occurred around valley heads (hollows) in the basin. This paper discusses geomorphological history of hollows before the landslides based on radiocarbon dating. Samples were collected from buried layers of charcoal (hereinafter, referred to as charcoal layers) in two valley heads with shallow landslide scars. The calibrated radiocarbon years of the charcoal layers are about 1200-1300 cal AD and 1300-1400 cal AD. The development history of the valley heads is estimated as follows. First, wild fires occurred around the valley heads in 1200-1400 AD and then charcoals were produced on the land surface. Subsequently, sandy soil was transported from the upper slopes to the valley heads and a thick sand layer was deposited above the charcoal layers. In addition, the sedimentation rates for landslide scarps and valley heads were calculated based on the calibrated radiocarbon years and thickness of soil layers estimated by comparison of airborne LiDAR DEMs obtained before and after the shallow landslides. The sedimentation rates were 0.9-2.1 mm/year for the landslide scarps and 2.1-6.9 mm/year for the valley heads. Furthermore, these slopes were stable for 600-800 years and shallow landslides of similar magnitude to the event in 2009 probably occurred around or before 1230 AD.

Impact of Understory Coverage and Tree Height on Sediment Transport Activity in Tenryu Artificial Forest, Japan

*Kautsar Qurratul Aini Binti Mahyudin[1], Fumitoshi Imaizumi[1]

1. Shizuoka University

Large-scale tree cutting that lead to deforestation could possibly lead to negative impact on ecosystem and the environment. Equivalent to the important factor of understory coverage in monitoring the overland flow and soil erosion, which include the soil particle detachment and transportation. In the interim, tree height could be considered as a parameter affecting energy of rain splash under canopy structure. In this study, we observed overland flow and soil erosion in 3 artificial forests with different tree height; tall tree, small tree and clearcutting sites. Within those sites, the effect of understory coverage on sediment transport activity was evaluated with different conditions of coverage: sparse grass understory grass, litter, fern densely understory, and without any understory coverage. We measured the soil type characteristic to figuring out the role of understory coverage and tree height in preventing soil erosion. We obtained the percentage of understory coverage (with understory) and monitored rainfall pattern overland flow and soil erosion annually in five replicated plots (approximately 1 X 2 m each) with and without understory. The highest overland flow occurred in the period with largest rainfall (total rainfall depth of 800 mm). In tall tree site (24 m), the prevention of overland flow and sediment transport activity by understory coverage were not essential due to capacity of overland flow was continuously high compared to without understory coverage. We found that the fern dense coverage at small tree sites (covered and uncovered understory) absorbed 95% of throughfall and stem fall, resulting in soil erosion activity compared to tall tree and small tree. Although the effect of tree cutting on amount of overland flow was clear, there was no relationship between understory coverage and amount of overland flow due to the crust formation induce in large amount of soil erosion activity. The tree height factor in small tree prevented 95% of high force of raindrop compared to tall tree that cause low dominant in soil detachment that lead to high sediment transport activity.

[H-QR04] Innovative Applications of Trapped-Charge Dating to Quaternary Geochronology

convener:Toru Tamura(Institute of Geology and Geoinformation Geological Survey of Japan, AIST), Shin Toyoda(Department of Applied Physics, Faculty of Science, Okayama University of Science), Yuji Ishii(National Institute of Advanced Industrial Science and Technology), Sumiko Tsukamoto(Leibniz Institute for Applied Geophysics)

Trapped-Charge Dating (TCD) is a general term for absolute dating methods that use trapped electrons in crystal lattice, such as optically-stimulated luminescence (OSL) and electron spin resonance (ESR) dating. TCD presented one of the most successful progresses in geoscience and archaeology over the last 20 years, and still has a great potential in innovative applications. Technical progresses in optical dating of quartz and feldspar grains enables determination of depositional ages in a broad range from 10 to 500,000 years. Rock surface dating provides a way to determine surface exposure ages as well as burial ages of gravels. Thermochronometry with TCD is a state of the art method to determine the degradation and uplift rates on high temporal resolution. Further efforts have been made on TCD for extracting chronological information of past seismic activities. Innovative IRPL (infrared photoluminescence) method has also recently been invented. This session covers a wide range of TCD applications to problems in Quaternary geochronology as well as its technical advances. Comprehensive reviews on successful TCD applications and contributions of unestablished, challenging researches are also welcome.

Optically stimulated luminescence (OSL) dating using quartz extracted from loess as archeo-sediments of Paleolithic site

*Yorinao Shitaoka[1]

1. Department of Environment System, Faculty of Geo-environmental Science, Rissho University

Datasets for a chronological framework of the Upper Paleolithic era in Nihewan Basin, northern China remain insufficient. Our team conducted optically stimulated luminescence (OSL) dating using fine quartz at Youfang site, and Loc. 73012 and Loc. 72117 of Hutouliang for additional dating studies. For this study, OSL dating was performed on loess as archeo-sediments from Erdaoliang site. Two samples were taken: one above the cultural layer (sample 1) and one below the cultural layer (sample 2).
Using the single aliquot regenerative-dose (SAR) protocol for course quartz (ca. 100 μm) extracted from loess of archeo-sediments, OSL dating was conducted. The OSL measurements were taken using an OSL reader (NRL-99-OSTL2-KU; Neoark Corp.). The value of paleodoses and their error were estimated using bootstrap method. Paleodoses of two samples were calculated using the central age model. The overdispersion (OD) values of sample 1 and sample 2 were, respectively, 24% and 12%. A sedimentary sample with OD of less than 20% was fully bleached as described by Olley *et al.* (2004). It is assumed that sample 1 was not well bleached. Therefore, the paleodose of sample 1 was obtained using the finite mixture age model. The main component contains a plurality (47%) of aliquots. OSL ages were found, respectively, as 19.0±0.98 ka for sample 1 and 23.9±1.2 ka for sample 2. The radiocarbon age obtained at this site was 18,085±235 yBP (no calibration). These OSL ages in this study are stratigraphically coherent.

Luminescence dating and age correction of marine terrace deposits in Kamikita Coastal Plain and Shimokita Peninsula, northeastern Japan

*Kazumi Ito[1], Toru Tamura[1]

1. Geological Survey of Japan, AIST

Middle and Late Pleistocene marine terraces formed during interglacial sea-level highstands are distributed across the coastal area in Japan. For Kamikita Coastal Plain and Shimokita Peninsula, northeastern Japan, the ages of marine terraces have been well defined by tephrochronology. Post-infrared infrared stimulated luminescence (pIRIR) dating of K-feldspar has been applied to date Pleistocene sediments since about 10 years ago. In this study, we applied pIRIR dating to date these marine terrace deposits and the age correction methods were discussed. The shallow marine deposits formed during interglacial highstands which are corresponding to Marine Isotope Stage (MIS) 5e, 7, 9, 11 (45 samples from 11 outcrops) were measured. We applied $pIRIR_{200/290}$ signal based on Ito *et al*. (2017) to D_e measurement and fading test. The fading-corrected ages based on Kars *et al*. (2008), except for 6 sample from 2 outcrops, are suitable to defined the stage of sea-level highstands, while all fading-corrected ages were overestimated compared with the expected ages. This age overestimation is corresponding with about 40~50 Gy. The dose recovery ratios of few samples were clearly high from unity, thus it was possible to the overestimation of D_e. On the other hand, $pIRIR_{200/290}$ signal is more difficult to bleach than the quartz OSL, K-feldspar $IRSL_{50}$ and $pIRIR_{50/290}$ signals, and this residual dose is about 10~20 Gy derived from the well-bleached modern beach sand. Additionally, in the previous study of Holocene marine sediments, the marine succession has formed by beach progradation since few thousand years (e.g., 6ka in Kujukuri strand plain, Tamura et al. 2008). This few Gy accumulated during beach progradation is added to residual dose of well-bleached modern beach sand, thus apparent residual dose of $pIRIR_{200/290}$ signals from whole shallow marine deposits may be >20 Gy. Considering this apparent residual dose, it may be possible to be concordant the fading- and residual dose-corrected ages with the expected ages. However, this apparent residual dose is corresponding with >10ka in study area, thus $pIRIR_{200/290}$ signal is useful to older samples, while it may be difficult to apply younger sample (e.g., MIS5a, 5c).

Comparison of luminescence readers using post-Infrared Infrared stimulated luminescence of K-feldspar from last interglacial marine terrace deposits

*Hayashizaki Ryo[1], Eiji Nakata[1]

1. Central Research Institute of Electric Power Industry

The two types of TL/OSL Readers, Risø TL/OSL Reader and Lexsyg series (Lexsyg Research and Lexsyg Smart), are widely used for luminescence dating. Some researches provide the same results of Quartz OSL dating using the two types of TL/OSL Readers (Lomax et al.2014), therefore it is thought that the two readers perform the same for OSL dating. However, few studies have compared with the two types of readers using K-feldspar OSL dating, especially where the samples are older than 100ka. This study examines post-infrared Infrared Stimulated Luminescence ($pIR_{50/200}IR_{290}$) dating from last interglacial marince terrace deposits using two types of TL/OSL readers (Risø TL/OSL-DA20 and Lexsyg Research). In addition to the results, we also discuss the differences between the readers, such as their analysis software for measuring fading rate and their differences in disc temperature during analysis.

Late Quaternary loess accumulation at the Rudak section in Uzbekistan, central Asia: Chronology and palaeoclimate implications

*Jingran Zhang[1], Xinying Zhou[2], Hao Long[3]

1. Nanjing Normal Univ., 2. IVPP, CAS, 3. NIGLAS

Many studies have been carried out to understand the nature of the loess formation and its palaeoenvironmental significance in different parts of Eurasia, especially Europe and China. However, in spite of its key position, our knowledge about the loess deposits at the core of the Eurasian loess belt in central Asia is still limited, particularly in term of absolute dating. This study presents a new luminescence chronology of a loess-palaeosol sequence (Rudak section) in the vicinity of the Gissar Range, Uzbekistan, using both quartz optically stimulated luminescence dating and polymineral post-IR IRSL dating techniques. The dating results suggested a loess accumulation history over the past 180 kyr, but a great depositional hiatus during the entire last glacial period, likely owing to too harsh climate conditions for favouring dust deposition and loess preservation in the piedmont areas of central Asia. Hence, contrasting with the traditional concept of continuous (quasi-continuous) deposition of loess, the direct stratigraphical correlation might be problematic for climatic interpretation of loess-palaeosol sequence in this area. Furthermore, magnetic susceptibility of Rudak section demonstrated the moisture peaks in phase with ice-volume minima over the glacial and interglacial cycles, indicating moisture variation in the Westerlies dominated central Asia was broadly consistent with that in monsoonal Asia on orbital timescales, but nearly contrasting picture with each other on the suborbital timescales, at least through the Holocene. The Westerlies dominated central Asia has generally experienced a dry first-half and a wet second-half of the Holocene, which is likely triggered by solar insolation gradients between mid-latitudes and high-latitudes and meltwater flux.

Dating of hydrothermal silicified sediments by thermoluminescence

*Naoya Obata[3,1], Takashi Goto[4,1], Chitaro Gouzu[1], Jun-ichiro Ishibashi[2], Shin Toyoda[3]

1. Hiruzen Institute for Geology and Chronology Co., Ltd., 2. Kyushu University, 3. Okayama University of Science, 4. Fuji Geological Institute

The ages of hydrothermal activities are key issues in estimating the geothermal processes under the sea floor especially such as ore formation. Silicified sediments, widely distributed in hydrothermal fields of the sea floor, are potentially subject of trapped-charge dating, and their ages will contribute to the issues. Coarse and fine quartz grains were identified in the hydrothermal silicified sediments under a polarizing microscope. We tried thermoluminescence (TL) dating for each grain extracted from hydrothermal silicified sediments in the Okinawa Trough. We first checked the characteristics of silicified sedimentary quartz, such as TL peaks, wavelengths, and the dose response. The distribution of the radioactive elements was obtained by using imaging plates. As results of TL dating, coarse grains were found to be older than fine grains. Tentatively it is interpreted that coarse grains originated in volcaniclastic sediments have incompletely reset by hydrothermal activity, whereas fine grains precipitated from hydrothermal solutions, indicating the ages of the hydrothermal activities.

Applications of trapped-charge dating techniques to hydrothermal mineral deposits collected from active seafloor hydrothermal fields

*Jun-ichiro Ishibashi[1], Naru Tsukamoto[1], Yusuke Okazaki[1], Taisei Fujiwara[2], Naoya Obata[2], Takashi Goto[2], Chitaro Gouzu[2], Shin Toyoda[3]

1. Department of Earth and Planetary Sciences, Faculty of Science, Kyushu University, 2. Hiruzen Institute for Geology and Chronology, 3. Okayama University of Science

Chronological studies of hydrothermal mineral deposits are useful, because accumulation of metal elements to be resource requires duration and evolution of mineralization processes in a time scale of 10^3 to 10^5 years. However, conventional radiometric dating techniques are difficult to be applied for hydrothermal deposits, because they grow up by repeated mineralization. We tried to yield practical applications of trapped-charge dating techniques, expecting they provide appropriate averaged ages. We conducted electron spin resonance (ESR) dating of sulfate minerals (barite) in hydrothermal deposits, expecting they provide ages of hydrothermal mineralization. We also conducted thermoluminescence (TL) dating of quartz in volcaniclastic and siliceous sediment. Quartz of coarse grain in the volcaniclastic sediment is considered to provide igneous ages of original volcanic rocks, whereas quartz of fine grain in the siliceous sediment is expected to provide ages of intense hydrothermal alteration. Our test field is a hydrothermal field in the Okinawa Trough, where mineralization of hydrothermal deposits occurs not only on the seafloor but also within the subseafloor sediment layers. Radiocarbon (^{14}C) datings of planktic foraminifera in the uppermost unconsolidated sediment indicated monotonous sedimentation since ~30ka TL datings of thick volcaniclastic sediment provided ages between 20-50 ka, which are roughly in accordance with the radiocarbon ages. On the other hand, ESR datings of hydrothermal barite obtained from 10 and 20 mbsf (meters below the seafloor) provided rather young ages around 5-6 ka. These results suggest subseafloor mineralization of the barite after sedimentation of the volcaniclastic sediment.

Luminescence dating of the late Quaternary terrestrial-marine interaction sedimentary history of the north Jiangsu coastal plain and the Yangtze River delta in China

*Lei Gao[1], Hao Long[1], Toru Tamura[2]

1. Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, 2. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

Abstract: Coastal deposits are ideal archives to decipher the history of interactions between the atmosphere, oceans and solid earth in view of exchanges of mass and energy, climate-induced sea-level changes and coastal sedimentary evolutions. Chronostratigraphy is one of the key clues to understand the links between them. However, robust age controls over glacial-interglacial timescales in Chinese coastal zones remain so scarse. Here, we apply luminescence dating methods, including single-aliquot-regenerative (SAR) quartz optically-stimulated luminescence (OSL) and feldspar/polymineral post-infrared infrared-stimulated (pIRIR) dating, to sediments from the north Jiangsu coastal plain (JSP) and the Yangtze River delta in China to ascertain their chronologies. In combination of sedimentology and microfossil analysis, the late Quaternary sedimentary environments are re-examined based on our newly refined chronostratigraphy. In the north JSP, the obtained chronostratigraphy of a invetigated core (EGWY02) revealed that terrestrial deposition occurred in marine isotope stage (MIS) 6, MIS 4-2 and the latest part of MIS 1, whereas marine-influenced sedimentation at MIS 5e, 5c, 5a and the majority of MIS 1. Specially, two sets of marine stratigraphic units (T1, T2) dated back to ~7 ka and 130-80 ka, respectively, were recognized, but no obvious MIS 3 transgression recorded in this core. In addition, the sedimentation rates (SR) resulted from Bayesian age-depth model show that two distinct high SR stages at 130-70 ka and 2-7 ka, corresponding to the global highstands of sea level and also strengthened East Asian summer monsoon (EASM); in contrast, much slower SR occurred through the last glacial as well as the late Holocene, when sea level was lower and the EASM intensity was weakened. However, in the Yangtze River delta, the chronostratigraphic comparison of our studying core (YZ07) with the adjacent cores along a south-north transection, suggested the tidal flat to delta deposits dated to the MIS3 at the basal part, which was erosionally overlain by terrigenous unconformity surface and fluvial deposit of the last glacial. This terrigenous unit is then overlain by the postglacial transgressive to regressive succession of tidal river, tidal sand bar, and delta front to tidal flat after ~13 ka. Both records in the north JSP and Yangtze River delta show strong links between the regional terrestrial-marine alternation sedimentary history and climate-induced global sea level changes, although the discrepancy in MIS 3 was existed between two regions, which might be due to the differences in distances of coring sites far from the offshore either or their paleotopographic relief.

Composite chronology of Paleolithic sites in Jebel Qalkha revealed by pIRIR dating

Risako Kida[1], *Toru Tamura[2], Seiji Kadowaki[1]

1. Nagoya University Museum, Nagoya University, 2. Institute of Geology and Geoinformation Geological Survey of Japan, AIST

Several Paleolithic archaeological sites occur in the Jebel Qalkha area, southern Jordan, providing valuable records of the cultural dynamics and palaeoenvironment during the dispersal of *Homo sapiens* out of Africa. We attempted optically-stimulated luminescence (OSL) dating for sediment samples taken from Epipaleolithic to Middle Paleolithic layers at multiple sites, including Tor Hamar, Tor Fawaz, Wadi Aghar and Tor Faraj. Test measurements revealed that the OSL characteristics of quartz grains are not suitable for dating; quartz OSL leads to variable equivalent dose depending on preheat temperature and does not result in an appropriate dose recovery. In contrast, post-IR IRSL (pIRIR) is characterized by a good dose recovery and its equivalent dose does not highly depend on preheat and measurement temperatures. pIRIR also shows modest fading rates. While quartz OSL is usually the first choice for dating sediments younger than 50,000 years, in this site K-feldspar pIRIR protocol is considered more appropriate. Thus we attempted the $pIRIR_{50/150}$ protocol of K-feldspar grains of 62–90 μm diameter. We obtained dates of 11–46 ka at Tor Hamar, 14–45 ka at Tor Fawaz, 36–50 ka at Wadi Aghar, and 53–66 ka at Tor Faraj, being approximately concordant with ages inferred from stone tools. This indicates that further examination of the composite chronology of these sites may help clarify timings of lithic cultural changes and environmental background from the Middle Paleolithic to Epipaleolithic periods, corresponding to the human population change from *Neanderthals* to *Homo sapiens*.

Probabilistic Hazard Assessment of Tsunami due to Large Earthquakes along the Nankai Trough

*Kazuhiro Ichijo[1], Yutaka Hayashi[1], Yasuyuki Kawazoe[2], Fumihiko Imamura[3], Hisashi Suito[1]

1. Ministry of Education, Culture, Sports, Science and Technology, 2. Japan Meteorological Agency, 3. International Research Institute of Disaster Science, Tohoku University

Earthquake Research Committee, the Headquarter of Earthquake Research Promotion (ERC/HERP) has released “*Probabilistic Hazard Assessment of Tsunami due to Large Earthquakes along the Nankai Trough*” (hereinafter-called PHAT) on 24 January 2020. This is the first report on hazard assessment of tsunami by ERC, and is based on "*Long-term evaluation of the Nankai Trough earthquake (Second edition)* " (ERC/HERP, 2013; hereinafter-called LTE2) and "*Tsunami prediction method for earthquakes with characterizing source faults (Tsunami Recipe)*" (ERC/HERP, 2017). PHAT evaluates the distribution of exceedance probabilities that will cause the tsunami height on the coast to be 3 m or more, 5 m or more, and 10 m or more due to various major earthquakes along the Nankai Trough within next 30 years. This abstract introduces the outline of PHAT.

The tsunamis targeted by PHAT are large repeating earthquakes along Nankai Trough whose seismic magnitudes and occurrence intervals has been evaluated by LTE2 as M8 to M9 class, and from 100 to 200 years, respectively. However, the so-called "largest-class earthquake" of Nankai Trough defined by the Cabinet Office is excluded from the target. The future possibility of occurrence of the largest-class earthquake cannot be denied logicaly because, very limited information of evidence on past occurrence of such huge earthquake is found from any written historical records or at least 2000 years-long sediment records.

PHAT assumed 176 patterns with different combinations of extent of epicenter area as next large earthquake cycle along the Nankai Trough by considering the diversity of it. In addition, according to the Tsunami Recipe, two or more cases having different large slip regions were prepared for each pattern in order to consider heterogeneity with respect to of the fault slip. As a result, source fault models of 348,345 cases were selected, and the distribution of tsunami height corresponding to each case were calculated.

Each case was weighted according to its similarity to past major earthquake along the Nankai Trough. Using these weights, the tsunami height computation results were superimposed at each evaluation point located at approximately 50-meter intervals along the coastline within potentially affected area due to the large earthquake along Nankai Trough. From the hazard curves obtained in this way, the exceedance probabilities of tsunami exceeding 3m, 5m or 10m within next 30 years was calculated. The upper limit of the excess probability is 0.743, which is the probability of occurrence probability of large earthquake occurring within the next 30 years from 2020 along the Nankai Trough.

The distribution of excess probability values has been compiled as maps for whole area and tables for each municipality. Each evaluation point or municipality is classified into 3 categories (less than 6%, from 6% to 26%, and 26% or more) according to its exceedance probability.

©2020. Japan Geoscience Union. All Right Reserved.

The characteristics of the map of "exceedance probability that a tsunami height on the coast will be 3m or more due to large earthquakes along the Nankai Trough within next 30 years" are as follows:

- Evaluation points classified into 26% or more are found in wide area.

- The Izu Islands and Kyushu, which are slightly away from the tsunami source, has locally large probability.

In the map of that of 5m or more, wide area centered on the Pacific side from the Kyushu region to the Tokai region indicate 6% or more, and some regions near the epicenter indicate 26% or more. The map of that of above 10m, some coastline near potential source area indicate from 6% to 26%.

According to three maps, the probability at inner bays in rias coast facing an open sea and the straight-shaped coast, which are in general sensitive to a tsunami source, and tends to be higher than surrounding area.

Characterized earthquake fault models along the Nankai Trough for probabilistic tsunami hazard assessment

*Kenji Hirata[1], Tadashi Kito[2], Nobuhiko Toyama[2], Hiroyuki Fujiwara[1], Hiromitsu Nakamura[1], Nobuyuki Morikawa[1], DOHI YUJI[1], Hisanori Matsuyama[2], Kenshi Ohshima[2], Yasuhiro Murata[3], Ryu Saito[3], Mariko Korenaga[4], Yuta Abe[4]

1. National Research Institue for Earth Science and Diaster Prevention, 2. OYO corporation, 3. KKC, 4. CTC

The National Research Institute for Earth Science and Disaster Resilience (NIED) began a research project on a probabilistic tsunami hazard assessment (PTHA) for Japan in 2012 (Fujiwara et al., 2013, JpGU). After years of research on the PTHA, the “Probabilistic hazard assessment of tsunamis due to large earthquakes along the Nankai trough” was published by the Headquarters for Earthquake Research Promotion (HERP) in 2020. Although the largest-class earthquakes were not included in this assessment, this was for the first time that the probability of tsunami hazard information had become openly available to the general public in Japan.A PTHA consists primarily of three components: the construction of earthquake fault models, tsunami simulations, and the analysis of hazard curves. In this study, we focus on theconstruction of ‘characterized earthquake fault models’ (CEFMs) based on the long-term evaluation by the HERP (2013) to cover various types of possible earthquakes along the Nankai Trough.
We divided the entire source region on the upper boundary of the subducting Philippine Sea plateinto 18 sub-regionsas HERP(2013) did, and constructed total of 3480 CEFMs as various combinations of the 18 sub-regions.
Based on the CEFMs and tsunami simulations, we conducted two types of PTHAs for next Nankai earthquake sequence. One consists of 3480 CEFMs (83 source regions, Mw7.7-9.0), including CEFMs for the largest-class earthquakes as well as CEFMs with super-large slip areas. In this type of the PYHA, 180 combination patterns of source regions and the corresponding 916,669 combination patterns of CEFMs were incorporated into the PTHA. The other PTHA consists of 2720 CEFMs (79 source regions, Mw7.7-9.1), not including CEFMs for the largest-class earthquakes and CFMs with super-large slip areas. 176 combination patterns of source regions and the corresponding 348,345 combination patterns of CEFMs were incorporated into the PTHA, which is equivalent to the PTHA published by HERP (2020). The differences between these PTHAs will be presented by Saito et al. (JpGU, this meeting) and Abe et al. (JpGU, this meeting).
This study is conducted as a part of the research project “Research on the hazard and risk assessment” at NIED.

Tsunami simulations for probabilistic tsunami hazard assessment in the Nankai Trough

*Ryu Saito[1], Kenshi Ohshima[2], Tadashi Kito[2], Yasuhiro Murata[1], Tomoyuki Shibuki[1], Mariko Korenaga[3], Yuji Dohi[4], Hiromitsu Nakamura[4], Kenji Hirata[4], Hiroyuki Fujiwara[4]

1. KOKUSAI KOGYO CO., LTD, 2. OYO Corporation, 3. CTC (ITOCHU Techno-Solutions Corporation), 4. NIED (National Research Institute for Earth Science and Disaster Resilience)

We have already reported the results of tsunami propagation simulations performed in each sea region along the Kuril Trench, the Japan Trench, the Sagami Trough, the Nankai Trough and the Ryukyu Trench (Takayama et al., 2016, JpGU; Saito et al., 2017, 2018, JpGU; Saito et al., 2016-2018, SSJ), along with a study on stochastic evaluation of tsunami hazards that would occur on coasts throughout Japan (Fujiwara et al., 2013, JpGU; Hirata et al., 2014-2018, JpGU; Hirata et al., 2018, SSJ). This time, we followed the method and concept of a probabilistic tsunami hazard assessment (PTHA) of earthquakes accompanying the interplate earthquakes excluding the largest class earthquake exceeding M9 announced by the government's Earthquake Research Committee (ERC) in January 2020. In addition, we calculated the tsunami propagation that would be caused by the Nankai Trough earthquake, taking into account the largest class of earthquakes excluded by ERC (see also Hirata et al., this meeting). Regarding whether to include the largest class earthquakes and others, in this presentation, we report the characteristics of tsunami heights simulated by the propagation calculation from the Kyushu to Kanto regions, that is, the Pacific coast, the Seto Inland Sea coast, and the Izu-Ogasawara Islands coast.

We describe the method of a tsunami propagation simulation. A tsunami propagation simulation used in this study estimated tsunami wave height along the coasts, solved by the non-linear shallow-water equation using a leap-frog scheme. These simulations were configured by a nested grid system consisting of four sub-regions from outer 1,350 meters to inner 50 m in a horizontal, landward inundation keeping, and transparent at the seaward edges. Initial wave height followed vertical displacement driven by seafloor deformation via Okada’ s equation (Okada, 1992). The sea surface deformation consisted of vertical and horizontal displacement of seabed deformation (Tanioka and Satake, 1996), and was filtered to remove high frequency components (Kajiura, 1963). The water level standard corresponded to mean sea level of Tokyo Bay (Tokyo Peil, T.P.). A seafloor and land topography model used was created using the topographic mesh data released by the “Nankai Trough Massive Earthquake Model Study Group” of the government's Cabinet Office. We converted the topographic mesh data with a minimum grid spacing of 10 m to 50 m, as in the nearshore tsunami calculation. In order to simulate the tsunami height from the epicenter to the coast, the calculation resolution was subdivided from offshore to shore at 1,350 m, 450 m, 150 m, and 50 m, and connected. PTHA in this study was conducted at approximately 420,000 points on a 50 m grid in the water area near the shoreline on the coast line.

The following is a brief description of a seismic source used in this study (for details, see Kito et al., this meeting). The seismic source used was a total of 2,720 characterized earthquake fault models (CEFMs) from Mw7.6 to Mw9.0 built based on 79 types of source regions diversified by combining 18 source regions shown in the long-term evaluation reports. In addition to these source regions and CEFMs, we adopted a total of 83 source regions, including the largest class of earthquakes excluded by ERC, and 3,480 types of CEFMs from Mw7.6 to Mw9.1. Therefore, the tsunami simulations were performed using 2,720 kinds of CEFMs that do not consider the largest class earthquake and 3,480 kinds of CEFMs that consider the largest class earthquake.

©2020. Japan Geoscience Union. All Right Reserved.

As a result of the tsunami simulation, the tsunami height was about 2 m at the maximum on the western coast of Kyushu and the Seto Inland Sea coast, which was lower than the other coasts. Conversely, along the Pacific coast, simulated tsunamis were relatively high around capes such as Ashizuri Cape, Muroto Cape, Shiono Cape, Daio-zaki, Irago Cape, and Iro-zaki. The tsunami height was less than 30 m for 2,720 CEFMs without considering the largest class earthquake, while the height was less than 50 m for 3,480 CEFMs considering them. The impact of including the largest earthquakes was remarkable around Ashizuri Cape, Muroto Cape, and Iro-zaki, and the tsunami rose about twice as much as without them.

The outputs form this study contributes to PTHA (Abe et al., this meeting) and stochastic research such as evaluation of coastal tsunami height including uncertainty. The use of the outputs is widely promoted by making them open access services (Dohi et al., this meeting).
This study was done as a part of the research project “Research on evaluation of hazard and risk” that is carried out by NIED.

Probabilistic Tsunami Hazard Assessment for Nankai Trough:Weight Ratio and Results of PTHA

*Yuta Abe[1], Mariko Korenaga[1], Shinichi Akiyama[1], Teppei Ono[1], Hiroyuki Fujiwara[2], Kenji Hirata[2], Hiromitsu Nakamura[2], Tadashi Kito[3], Yasuhiro Murata[4]

1. ITOCHU Techno-Solutions Corporation, 2. National Research Institute for Earth Science and Disaster Resilience, 3. OYO Corporation, 4. Kokusai Kogyo Co., Ltd.

Earthquake Research Committee (ERC)/HERP (2020a) announced a probabilistic tsunami hazard assessment(PTHA) for the next Nankai earthquake based on the long-term evaluation reports for Nankai earthquake (ERC, 2013; ERC, 2020b). Although ERC (2020a) excluded possible maximum-sized ruptures over M9 on their PTHA, NIED conduct another PTHA for the next Nankai earthquake by adding earthquakes which have maximum-sized ruptures over M9 (Hirata et al., this meeting). In this presentation, we explain the setting of weight ratio on the two PTHAs and compare the results of the PTHAs.

ERC (2020a) constructed 79 earthquake source regions(ESR) by the combinations of 18 segments and a number of characterized earthquake fault models (CEFMs) for each ESR. As occurrence patterns for the next Nankai earthquake, they constructed 176 combos of ESRs and assigned weight ratio them. First, they divided the combos of ESRs into two groups; Group I had ESRs where the Tonankai and Nankai regions were ruptured individually (e.g.,1944 and 1946 sequence) and Group II had ESRs where both the Tonankai and Nankai regions were simultaneously ruptured (e.g.,1707 Hoei). The weight ratios for Group I vs Group II were assigned 2/3 vs 1/3 by taking account for occurrence pattern history. Next the combos of ESRs of Group I and II were addittionally devided into two groups; 2 segments of Tonankai region and 2 segments of Nankai regions ruptured simultaneously or individually where weight ratios were assigned 4/5 vs 1/5, respectively. The combos of ESRs were devided into two groups also about plate subduction direction; only ESRs with middle depth zone were ruptured or the others where weight ratios were assigned 4/5 vs 1/5, respectively.

The present study follows the methodology of ERC(2020a) principally, but newly adds (i) CEFMs in Group III that consists of maximum-sized ruptures over M9 and (ii) CEFMs with a super large slip(4 times amount of average slip) which is allowed to exist when earthquake ruptures reach the trough axis. Then we construct 83 ESRs and 180 combos of ESRs (Kito et al., this meeting) and conduct a PTHA with them. The weight ratios for Group III and GroupI&II are assigned 1/21 vs 20/21 based on the idea in “National Seismic Hazard Maps for Japan in 2014“(ERC,2014).

By adding earthquakes of maximum-sized ruptures and CEFMs with a super large slip, tsunami hazard curves exceed those of ERC(2020a) along coasts facing the Pacific between Kyushu and Boso Peninsula, especially for lower probability level. For example, the probabilistic coastal tsunami heights where exceedance probability in 30 years (P30) is equal to 3% are ~0.3m on average (~2.3m at maximum) larger than the PTHA of ERC(2020a), and those where P30 is equal to 0.3% are ~0.8m on average (~9.1m at maximum) larger. This suggests that when we want to know the tsunami risk of Nankai earthquake for frequency of once in a millennium or less, it is important to consider earthquakes of maximum-sized ruptures. However, the scientific evidence to the weight ratio to Group III vs Groups I &II is not so strong. We conduct a case study for weight ratio of Group III vs Groups I &II and show how the weight ratio affects PTHA largely.

Consideration of tsunami source generated in the Hyuga-nada region in 1662

*Kei Ioki[1], Yusuke Yamashita[2], Yoshihiro Kase[3]

1. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology, 2. Disaster Prevention Research Institute, Kyoto University, 3. Geological Survey of Hokkaido, Hokkaido Research Organization

Hyuga-nada region is located at the south-western part of Nankai Trough, in the Pacific Ocean. M7-class interplate earthquakes are repeatedly occurred by the subducting Philippine Sea plate beneath the Eurasian plate. The largest earthquake in this area was the 1662 Hyuga-nada earthquake (M=7.6) which occurred off Miyazaki Prefecture, south-eastern area of Kyushu region, Japan, and generated tsunami (after called the 1662 tsunami). The tsunami heights were estimated at least 4-5 m along the coast of Miyazaki city by historical records. The 1662 tsunami was much larger than tsunamis generated by usual M7-class interplate earthquakes. This region is also active area of the shallow slow earthquakes. It is known by the 2011 Tohoku earthquake that focal area of shallow slow earthquakes also become a tsunami source area. So, we hypothesized that the 1662 unusual large tsunami was caused by the coseismically slipping of focal area of shallow slow earthquakes. We firstly constructed the fault model of the 1662 earthquake based on the recent result of geophysical observation. To examine the tsunami source of the 1662 earthquake, we surveyed the 1662 tsunami deposits in the lowland along the coast of south-eastern Kyushu region. As a result, sandy event deposits interbedded with clay (organic clay) were recognized at several surveyed points. Based on facies features, these event deposits were possibly formed by the 1662 tsunami. Numerical simulation of the tsunami was carried out using the constructed fault model. Calculated tsunami inundation area can explain distribution of the likely tsunami event deposits at Komei, Miyazaki Prefecture. Furthermore, this study compares calculated tsunami inundation areas, distribution of other surveyed tsunami deposits and tsunami heights of historical records. Tsunami source of the 1662 earthquake proposed by our study could better explain geophysical, geological and historical records.

Source of the 1923 great Kanto earthquake explaining observed tsunami waveforms

*Yumi Nakadai[1], Yuichiro Tanioka[1]

1. Hokkaido University

One of the most devastating natural disaster in Japan was caused by the 1923 great Kanto earthquake occurred just beneath the Tokyo Metropolitan area. The number of casualties by the earthquake was more than 100,000. The number of injured people was reached 2 million. In the southern Kanto region where the Philippine Sea plate is subducting along the Sagami trough, great underthrust earthquakes of M7-8 have repeatedly occurred. They also generated large tsunamis. It is, therefore, important to investigate the generation mechanism of large tsunamis that occur in such areas.

The 1923 Kanto earthquake is the most recent great earthquake along this plate interface. Source models for the 1923 event have been studied by many researchers using seismological and geodetical data. Aida (1993) proposed source models of the 1923 earthquake using regional tsunami heights from historical documents and experiences at the time of the earthquake. Namegaya et al. (2011) constructed a fault model consists of 34 subfaults and estimated the slip distribution by inversion of the co-seismic vertical deformation. Tsunami waveforms generated by the 1923 earthquake were also recorded by several tide gauges along the Pacific coast in Japan and reported by the Imperial Earthquake Investigation Committee (1926). However, those data have not been analyzed to estimate the source of the earthquake.

In this study, we used those variable tsunami waveforms to study the source of the earthquake. First, we digitized historical tsunami waveforms recorded at ten tide gauge stations, Ayukawa, Minatomachi, Choshi, Osaka, Owase, Kushimoto, Urado, Tokyo bay (Chiba, Shibaura, Fukagawa). Next, we needed to correct the bathymetry of Tokyo bay because the bay has been reclaimed significantly since the time of the earthquake. Finally, tsunami numerical simulation was conducted using previously proposed two source models (Aida,1993; Namagaya et al., 2011). Then, the computed tsunami waveforms at tide gauges were compared with the observed ones. The results of the comparison showed that computed tsunami waveforms from the source model estimated by Aida (1993) tended to overestimate the amplitude of observed waveforms. In Tokyo bay near the epicenter, computed waveform showed twice the amplitude of the observed waveform. On the other hand, the computed tsunami waveforms from source model estimated by Namegaya et al. (2011) well explained the observed tsunami waveforms. Especially at Tokyo bay, Minatomachi and Urado, the computed tsunami heights explained the observed heights much better than those computed from the Aida model.

This result indicates that the tsunami generation due to the 1923 great Kanto earthquake was a typical co-seismic vertical deformation caused by the earthquake.

Volcanic tsunami earthquakes repeating at submarine calderas (2): Kinematic source modeling of the 2015 Torishima earthquake

*Osamu Sandanbata[1], Shingo Watada[1], Kenji Satake[1], Hiroo Kanamori[2], Luis Rivera[3], Zhongwen Zhan[2]

1. Earthquake Research Institute, the University of Tokyo, 2. California Institute of Technology, 3. Université de Strasbourg, CNRS, IPGS UMR 7516, F-67000 Strasbourg

1. Introduction

Almost every decade, v*olcanic tsunami earthquakes* occurred at a submarine volcano named Smith Caldera near Torishima Island in Japan (Torishima earthquakes). These earthquakes generated disproportionately large tsunamis for their seismic magnitudes (M_w 5-6) [e.g. *Fukao et al.*, 2018, Sci. Adv.]. In order to determine their physical mechanism, we constructed a kinematic source model based on analyses of tsunamis and long-period seismic waves. Here, we present the detail of kinematic source modeling of the 2015 Torishima earthquake. The overview of the project, including the physical mechanism, characteristic seismic properties, causes of tsunami earthquake nature and similarities of recurrent earthquakes, will be presented by *Sandanbata et al.* in "Active Volcanism (S-VC45)" session.

2. Hypothetical fault systems inferred from initial sea-surface displacement

We started the kinematic source modeling of the 2015 Torishima earthquake by estimating the initial sea-surface displacement around Smith Caldera by the tsunami waveform inversion. We used tsunami waveforms recorded at ocean-bottom pressure gauges deployed in the southern oceanic region of Japan, such as a temporary array [*Fukao et al.*, 2018], DONET, the Deep Sea Floor Observatory off Muroto Cape, and the DART system. We found (1) a large uplift concentrated just over the caldera floor, and (2) clear peripheral subsidence at least along the northern side of the rim structure.

Based on the results, we hypothesized a sub-caldera fault system composed of ring and horizontal faults (Fig.a). In the following sections, we examine whether the hypothetical fault system explains both tsunami and long-period seismic records. We also investigate the detailed fault geometries employing multiple fault models with variable fault parameters (i.e. depth of the horizontal fault, dip angle and length of the ring fault).

3. Inversion of tsunami waveforms for slip distributions of sub-caldera ring and horizontal faults

We determined slip distributions on the sub-caldera ring and horizontal faults from the tsunami records by applying a new efficient technique for computing tsunami Green's functions from subfault slips. In most cases, inverted slip distributions consist of *thrust slip on an inward-dipping ring fault* and *asymmetric opening and closing of a horizontal fault* (Fig.a).

The slip distributions on the multiple fault models accurately reproduce the tsunami records (Fig.b), indicating that these are plausible models for explaining tsunami excitation of the Torishima earthquake. However, if the ring fault extends to a horizontal fault lying at a depth of about 4 km below the caldera floor, slip direction of the ring fault becomes opposite between the upper and lower half portions, which we consider unrealistic. Hence, we believe that the horizontal fault lies at a shallower depth of approximately 2 km.

4. Forward modeling of long-period seismic waves from slip distributions

©2020. Japan Geoscience Union. All Right Reserved.

Finally, we investigated the plausibility of the slip models by comparing long-period seismic records at the F-net and GSN stations with their synthetic waveforms. Among the slip models, one with a ring fault with a 75° dip angle extending along an approximately three-quarter portion of the rim structure can best reproduce the observed long-period seismic waves (Fig.c). The waveforms of horizontal components and overall amplitude are sensitive to dip angle and length of the ring fault, respectively. This helps us to constrain the detailed fault parameters well.

5. Conclusion

We concluded that the slip model thus obtained can explain quantitatively both tsunami and long-period seismic records, and is a good kinematic source model of the 2015 Torishima volcanic tsunami earthquake. The source model consists of *thrust slip on inwardly down-dipping ring fault extending partially along the rim* and *asymmetric opening and closing of a sub-caldera horizontal fault* is attributed to the *trapdoor faulting* at the active submarine caldera.

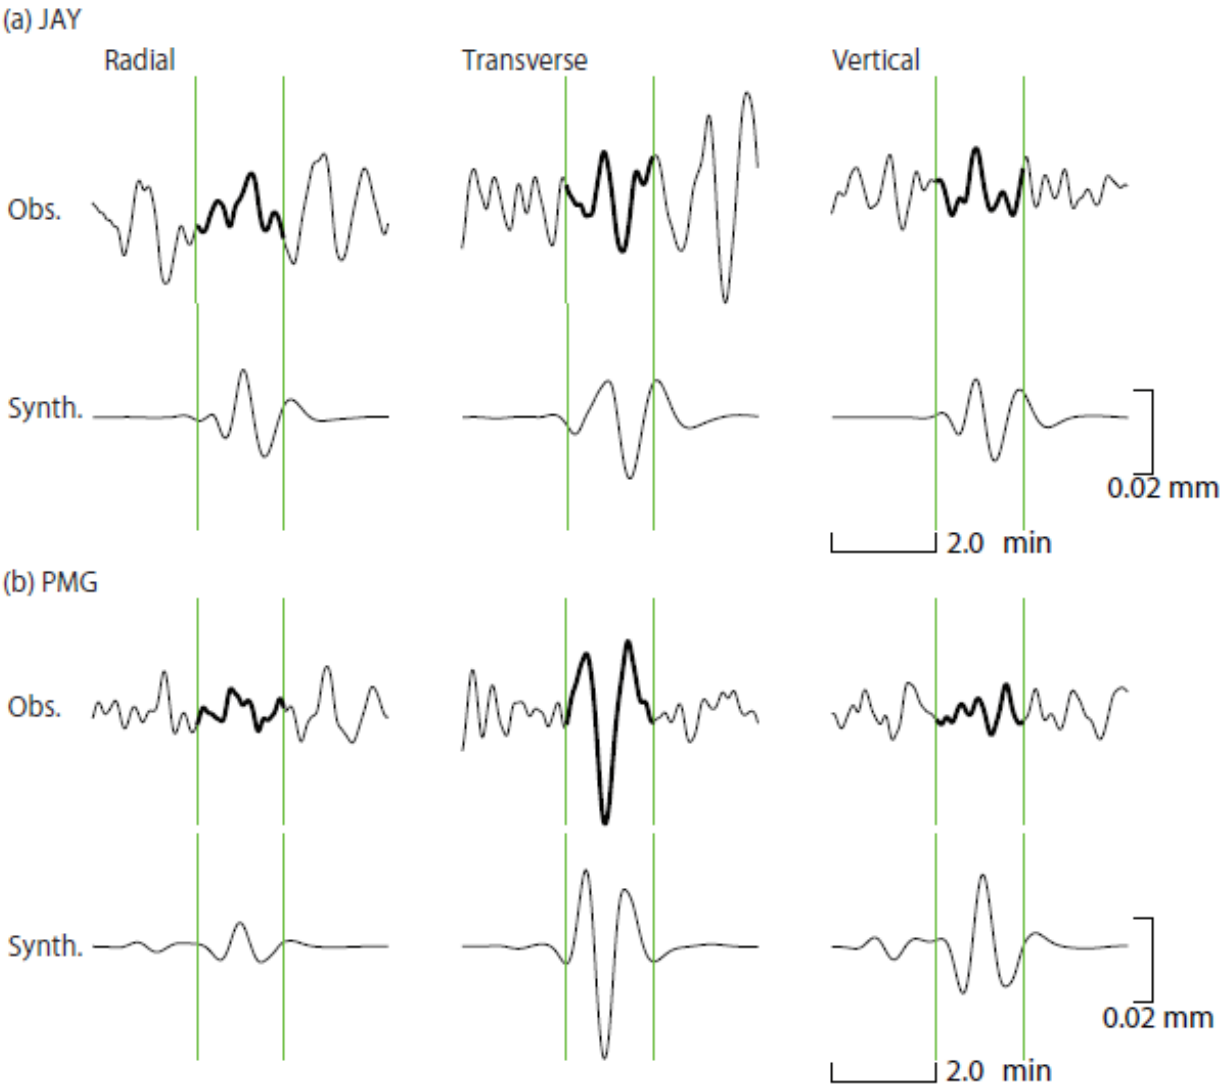
Sliding direction of the landslide that caused the 1998 Papua New Guinea tsunami

*Akio Katsumata[1], Yasuhiro Yoshida[2], Kenji Nakata[1], Kenichi Fujita[3], Masayuki Tanaka[1], Koji Tamaribuchi[1], Takahito Nishimiya[1], Akio Kobayashi[1]

1. Meteorological Research Institute, Japan Meteorological Agency, 2. Meteorological College, Japan Meteorological Agency, 3. Geospatial Information Authority of Japan



On 17 July 1998, a tsunami caused serious damage on the northern coast of Papua New Guinea about 20 min after an Mw 7.0 earthquake. The tsunami has been attributed to a submarine landslide that occurred about 13 min after the mainshock because its arrival at the coast was too late and its height too great to be the direct result of the fault slip of the earthquake. We found long-period (pass-band 50-100s) seismic phases possibly corresponding to the landslide event at JAY (about 150 km from the epicenter) and PMG (about 920 km from the epicenter). We investigated seismic records at nearby six stations. However, no possible phases were found expcept for JAY and PMG.

We tried to construct synthetic records for the observed records at JAY and PMG by the method of Takeo (1985) . To fit the synthetic records to the observed ones, various horizontal force directions were assumed, and checked cross-correlation functions between them. The landslide start time was adjusted to fit the synthetic waves to the waveform at JAY, and it was 12 min and 29 s after the mainshock origin time. The peak amplitudes of synthetic records were adjusted to the observed ones. The figure shows the comparison between the observed and synthetic records. The force size was estimated at 2-6 $X10^{12}$ N, and a landslide duration of 40 s showed the best fit. This force value was of the same order of magnitude estimated based on tsunami simulations in previous studies. The volume and the acceleration assumed for the tsunami simulations were confirmed with the observed seismic waves. The force of $6X10^{12}$ N is comparable to the force estimated by Kanamori and Given (1982) for the debris avalanche associated with the 1980 Mt St. Helens eruption (10^{13}N). The seismic waveform comparisons indicated that the force direction was oriented northeastward for both JAY (N72E) and PMG (N55E). A northward landslide was assumed in many previous tsunami simulations. There would be a possibility that the slump motion may have been oriented northeastward, which is along the downward direction of the topography.

Simulation of reflected tsunami wave caused by the three cases of earthquake off Fukushima prefecture

*Kenji Nakata[1], Takeyasu Yamamoto[1]

1. Meteorological Research Institute, Japan Meteorological Agency

A tsunami, which was generated by the earthquake off Fukushima, was reflected on the coast of Fukushima Prefecture and propagated toward Sendai Bay, so 1.4 m height of tsunami was observed at the Sendai New Port on November 22, 2016.

In this study, we investigated similar phenomena that high reflected tsunamis were observed. We firstly searched the similar phenomena in tsunami cases occurred east off Tohoku and Kanto districts, the following three cases were detected:

July 19, 2008 (Mw 6.9),

July 12, 2014 (Mw 6.5),

December 20, 2008 (Mw 6.4).

Next, we executed tsunami simulations to reproduce these observed tsunami waveforms. For reproduction, we study accurate wave sources, propagation processes including dispersibility, and observation points including resolution of surrounding terrain.

The analysis showed that both the first wave and the reflected wave were reproduced for the cases of July 2008 and July 2014, whereas the calculated amplitude of the reflected wave was smaller than the observed one in the case of December 2008.

In the case of July 2008, shifting the horizontal position of the optimal fault by 0.2 degrees changes the amplitude ratio between the direct wave and the reflected wave, and changes the appearance of the predicted waveform.

Real-Time Tsunami Detection Based on Ensemble Empirical Mode Decomposition

*Yuchen Wang[1], Kenji Satake[1], Takuto Maeda[2], Masanao Shinohara[1], Shin'ichi Sakai[1]

1. Earthquake Research Institute, University of Tokyo, 2. Graduate School of Science and Technology, Hirosaki University

Offshore bottom pressure gauges (OBPGs) are useful in tsunami early warning because they are able to detect tsunami in real time. A reliable tsunami detection algorithm for OBPGs should be able to identify the tsunami signals and characterize the tsunami amplitude accurately, at a small computational cost. Traditional methods, like the DART algorithm adopted by the National Oceanic and Atmospheric Administration (NOAA), have to rely on the prediction of the tides and other lower frequency signals. These algorithms can detect a tsunami by subtracting predicted pressures from the observation, but they cannot properly identify its waveform. And they are unable to capture the feature of the background sea noise.
In our research, we propose a method of real-time tsunami detection based on Ensemble Empirical Mode Decomposition (EEMD). EEMD decomposes the time series into a set of intrinsic mode functions (IMFs) (Huang et al., 1998; Wu, 2005). Unlike Fast Fourier Transform or wavelet analysis, it does not need a priori basis. Instead, it adaptively determines the natural oscillatory modes embedded in the original signal. Therefore, it is applicable to nonlinear, non-stationary data like tsunami signals. In our practice, we use the series of the OBPG record of the past three hours, and then we conduct EEMD and obtain the IMFs. The tsunami signals can be separated from the tide signals, seismic signals, as well as background noise. By comparing the value with a threshold of 2 cm, we could decide whether the tsunami has arrived. We apply our method to the tsunami record of OBPGs of the 2016 Fukushima earthquake, Japan (M7.4; Gusman et al., 2017). Five OBPGs owned and operated by the Earthquake Research Institute recorded the tsunami generated by the earthquake. We retroactively conduct EEMD to the data. Our method automatically extracts tsunami-signals from the low-frequency components (e.g. tide) and the high-frequency components (e.g. seismic waves). The tsunami arrival is easily determined by setting the threshold. We compare our algorithm with STA/LTA (Short Time Average over Long Time Average) method (Allen, 1982). Our method is less influenced by the tide signals and is able to estimate the tsunami amplitude after detection. We also apply our method to the extremely large case of the 2011 Tohoku earthquake (M9.0), and the extremely small case of the 1998 off Sanriku earthquake (M6.1). The EEMD algorithm is able to detect and characterize the tsunami of the extremely large case, but it could not work for the extremely small case.

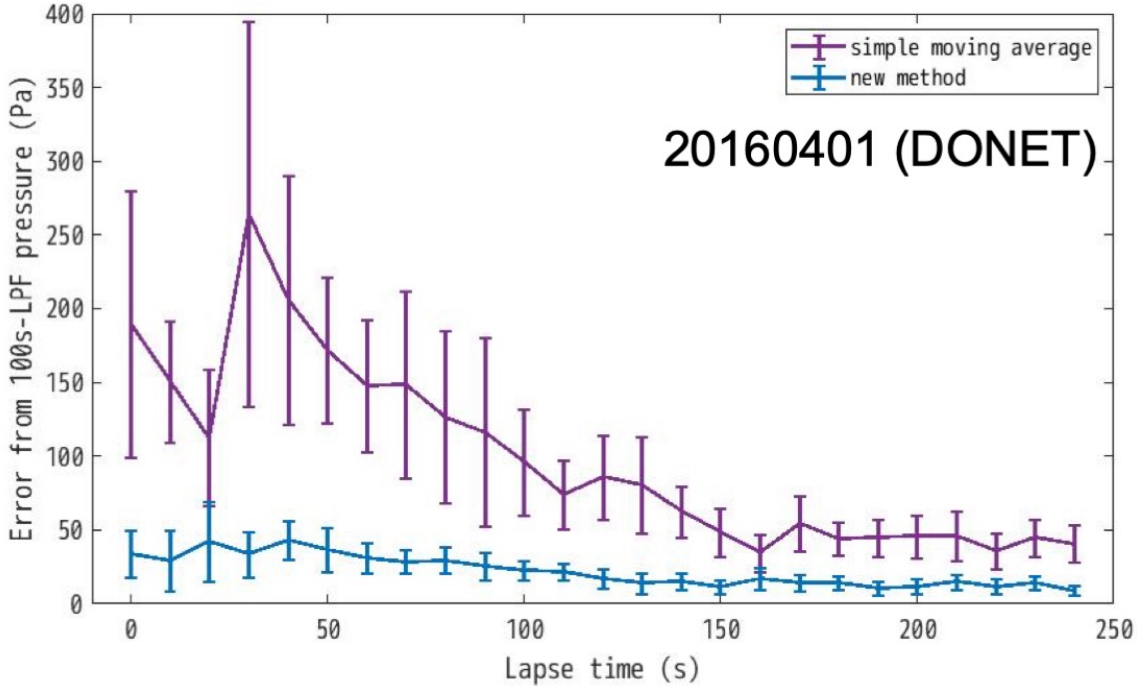
Early estimation of tsunami height from near-fault ocean bottom pressure records: Comparison of DONET and S-net data

*Ayumu Mizutani[1], Kiyoshi Yomogida[1]

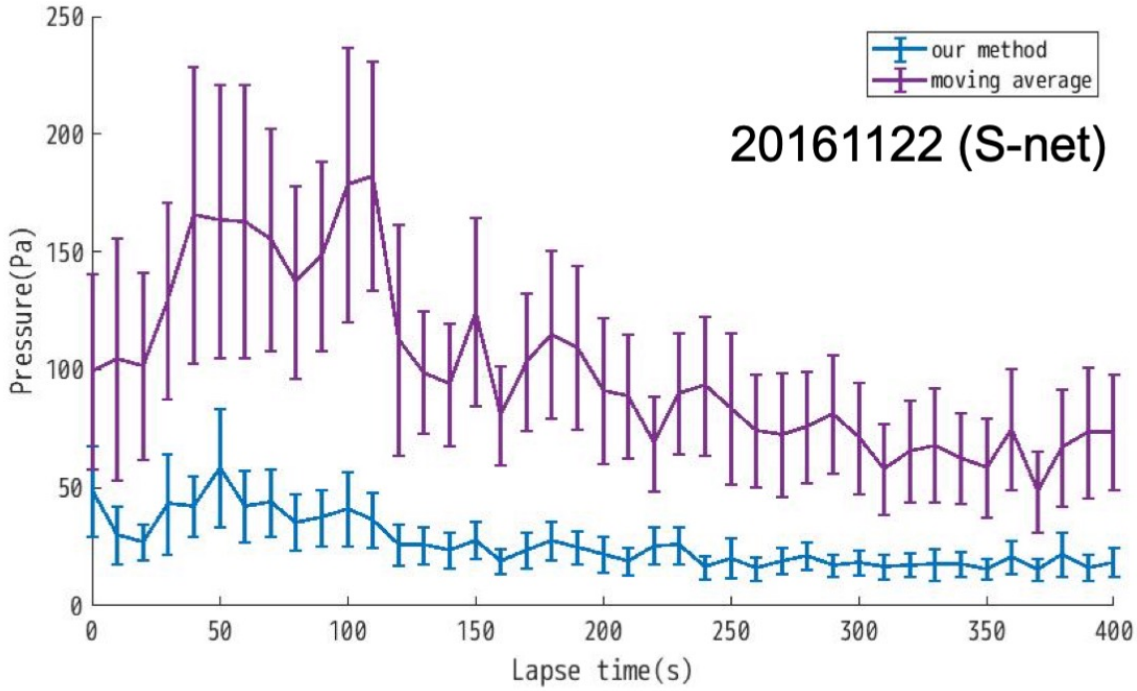
1. Graduate School of Science, Hokkaido University

Ocean-bottom observation networks for earthquakes and tsunamis such as S-net and DONET have been deployed in the offshore Japan. These networks are designed to record tsunamis in terms of water pressure changes. During an earthquake, however, water pressure changes not only by tsunamis (i.e., sea surface heights) but also by water depth changes of instruments, vertical accelerations of a seafloor (i.e., reaction force from water column), and radiated P waves or ocean acoustic waves (e.g., Saito and Tsushima, 2016).

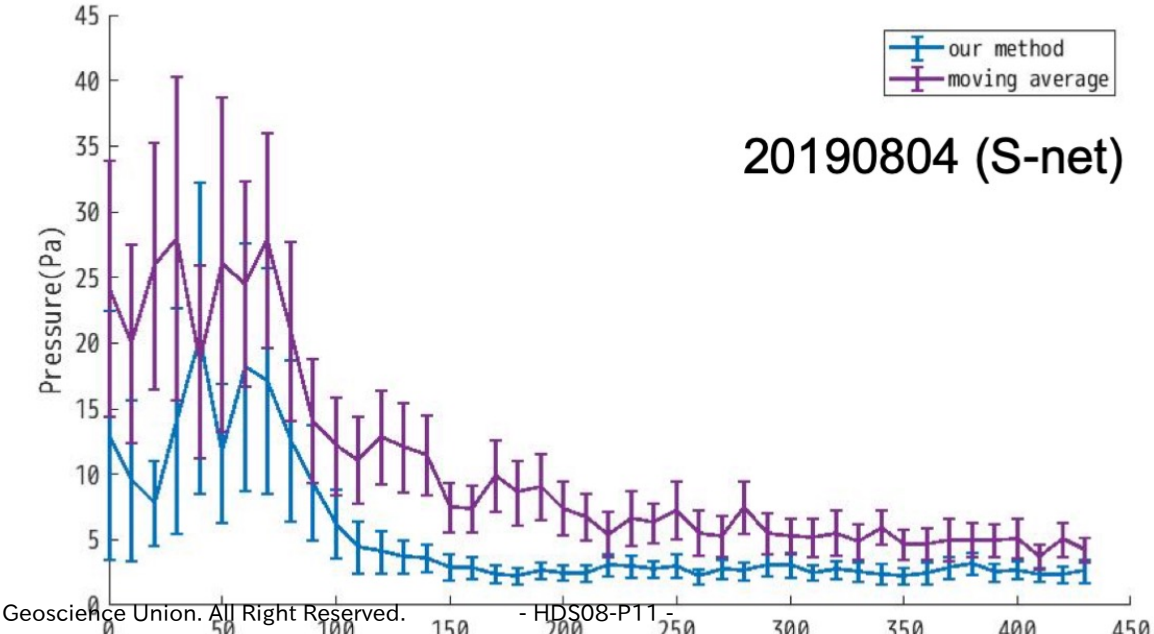
To extract only tsunami and sea bottom displacement components from coseismic ocean bottom pressure (OBP) records, we developed a new scheme based on the assumption that an OBP gauge records sea bottom acceleration at frequency range of 0.05–0.15 Hz (Mizutani and Yomogida, 2020, submitted). We applied it to DONET OBP records of the 2016 Off-Mie earthquake (M_w 6.0), and succeeded to extract tsunami and sea bottom displacement components (i.e., 100-s low pass filtered waveforms) only after 30 seconds of its origin time.



In this study, to confirm the validity of the above method, we applied it to the S-net OBP records associated with the 2016 and 2019 Off-Fukushima earthquakes of M_w 7.0 and 6.4, respectively. While relatively large tsunamis (~1 m) were observed for the 2016 event, no tsunamis for the 2019 event because of its depth was 45 km.



In both cases, the resulted waveforms show better agreement with 100-s low pass filtered waveforms than the ones that are applied simple moving average, similar to our previous result with their discrepancies reduced by half with our method. In other words, our method certainly removes the sea bottom acceleration components from the coseismic OBP records even with S-net data.



For the 2019 event, however, three stations (S2N02, S2N12, and S2N15) recorded the subsidences of about 30 cm. This may be caused by not the sea bottom displacement of each station but the rotation or tilt of OBP gauge, which were induced by strong ground motions. For more reliable tsunami early detection, we need to consider such unexpected signals.

Analytic solutions of seismic tsunamis' initial waveforms: a mathematical study

*Chi-Min Liu[1]

1. Department of Civil Engineering, Chienkuo Technology University

Analytical solutions of initial waveforms of seismic tsunamis are mathematically derived in this paper. Using the linear potential theory, solutions of integration forms for three fundamental seabed deformations, which include rectangular, sine and cosine liftings, are firstly solved with the help of integral transforms. Next, for the initial waveform that means the wave profile at the time when the seabed deformation stops, analytic (closed-form) solutions are derived by simplifying previous solutions with some mathematical techniques. These analytic solutions constitute an important basis which provides the accurate initial waveform and conditions for performing the subsequent numerical calculations.

Predictions of tsunamis caused by possible outer-rise earthquakes in the Japan Trench

*Toshitaka Baba[1], Naotaka YAMAMOTO CHIKASADA[2], Yasuyuki Nakamura[3], Gou Fujie[3], Koichiro Obana[3], Seiichi Miura[3], Shuichi Kodaira[3]

1. Graduate School of Social Science and Technology, Tokushima University, 2. NIED, 3. JAMSTEC

Great interplate earthquakes often induce outer-rise earthquakes in the subducting plate. An M8-class outer-rise earthquake which will be a pair of the 2011 Tohoku earthquake has not occurred yet, so it is anticipated to occur. We have conducted detailed seafloor topographic surveys, passive and active seismic observations to create possible 33 faults of outer-rise earthquakes near the Japan Trench axis in an area from 36.5 to 40.5 degrees north latitude. In this study, we predicted tsunamis caused by these outer-rise earthquakes using numerical simulations. Actual earthquakes do not exactly match the fault parameters of the assumed faults. Therefore, variations on the predictions due to the uncertainty of the assumed parameters were evaluated using the values of K and kappa of Aida (1978).
Each fault was modeled by one rectangular plane connecting endpoints of corresponding horst-and-graven structure on the seafloor. This defined fault length (L) and strike of the fault plane. The upper depth of the fault was set to be 0.1 km below the seafloor. Dip and rake angles were 60 and 270 degrees, respectively. An earthquake scaling law complied by outer-rise earthquakes around the world (Á lvarez-Gómez et al., 2012) determined earthquake magnitude from the fault length. The fault width was the same as the fault length (L=W). But when the lower edge of the fault was deeper than the bottom of the seismogenic zone (40 km), the width was shortened to match the depth of the bottom. The slip amount on the fault was determined by fault area (L x W) and magnitude assuming rigidity of $5x10^{10}N/m^2$.
In tsunami calculations, initial sea surface displacements were calculated assuming that the crust is a homogeneous elastic body in half-space (Okada, 1985). Additionally, horizontal movement effects (Tanioka and Satake, 1996) and a hydraulic filter based on the linear potential theory (Kajiura, 1963) were applied to the tsunami generation. The nonlinear long-wave equations were solved on a uniform finite-difference grid using JAGURS (Baba et al., 2015; 2017) for tsunami propagations. The interval of the grid points was 18 arc-sec. A nesting algorithm was not applied in this study. The large outer-rise fault model (No. 9, L=332 km, Mw=8.66) caused the maximum tsunami which reached 27 m at the coast in northeast Japan.
We repeated tsunami calculations using the fault parameters with variations. The marine seismic surveys showed that the dip angle of the outer-rise faults changed in a range from 45 to 75 degrees. Tsunamis from fault models with a dip of 45 and 75 degrees were calculated by the same method described above. Besides, a compound fault model consists of the upper half with 75 degrees and the lower half with 45 degrees was examined. Rake angle was changed in a range of ±15 degrees. We also performed calculations with models consisting of small subfaults with dimensions of about 60 km instead of a single large rectangular fault, other earthquake scaling laws and dispersive tsunami effects. The strike angle was unchanged because it can be determined from the seafloor topography. In results from the numerical tsunami simulations, using the difference earthquake scaling laws showed the most significant effect on the predicted tsunami heights which were changed by about 50 % on average of the 33 faults. The predicted tsunami heights were changed by a range from 5 to 10 % for changing the dip angle, about 5% for considering tsunami dispersion, about 2% for changing the rake angle, and about 1% for using the subfaults.

Influence of coastal structures on probabilistic tsunami inundation assessments

*Toru Takeda[1], Toshitaka Baba[2], Tsuneo Ohsumi[3], Hiroyuki Fujiwara[4]

1. Graduate School of Advanced Science and Technology Education Department of Intelligent Mechanical Systems Engineering Construction Creative System Engineering Course, Tokushima University, 2. Graduate School of Science and Technology, Tokushima University, 3. National Research Institute for Earth Science and Disaster Prevention , 4. National Research Institute for Earth Science and Disaster Prevention

Studies on probabilistic hazard assessments are common in recent years to quantitatively understand the risks of disasters. For tsunami, probabilistic tsunami height assessments along the coast were conducted. But probabilistic tsunami inundation assessments are not shown yet because these need a huge number of tsunami calculations with highly resolved topographic data (~10m). However, recent developments of high-performance computers enable us to make a probabilistic tsunami inundation map if the study area narrowed down. We created a tsunami inundation database for Tokushima Prefecture along the Nankai Trough. Using the database, we estimated the probability of tsunami inundation on land by multiplying the occurrence probability based on the G-R law (Takeda et al., JpGU, 2019). Unlike the tsunami height on the coast, the inundations of the tsunami on land are greatly affected by the coastal structures. In this study, we created a new tsunami database without coastal structures to assess the contributions of coastal structures on the tsunami inundation probability.
Procedures for making the probability map without coastal structures were the same as that of the previous report except for non-considering coastal structures. We used Hirata et al. (2017)’ s 3967 faults models of the Nankai Trough earthquakes, and calculated tsunami propagations and inundations caused by the all fault models using the nonlinear shallow water equations. A nesting algorism was applied to improve the spatial resolution in the study area. Only the topographic data provided by the Cabinet Office was used. The coastal structure data was not involved in the calculations. We defined the relative weights among the earthquake fault models using the G-R law. The weights were used in superimposing all inundation maps to estimate the probabilities of tsunami inundation without the coastal structures. Comparing the probability maps with and without the coastal structures showed the great importance of the coastal structures reducing the tsunami impacts in the wide area. In particular, the probability of inundation was decreased very much in areas near the sea or river. The coastal structures reduced the probability by 60 % at the maximum near the estuary. However, it is surprising to us that, in some areas near the upstream, the probability of inundation was increased by about 30% with considering the coastal structures.
We will evaluate target earthquakes with a magnitude of 8.0 or more, evaluate tsunami arrival time, and analyze another area.
Acknowledgments: This work was supported by JSPS KAKENHI Grant Number 19H02409.

Simulations of sediment movement for tsunami deposits in Kamoda Pond along the Nankai Trough

*Takuya Saito[1], Toru Takeda[1], Kei Yamashita[2], Toshitaka Baba[3]

1. Graduate School of Advanced Science and Technology Education Department of Intelligent Mechanical Systems Engineering Construction Creative System Engineering Course, Tokushima University, 2. International Research Institute of Disaster Science, 3. Graduate School of Science and Technology, Tokushima University

One of the lessons learned from the 2011 off the Pacific coast of Tohoku Earthquake occurred in 2011 is a necessity to investigate the history of the occurrence of past earthquakes and tsunamis as old as possible. In this survey of past earthquakes, tsunami deposits give important information as physical evidence. After the 2011 off the Pacific coast of Tohoku Earthquake, tsunami sediment surveys have been vigorously conducted. Also, sediment movement simulation models for predicting tsunami deposits have been developed by Takahashi et al. (1999, 2000, 2011) and Fujii et al. (1998). However, comparisons between the survey results and the simulation results have been insufficient yet. The authors have compared tsunami deposits in coastal lakes along the Nankai Trough (Okamura et al., 2012) using the sediment transport model (STM) of Takahashi et al. For the source models, we used the largest class Nankai Trough earthquake assumed by the Cabinet Office and the 1707 Hoei earthquake (Furumura et al., 2011). But the difference from the survey results was observed at Kamoda Pond, one of the survey points by Okamura et al. They confirmed tsunami deposits at the sediment layer at two thousand years ago, but the all source models in the simulations didn’t cause any sediment movement in the pond. In this study, therefore, we focused on Kamoda Pond and examined whether tsunami inflow and sediment migration could occur in Kamoda Pond from three viewpoints: a submarine active fault, splay fault, and tsunami database.

The submarine active fault is the Kitan-Naruto strait section of the Median Tectonic Line fault zone, and the splay fault branches from the plate interface near Cape Muroto (Okamura, 1990). We examined whether each fault brings tsunami sediments in Kamoda Pond using STM. Also, from a tsunami database constructed by performing a large-scale tsunami calculation using 3967 earthquake scenarios of Hirata et al. (2017) and high-precision terrain data in the Nankai Trough. Scenarios that bring tsunami to Kamoda Point were searched from the tsunami database.

As a result of the investigation, Kamoda Pond was inundated in the case of considering the splay fault and in 13 scenarios of the tsunami database, in which a large slip area and a very large slip area were located in the area between the Kii Peninsula and Cape Muroto. The Cabinet Office's source model considered as "the largest class earthquake considering all possibilities" may not be the largest in some coast along the Nankai trough. However, we need more investigations to make sure that the Cabinet Office's source models do not inundate to Kamoda Pond by varying calculation conditions such as topography and tide level.

Acknowledgments: In this study, we used the sediment transport model developed by Takahashi et al. (1999, 2000, 2011). This work was supported by JSPS KAKENHI Grant Number 19H02409.

[H-DS09] Landslides and related phenomena

convener:Masahiro Chigira(Disaster Prevention Research Institute, Kyoto University), Fumitoshi Imaizumi(Faculty of Agriculture, Shizuoka University), Gonghui Wang(Disaster Prevention Research Institute, Kyoto University)

Mass movements, such as landslides, rockfalls, and debris flows, have been occurring extensively in a large number of countries, causing heavy damage. In order to understand them and mitigate induced disasters, we invite contributions that report and discuss on mass movements and related phenomena, focusing on improved understanding of their characteristics; new insights into landslide mechanisms; the development of new approaches to monitoring; novel approaches to behavior forecasting and prediction; studies of successful landslide management; and the development of methods for hazard and risk evaluation. In particular, papers about recent landslide hazards, such as those induced by 2015 Kundasang earthquake in Malaysia, 2018 western Japan rainstorm, and 2018 Hokkaido earthquake are welcome.

A new method for landslide extraction using optical and SAR images

*Yuga Kumagai[1], Masaru Fujita[2], Yasukuni Okubo[2], Kiichiro Kawamura[1]

1. Yamaguchi University, 2. Japan Space Systems

Number of hazards dramatically increases in the world with global warming effects. For a decade from 1993 to 2002, 17% of fatality with various hazards is caused by landslides.
In recent years, some space agencies have released satellite data through their web pages in order to promote private use. With these datasets, we could understand surveillance of land surface motion risks. These supplies associated with satellite technology can open to study various hazards in any regions as developing countries, mountain regions, deserts and so on without a bunch of infrastructures.
Two acquisition systems by satellite technology can be used for the land surface motion analyses. One has an optical sensor detecting the sun light reflected from a ground surface. A NDVI value is one of the most useful tools that using optical satellite data to survey roughly a landslide activity. It is calculated with near infrared and visible red-light bands, and it can find vegetation area. If landslides occur in a research area, NDVI will decrease. Thus, we can see landslide activities using the NDVI values.
The other is a Synthetic Aperture Radar (SAR) system using a microwave. The microwave is transmitted from the satellite and the reflected wave from a ground surface is detected. SAR images are not affected by clouds because microwave passes through them.

In this paper, we discuss a new method to extract landslides efficiently using a combination of two acquisition systems; optical and SAR systems. Because of heavy rains and mountain region, there are many rain hazards and flush floods, and landslides in this district. We can use optical datasets at there, but most of them are widely covered with clouds, so that we need to confirm a new methodology.

We selected fifteen optical datasets without cloud covers from November 2016 to November 2019.
First, we examined the analyzed conditions using the optical datasets. The optical datasets should be generally controlled with shooting conditions as a sunlight direction, a sunlight intensity, a satellite direction and so on, so we chose three different conditions in the optical datasets. Therefore, we analyzed a small area being 2 km^2 or smaller in optical studies.
Second, we collected the SAR datasets in August 1^{st}, 4^{th}, 13^{th} and 16^{th} 2017 on the ESA website. We analyzed surface characteristics and topographical change using these datasets. Datasets of Augusts 1^{st} –13^{th} and August 4^{th} –16^{th} have descending and ascending orbit data, respectively. Land Cover Change Detection method and interferometric analysis were used to reveal the surface characteristics and topographical change, respectively.

As a result of calculation with the NDVI value (Expression; (NIR-R)/(NIR+R)), a vegetation field has higher number. With this value, we confirmed landslides that occurred in August 2017 using drone system from ground survey. As we follow the transition, we found a tendency of vegetation field/bare field percentage transition in the research area through years. The percentage rises in February to May, then it gradually decreases until next February. However, there are some rapid increases in the gradual decreasing period (from May to February). It might be affected by acquisition conditions because there is no apparent sign in an actual image. As a conclusion, it is hard to extract the change based on the effect of landslides.
As a result of SAR data analyzing, we found some surface characteristics and topography changes that occurred in the period. Some of them are on slopes and the others are between mountains. We can detect landslides within approximately 300 m diameter when they are assembled in a small region, but a

single landslide is not detected with the method. Most of landslides on slopes show both topography and surface characteristics changes but some of them demonstrate only topography change. There is an area that shows topography and surface characteristics changes even though it has no apparent change in the optical images through the period. These results need to be confirmed with ground survey. The result of Land Cover Change Detection shows the changes of landslides and artificial activities as same results. It is also necessary to confirm this result with ground survey or optical images.

Landslides caused by the 2018 Hokkaido Iburi-tobu earthquake - Shallow slides of tephra deposits and deep-sheeted bedrock slides -

*Makoto Kaneko[1], Norio Oyagi[1], Hiroshi, P. Sato[2], Yusuke Muramiya[1]

1. Fukada Geological Institute, 2. College of Humanities and Sciences, Nihon University

The 2018 Hokkaido Iburi-tobu earthquake (M 6.7) caused several thousands of the shallow slides and more than two hundreds of the deep-seated landslides. The shallow slides are attributed to the surface tephra, which was deposited in the late Pleistocene and Holocene, on the hilly slopes in the low-relief mountainous area. In the area there are several damaged locations, especially the residential site of Yoshino where is located on debris and/or alluvial cones in front of the undercut slopes. One of the largest deep-sheeted landslides lying on the Karumai Formation of Miocene deposits showed a spread-type movement and made the landslide dam blocking the Hidakahoronai River. So many landslides of spread-type were reported as earthquake induced ones in recent and ancient times in Japanese Islands that we consider those landslides of this type to be useful for the archive bodies of the old earthquakes.

The geomorphic characteristics of landslides induced by The 2018 Eastern Iburi earthquake, Hokkaido

*Rasis Putra Ritonga[1], Takashi Gomi[2,4], Hefryan Sukma Kharismalatri[2], Rozaqqa Noviandi[3], Yoshiharu Ishikawa[4]

1. United Graduate School of Agricultural Science, Tokyo University of Agriculture and Technology, 2. Institute of Global Innovation Research, Tokyo University of Agriculture and Technology, 3. International Environmental and Agricultural Science, Tokyo University of Agriculture and Technology, 4. Graduate School of Agriculture, Tokyo University of Agriculture and Technology

Up to 6000 landslides over 400 km^2 in Iburi Sub-prefecture, Hokkaido were induced by the Eastern Iburi Earthquake (EIE) on 6th September 2018. These landslides are unique because of their unusual topography, shape, and location where landslides occurred on hillslope. First, the landslides occurred on rather gentle and hilly topography (<500 m) with several landslides collapsed on entire hillslope and reaching valley while the others stopped on the middle part of hillslope. Moreover, those landslides formed into various shapes. Such unusual characteristics may affect sediment movement and production. We identified 1440 landslide scars in 18.87 km^2. Among them, 84% of landslides has area <3×10^3 m^2 while the greatest landslides area was 18×10^3 m^2. Landslide topography characteristic was examined based on frequency distribution of elevation, slope gradient, etc. Eastern Iburi area has elevation of 20-300 m with 75% of landslides were occurred on elevation of 100-200 m. Regarding slope gradient, landslides occurred over the whole range of gradients with 60% of them was occurred on the slope ranging from 25-35˚. Landslides tend to occur gradually until topography slope of 25˚, and increase rapidly as the topography slope increase until 35˚, then decrease after. However, Eastern Iburi topography range of >35˚ tends to collapse. Based on landslide shape characteristics of the ratio of length and width (L/W ratio), 92% of landslides had 1 to 3 of L/W ratio with 2 of mean value. Relationship between normalized distance to stream and ridge line indicates the locations of landslide occurrence on the hillslope. We found 56.4% of the landslide clustered near the stream and ridge, followed by near the ridge of upper quart of the slopes (11.5%), and near the stream lower quart of the slopes (3.8%). Meanwhile, the largest landslide area was found in those occurred near ridge and stream, followed by near the ridge, and near the stream for 2459 m^2, 797 m^2, and 236 m^2 respectively. Our study showed that those unique landslide characteristics may very advantageous for understanding the possible subsequent sediment transferred to channel in sediment management practice after earthquake.

Relationship between the subsurface structure and the deformation area accompanied with the 2018 Hokkaido Eastern Iburi earthquake in a fill in Atsuma town, Hokkaido

*Issei Doi[1], Ryokei Azuma[2], Yuki Maenaka[2], Toshitaka Kamai[1]

1. Disaster Prevention Research Institute, 2. Faculty of Technology, Osaka Institute of Technology

Accompanied with the 2018 Hokkaido Eastern Iburi earthquake, some residential area suffered from landslides in Atsuma town, Hokkaido. The geology there was artificial fill on the tephra layer which overlay the sedimentary rock. It is important to know how the landslides were generated from the prospective of the subsurface structure for the mitigation of the residential areas with similar geological settings.

We conducted the surface wave exploration in and around the fill. As a result, low velocity zones were estimated, whose bottom shape was parallel to the old terrain. The thickness of the low velocity zones was larger than that of the fill. Kurosawa et al. (2019) showed that the slip surface was situated in the layer of Ta-d for our studied landslide. Comparing with the drill hole information, the low velocity zones that we estimated were corresponding to the moving body of the landslide which included the tephra layer as well as the fill.

Seismic site response of tephra slope: a case study for the landslides triggered by the 2018 Hokkaido Eastern Iburi Earthquake

*Gonghui Wang[1], Ning Ma[2], Issei Doi[1], Gen Furuya[3], Naoki Watanabe[4], Satoshi Ishimaru[5], Hiromichi Koyasu[5]

1. Kyoto University, 2. Southwest Jiaotong University, 3. Toyama Prefectural University, 4. Niigata University, 5. Hokkaido Research Organization

During the 2018 Hokkaido Eastern Iburi Earthquake, a huge number of landslides were triggered on the tephra slopes, resulting in great damage to local properties and 36 casualties. Although one large landslide was initiated with its sliding surface being in the bedrock of sandstone and siltstone, most of them occurred on the tephra slope. To understand the initiation and movement mechanisms of these landslides occurring on tephra slopes, understanding the coseismic response of the slopes during the earthquake is of great importance. To achieve this, we conducted microtremor observation on the tephra slopes on Yoshino and Tomisato areas, Atsuma immediately after the earthquake. We also installed seismometers on the tephra slope near the Yoshino area and performed continuous earthquake observation. Through analyzing the observed results and comparing them with those recorded in some earthquake observation stations during the mainshock, we examined the site response features of these tephra slopes and then the possible initiation mechanism of these tephra landslides during the earthquake.

Microtremor Survey and Spectrum Analysis of a Coseismic Landslide: a Case Study in Subao Village, Ningxia, China

*Xiaobo LI[1,2], Jingshan BO[1], Issei DOI[2], Gonghui WANG[2], Toshitaka KAMAI[2]

1. Institute of Disaster Prevention, China Earthquake Adiministration, 2. Disaster Prevention Research Institute, Kyoto Unviersity

Coseismic landslides usually cause severe casualties and economic losses. The study of the spectrum characteristics of coseismic landslide sites is crucial to better understanding the possible site response during an earthquake, and then evaluate the risk of landslides. Therefore, we chose the Subao landslide to carry out microtremor survey and spectrum analysis. Subao landslide located in Subao village, Xiji County, Ningxia Hui autonomous region, China, which was a giant coseismic loess landslide induced by 1920 Haiyuan great earthquake. The plan of the landslide was irregular, with a length of nearly 1435 m, a width of almost 400 m, a height of nearly 172 m, and a mean thickness of almost 30 m, which indicated it was a typical low-angle and long-runout landslide.

To study the spectrum characteristics of the Subao landslide site. We applied a digital accelerograph to measure the microtremor on the displaced material, the outcropped surface of rupture, and also the slope outside of the landslide area. Based on the microtremor data, we used the open-source software Geopsy (http://www.geopsy.org/) to calculate and analyze the H/V value for all the measured data. Combined with three boreholes data, we can draw the following conclusions. (1) Most H/V curves of soil mass of the slope around the landslide had a clear peak, the range of the predominant frequency is 2.2 ~ 2.9 Hz, the peak amplification factor is 2.3 ~ 4.0, which reflected the magnification effect of ground motion about the soil mass and terrain. (2) H/V curves of the displaced material were relatively gentle, multi-peak type, and no significant predominant range. The peak amplification factor is 1.9 ~ 2.2, reflecting the complex interface of the soil after sliding and without amplification effect of the ground motion. (3) H/V curves at the outcropped surface of rupture had a narrow and steep predominant frequency band. The range of the predominant frequency is 2.4 ~ 2.6 Hz, and the peak amplification factor is 4.6 ~ 4.8, which was showing a significant topographic effect. (4) Compared with the stable soil mass of slopes around the landslide, the landslide deposits were of complicated soil structure, and the spectral characteristics were not distinct, therefore unable to well reflect the spectral features of the landslide site.

Accordingly, we found that the spectral characteristics of the slope around the landslide area are the reliable parameters for studying the dynamic stability and disaster mechanism of the landslide. The results would not only provide a criterion for the reasonable establish of geomechanical models of slopes but also provide the vital calculation parameter for the inversion of ground motion based on the coseismic landslide.

Pore structure characteristics of wide-grading loose soils in the Wenchuan earthquake area

*Yifei Cui[1], Chaoxu Guo[2]

1. State Key Laboratory of Hydroscience and Engineering, Tsinghua University, 2. Fujian Academy of Building Research, Co.LTD., Fujian Key Laboratory of Green Building Technology

The 2008 Mw 7.9 Sichuan earthquake in China triggered nearly 200,000 landslides. Field observations show that wide-grading loose soils (WGLS) are a special slope deposit after earthquake that often serve as a source for debris flows in the western mountainous area of China. Previous research indicated that rainfall infiltration induced the migration of fine particles within soil slopes and lead to the initiation of shallow failure and subsequent debris flows. Clearly, soil pore structure exerts a profound influence on seepage during rainfall infiltration, which is closely related to soil permeability and corresponding internal erosion. The scientific challenge lies in how to systematically characterize WGLS pore structure so that it provides a foundation for future numerical simulations of fine particle migration-induced debris flows. In this study, the characteristics of WGLS pore structure were analyzed quantitatively using scanning electron microscopy. The results revealed that the pore size distribution of WGLS exhibited a bimodal nature separately occurring at 12 μm and 72 μm, and the pore radius of WGLS can be well-characterized using Rayleigh distribution with modified scale parameters. The pore complexity of all samples exceeded 0.75, which indicates a low aspect ratio for each pore. Meanwhile, it is verified that a lower Euler number (pore topology characterizes index) has high pore connectivity and high macro porosity in WGLS. The average diameter of the fine particles that migrated was then determined with a laboratory seepage test. Through a preliminary jamming probability analysis, both average pore complexity and 3D Euler number are significant contributors to the jamming probability of a soil sample during rainfall-induced fine particle migration, and jamming is most prevalent along the WGLS slope.

Seismic Response of Rock Wedges under Dynamic Loading Revealed by Shaking Table Test

*Hung-Hui Li[1], Chi-Chieh Chen[1], Chang-Liang Chun[1], Ming-Han Lin[1], Chen-Shi Ping[1]

1. Chung-Cheng Institute of Technology, National Defense University of Taiwan

Rock slope failures are one of the most common natural disasters in Taiwan, and its stability depends upon the slope geometry, geological discontinuity, and mechanical properties of the rock mass, and greatly affected by earthquakes and rainfall as well. In northern Taiwan, the rock wedge exists frequently on the slope of the coastal road, and the rock slope failure is a potential threat to transportation safety.

To investigate the stability and seismic response of rock wedge under dynamic loading such as earthquake, this study adopts the physical model experiment and numerical analysis simultaneously to explore the seismic response of the single wedge block. The geometric factors, including the slope and wedge angles, and dynamic loading with different acceleration are considered. The results of the seismic response are discussed, and the critical acceleration which induces wedge block sliding are compared with the analytical results proposed by Kumsar et al. (2000).

In the physical model experiment, it shows that the smaller slope angle is, the sliding faster wedge block is. In the shaking table test, under the constant interaction angle 27˚, the smaller critical acceleration of the wedge block was observed when the slope angle is smaller and the wedge angle is larger, and the numerical analysis consequence presents identical results. Besides, when the slope angle is steeper and the wedge angle is lower, the sliding friction threshold is lower. In other words, when the friction of a fresh joint surface is continuously reduced due to weathering or water seepage, a wedge block with steep slope angle and small wedge angle have less tendency to slide result from lower friction angle.

Seismic Response of Dip-Slope with Various Roughness of Weakness Revealed by Shaking Table Test

Wen-Zhang Chen [1], Ming-Han Lin[1], KAI-YANG LIN[1], *Hung-Hui Li[1]

1. Chung-Cheng Institute of Technology, National Defense University of Taiwan

The long-term interaction between the Eurasian Plate and the Philippine sea plate has caused frequent earthquakes and slope disasters in Taiwan. There are approximately 18,500 earthquakes in Taiwan per year which is alleged by Central Weather Bureau. It is obvious that slope disasters seriously threaten the safety of transportation facilities and residents. In the research of seismic-induced landslides, dip slope failure has always been an important issue in Taiwan. This study aims to investigate the seismic response of dip-slope with various joint roughness coefficient (JRC) of weakness and consider the influence of dynamic loading with various combinations of frequency and amplitude of cyclic motions
The preliminary results of this study are as follows: (1) As JRC increases, the critical acceleration that causes the block sliding increases; (2) when the inclination angle of joints increases, the critical acceleration decreases; (3) When the number of model layers increases, the acceleration at the top of the model is amplified.

Analytical solutions for submarine avalanche entraining/detraining process

*Yi Ping Lu[1], Chi-Yao Hung[1]

1. National Chung Hsing University

Landslides, debris flows, and submarine avalanches are the geophysical examples that alter their volume and travel distance by entraining or detraining granular material at the base. Here, we focus on the entraining/detraining process of submarine landslides. We propose a depth-averaged model using conservation equations for mass, momentum, and kinetic energy. We assume a linearized mu(I) rheology and Coulomb friction law along the side boundary. To obtain the analytical solution, we simplify the model to become a simple nonlinear diffusion equation. Also, a scaling analysis is applied to derive the validity of our simplified model. To check the simplification, we use the HLL scheme and finite volume numerical method to solve the full equation. To verify the model, we propose a new submarine dam break experiment. The experiment is conducted with a new Refractive-Index-Matching (RIM) material. The motion of the granular is monitored with a high-speed camera, and the velocity field can be obtained with Particle Tracking Velocimetry (PTV) method. In the end, we compare the numerical simulation, the analytical solution, and the experimental measurement.

Slope failure - debris flow events in rhyolitic and granitic areas in Hiroshima triggered by 2018 torrential rainfall and its implications for disaster risk reduction –a quantitative approach by photogrammetry and field survey

*Toshihiko Sugai[1], Kunnga Mergen[1], Natsuki Sasaki[1], Sako Hasegawa[1], Shoichiro Uchiyama[2]

1. Department of Natural Environmental Studies, Institute of Environmental Studies, Graduate School of Frontier Science, The University of Tokyo, 2. National Research Institute for Earth Science and Disaster Resilience

Introduction
2018 torrential rainfall hit western Japan and large areas were covered in debris and mud. This study focused on several slope failure –debris flow depositional events occurred in both rhyolitic and granitic mountainous areas in Hiroshima Prefecture and estimated geomorphological changes quantitatively through the events by field survey coupled with photogrammetry. Furthermore, geomorphological land classification and river segmentation based on reach type classification was carried out to discuss the relationships between 2018 geomorphic changes and the surrounding geomorphic development history.

Case study in rhyolite mountain area
Two contrasting slope failure events named as case E and case W occurred on rhyolitic mountain slopes were picked up in the Kurose, Higashihiroshima city. In the case of E, the failure sediments became debris flow and went down through dissected river valley, destroying several Sabo dams alternately from side to side. At the mountain foot, the debris flow slightly denuded peaty silt at the bottom and eroded previous debris flow sediment laterally, and then deposited with the thickness of around 2 m, accompanying gigantic gravels including huge blocks of the destroyed Sabo dam on the depositional surface with upward coarsening structure. Lots of driftwood jammed behind the gigantic gravels with its long axis perpendicular to the flow direction. The debris lastly broadened the depositional area up to 100m.
In the case of W, failure sediments went down along the shallow unclear valley slightly denuding the surface soils keeping the width of the fluid area about 50 m. Reddish colored strongly weathered crust can be observed below the debris and the transportation area gradually changed into deposition area. The debris of the case W was much finer and slightly thinner than that of case E, with lots of driftwoods whose long axis parallel the flow direction.
To summarize in rhyolitic mountains partly covered with reddish weathering crust, even slightly dissected slopes (case W) may failure triggered by unprecedented heavy rainfall, while already dissected slopes (case E) may failure much more frequently to produce debris flows with huge gravels and continue to develop the dissected valleys progressively.

Case study in granitic mountain area
Concerning granitic mountain slopes, Kawasumi (KWS) in Kumano town, Yanohigashi (YNH) in Hiroshima city, and Koyaura (KYU) and Sakahigashi (SKH) in Saka town were picked up. KWS and YNH locate on artificially modified debris flow fan surfaces and/or mountain foot erosional gentle slopes, where plural small steep valleys met before the housing development. The distance between the present outlet of the valleys and valley heads are rather short, about 500m with steep slopes, and the 2^{nd} is the stream order of the valley defined as the Strahler system of stream ordering. Debris with huge core stones deposited below the outlet of the valley.
KYU and SKH locate on small alluvial lowlands produced by fluvial depositional processes by 5^{th} order

©2020. Japan Geoscience Union. All Right Reserved.

streams whose drainage basins have a dozen of slope failures occurred by the 2018 heavy rainfall. The river course can be divided into 3 segments of 1, 2a and 2b, based on the reach types consisting the segment. Segment 1 locates upstream of the fan apex characterized by marked lateral erosion by braided channel reaches. Segment 2a locates the upstream part of the alluvial lowland with the longitudinal slope of about 6 percent characterized as debris flow fan where braided channel potentially migrates laterally without artificial channel fixing. Segment 2b locates the downstream part of the lowland characterized by straight artificial channel on fan delta with the slope of less than 6 percent.
Because the drainage basins behind KYU and SKH may produce debris flows by valley-head failures frequently, the river side narrow plains in Segment 1 are not suitable for land use. Outside areas of the curved channels in Segment 2a are the same because debris flows directly hit the areas. Actuary crevasse spley was formed at the area by the 2018 event. Along Segment 2b sand and mud tend to flow over the bank and cover the lowland widely.

In conclusion, it is critical for mitigating flooding and debris flow disasters to evaluate the diversity of local geomorphic conditions quantitatively based on the regional geomorphological development history which has produced the conditions through time. Thus, nationwide-geomorphological classification mapping based on the local landform development history is crucial, and to do this we need to learn much more from the floods and landslides triggered by torrential rain in western Japan 2018.

The effect of rainfall event characteristics on event-based landslide susceptibility map

*Chun-Yi Wu[1], Chiao-Ling Hsueh[1], Sheng-Yu Lin[1]

1. Department of Soil and Water Conservation, National Chung Hsing University

The landslide susceptibility models can be established based on either a long-term landslide inventory or a specified rainfall-induced landslide event. The susceptibility models established using different rainfall events may result in dissimilar susceptibility maps in the same area. The effect of rainfall event characteristics on event-based landslide susceptibility map needs to be discussed and as a reference for selection of a proper event to establish a susceptibility map. This study will be conducted in the Shihmen watershed, which has an area of 760 km^2 and is one of the main water sources for northern Taiwan. Landslide inventory caused by rainfall events in the Shihmen watershed will be collected during the period from 1996 to 2015. The intrinsic geomorphological and extrinsic rainfall factors of each individual slope unit will be derived, screened, and entered in the logistic regression to train the susceptibility model for each rainfall event. The prediction ability of the susceptibility model established based on one specified event will be compared according to the validation results of the others. The AUC values of the success rate curves (SRC) of the others will be calculated sequentially and then averaged to represent the ability of the model to predict landslide occurrence. This research is looking forward to understanding the relationship between the AUC values calculated for different rainfall events and the corresponding rainfall characteristics, and choosing the best susceptibility map to represent the characteristic of the Shihmen watershed.

Keywords: landslide susceptibility, event-based landslide model, rainfall characteristic, Shihmen watershed

Non-plastic fines content effect on the initiation and movement of rainfall-induced landslides in small flume tests

*Chao HUANG[1], Gonghui Wang[2]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University, Kyoto, Japan

Introduction

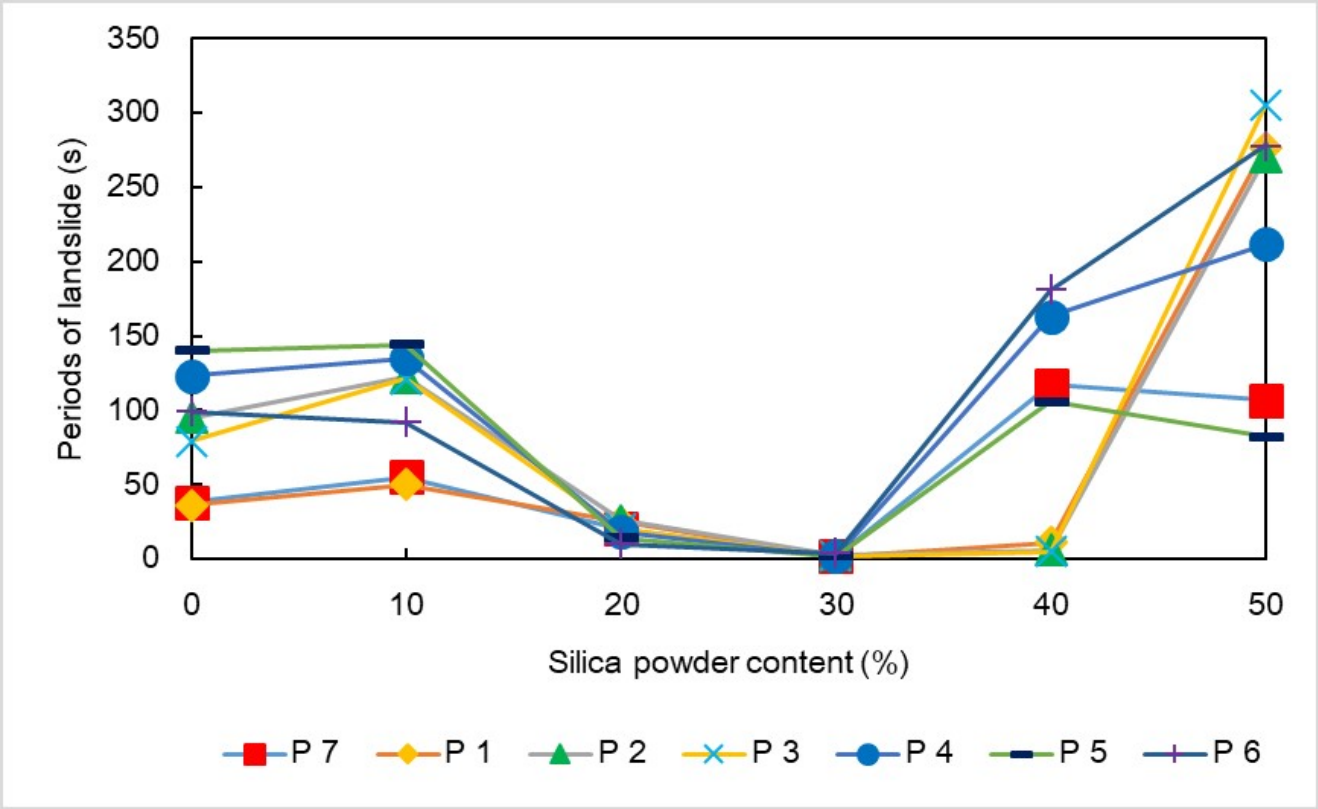
Landslides locally constitute an important natural hazard on Earth, causing great loss of properties and casualties. For original slope, some landslides with long traveling distances tend to occur on the material rich in fine soil particles like granitic soil generated by weathered coarse-grained granite, such as the 2014 Hiroshima landslides triggered by rainstorm. Debris avalanches are a kind of high-speed landslides. A hypothesis of dynamic fragmentation has been proposed as one of the reasons for their high mobility. Presence of fine-grained material may lower the shear resistance of the sliding debris. Some rock avalanche deposits show “inverse grading”. Wenchuan earthquake induced coseismic landslides and landslide dams, and some dams composed of unconsolidated fine debris. Recent study revealed that the secondary landsliding phenomena had been widely triggered on these landslide deposits, and the initiation and movement of these landslides are greatly related to the involvement of fine materials. Nevertheless, the detailed roles of fine materials had not been clarified. Therefore, study will focus on examining the effect of non-plastic fines content on the initiation and movement of rainfall-induced landslides through flume tests.

Material and Method

Samples for the tests are mixture of silica sand No. 7 with differing contents (0%, 10%, 20%, 30%, 40% and 50%) of silica powder by weight. Before setting, the mixtures were prepared to have an initial water content of 10%. During test, the flume was sloped to 20˚. Tilting transducers are installed at mid-depth within the soil model to monitor the possible inclination of the soil mass. Artificial rainfall (100 mm/h) was simulated by sprinklers mounted above the soil model to trigger landsliding.

Result

In general, the entire process required 30–45 min for slope wetting, and few minutes for failure. In the series tests on silica 7 and its mixtures with 10%, 40%, 50% silica powder, retrogressive sliding occurred in each test. However, in the series tests on the mixture of silica 7 and 20%, 30% silica powder, flowslides were initiated.



The figure shows the different periods of landslides in the flume tests. As shown in figure, the colorful point presents the results of each tilting transducers in the flume tests. It is noticed that the curve firstly decreases with increasing fine particles content until reaching 30%, then grows up with further increasing fine particles content. The period of landslide reaches to the lowest value when the silica powder content is at 30%. Videos recorded by cameras indicate that landsliding transforms from retrogressive one to fluidized landsliding with collapsed failure with the increasing of fines content, while the landslide type transforms from debris avalanche to retrogressive landslide with greater percentage (>30%) fines content.

Conclusion

Non-plastic fines content has an effect on the initiation and movement of rainfall-induced landslides in flume tests. With the increasing of fines content, the landslide type transforms from retrogressive landslide to flow sliding, while the landslide type transforms from flow sliding to retrogressive landslide with greater percentage (>30%) fines content. Periods of landslides and tilting rates of inner soil mass vary with increasing non-plastic fines content. Under the tested conditions, when the fines content reaches to 30%, the period of landslide is the shortest.

The influence of the orientation of weak planes on slope deformation

*Chao-Yu Wang[1], Kuang-Tsung Chang[1]

1. National Chung Hsing University

With different orientations of weak planes, the accumulated displacement or deformation of slopes at failure are different. This study aims to examine how the orientation of weak planes influences the slope deformation behavior. A small-scale physical model is used for laboratory experiments. By using the PIV program, we analyze the deformation behavior of slopes with different orientations of weak planes under loading and rainfall conditions. The materials used in the slope model are small blocks made of quartz sand, clay, gypsum, cement, and water according to the mixing ratio. The 30 ˚slope models are composed of stacked blocks, and the dip angles of weak planes are 30 ˚or 60 ˚. The thicknesses of the blocks are 1 cm and 2 cm to simulate different spacings of weak planes. Two methods are used to make the slope models failure. One is a loading force on to the top of the slope models, and the other is rainfall to weaken the slope materials. We take pictures per minute in the experiments for the PIV program to analyze the displacement vectors of the sliding area. The relationships between the accumulated displacement of slopes at failure and the orientations of weak planes will be examined.

Keywords: weak planes, physical model, slope deformation

Can we detect the acceleration of long-term gravitational deformation on steep slopes before catastrophic events? -A case study on two large-scale rapid landslides in Kii peninsular, Japan-

*Teruyuki Kikuchi[1], Norio Oyagi[2], Makoto Kaneko[2], Koki Sakita[3], Teruyoshi Hatano[4]

1. JP-Design. co. ltd., 2. Fukada Geological Institute, 3. Okayama University, 4. Electric Power Development Co., Ltd

1. Introduction

Landslides are the combined effect of the risk and trigger mechanisms. To clarify the collapse process, collecting and analyzing multiple cases should be collected, analyzed, observed, and evaluated over a long period of time. The 2011 typhoon talus that hit the Kii Peninsula in Japan, along with the accompanying heavy rainfall, triggered several large and rapid landslides with volumes larger than 105 m^3 (Chigira, 2013).

2. Method

Table 1 shows the target sites, some of which had been observed several times from 1948 to May 2012, after the disaster. We recorded qualitatively the surface deformation on the high and steep slopes through field survey and “sequential-comparative air-photo analysis” using aerial photographs obtained during five seasons.

3. Result

3.1 Akatani

Figure 1 shows Area B already shows a clear decay surface in the 1948 aerial photograph. Aria B's moving bodies have been lost because of collapse. This area corresponds to the undercut slope of Akatani, and side erosion by rivers is considered to have caused past collapse.This Area received heavy rain together with the previous deformation from 1994 to April 2011.Consequently, the entire C became unstable and slid along with the upper Area A. This reasoning is clear in the following points of the 2011 aerial photograph. The collapse of Area C occurred, and the upper bare-land area increased.

3.2 Nagatono

This deep-sheeted landslide can be divided into nine areas (A to I). Each area is surrounded by a thick broken line inside the main scarp, which shows the sliding cliff that is the outermost part of the 2011 collapse. The deformation structure is a cliff-like steep slope with a small displacement at the head of Area A. The lower part of the slope was displaced downward using this steep cliff as a sliding cliff. Area C is a valley with a depth of 370 m, and its lower part reaches the riverbed of Nagatono Area D has repeated small-scale collapse.

4. Discussion and Conclusion

To predict the location of the deep-sheeted landslide, we performed a comparative interpretation using the aerial photographs taken during the five periods before the disaster. Therefore, we found some displacement and deformation in the microtopography that was a precursor to the heavy-rain disaster of September 2011.

In the future, we will expand the survey area both locally and temporally to clarify the development process and try to make it compatible using quantitative methods, such as the aviation laser measurement data method.

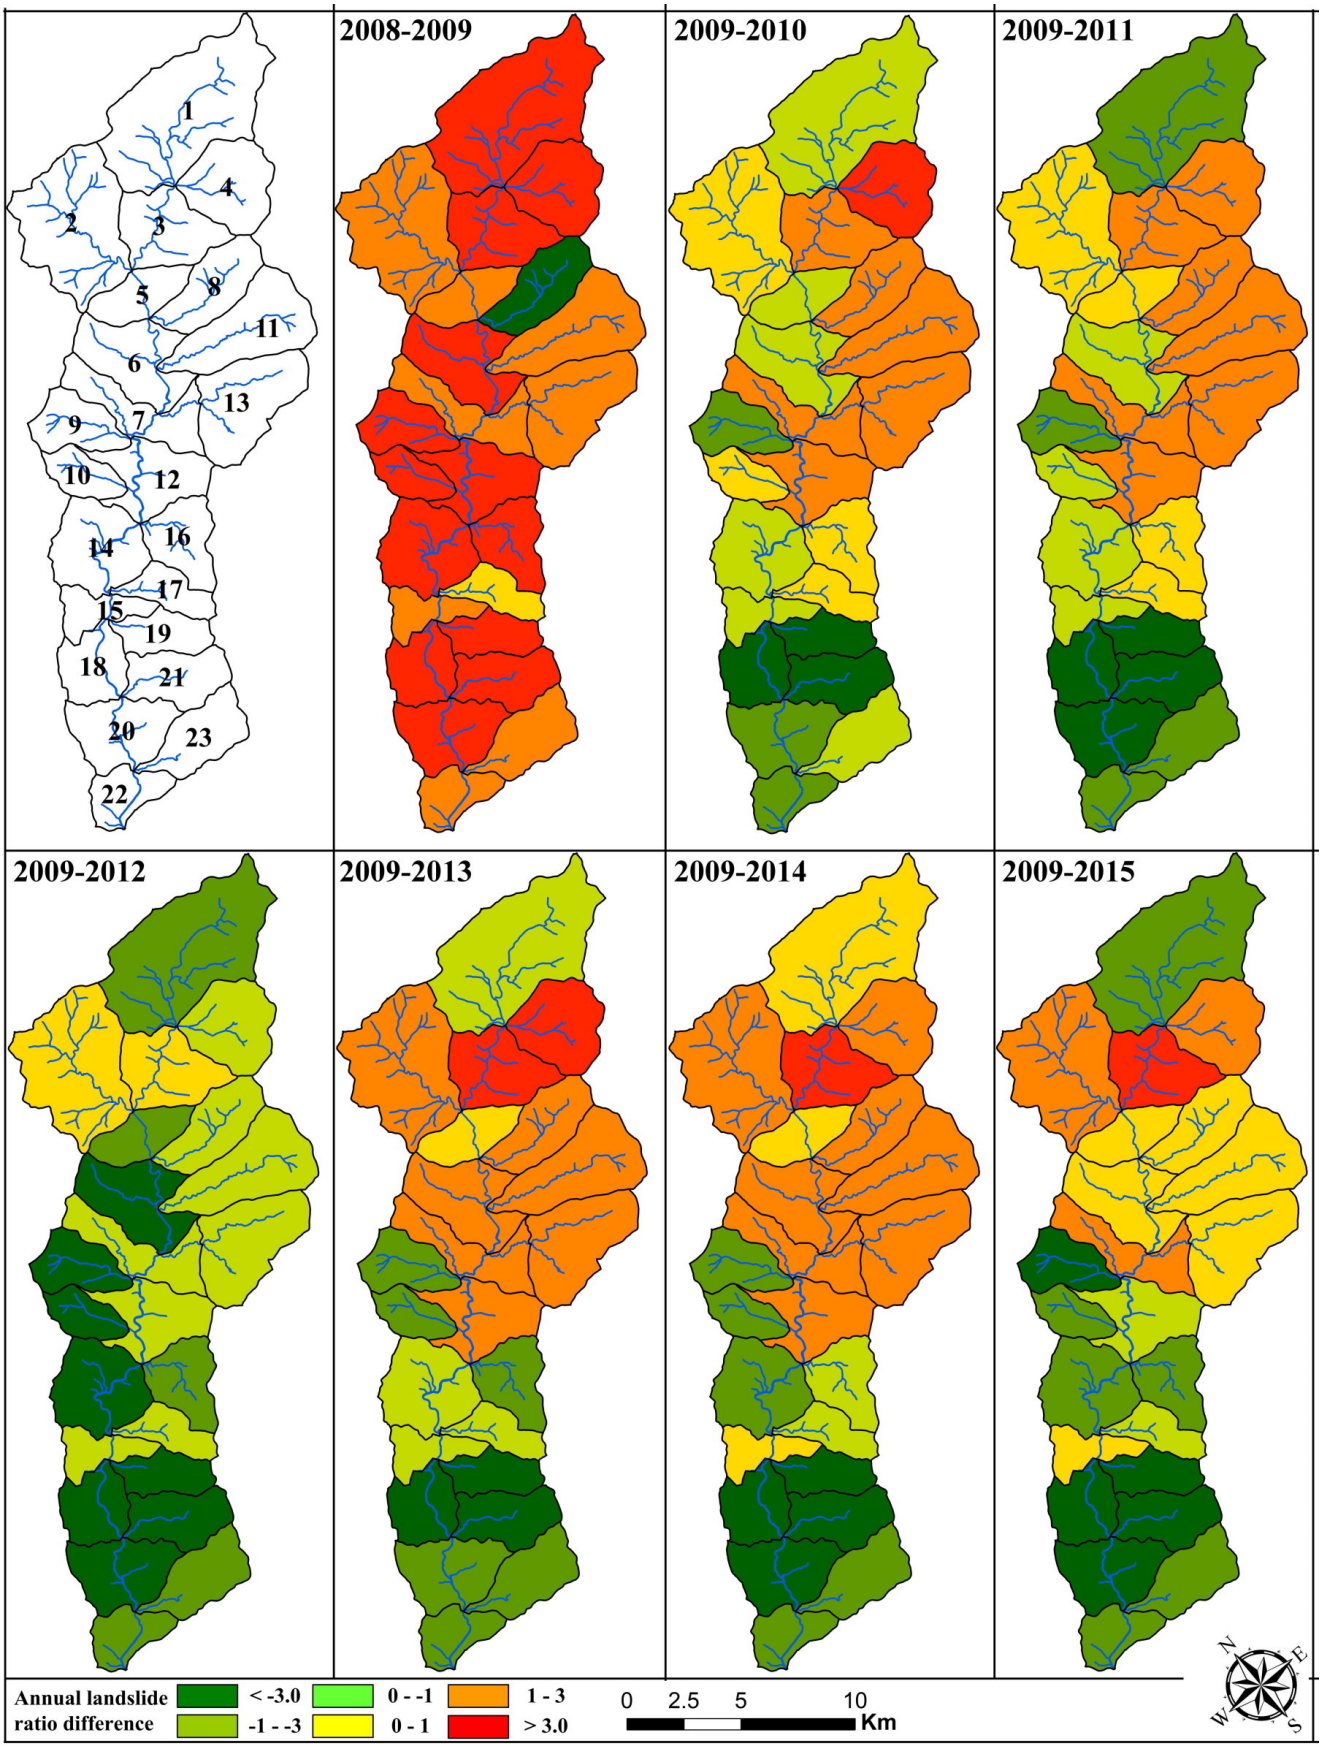
Long-term distribution and evolution of landslide in the landslide-prone watershed: A case study in the Chishan river upstream watershed in Taiwan



*Chengyi Lin[1], Chunuhung WU[1]

1. Feng Chia University

The research focuses on the long-term distribution and evolution of landslide in the Chishan river watershed in Taiwan. Numerous landslide had been induced by 2009 Typhoon Morakot in the Chishan river watershed, and the landslide ratio was 6.5%. It has been ten years from 2009 Typhoon Morakot to now, and this research uses annual landslide inventories from 2008 to 2015 to analyze the evolution of landslide induced by 2009 Typhoon Morakot. The Chishan river upstream watershed has been reported as the watershed in which the landslide was hard to recover by Wu (2017 and 2019). The landslide ratio in the upstream watershed in 2009 was 5.59%, and that in the following 6 years were larger than 3.87%. The count and area of landslide from 2009 to 2015 are the highest in 2010, not 2009. The research uses topographic position analysis of landslide to determine the characteristic of landslide location, and the topographic position analysis was to decide the main inducing factor for landsliding. The ratio of down-hillslope landslide area to the all landslide area has been gradually increased from 2009 to 2015. The ratio of down-hillslope landslide area to the all landslide area in 2009 was 67.6% and that increased to 75.3% in 2015. This data means that the riverbank erosion was a dominant factor for the landslide distribution and evolution from 2009 to 2015. We also estimate the new and old landslide percentage in the upstream watershed, and the mean old and new landslide percentage from 2009 to 2015 are 60.1% and 39.9%. This means that near or over 50% of landslide induced by 2009 Typhoon Morakot is still hard to recovery in 2015. The river intersection area and the river source area are the two main areas where the landslide is problematic to recover and easily induced from 2010 to 2015. The main strata in the upstream watershed includes the Nankang formation, Changchihkeng Formation, and Nanchuang formation. The accumulated occupied percentage of the three strata in the upstream is around 87.9%. The composition of the three strata is slate, sandstone and shale, i.e. three landslide-prone lithologies. The landslide occurred in the three strata in the upstream watershed in 2009 occupies 85.3% of the total landslide in the upstream, while that in 2014 still occupies 87.8 % of the total landslide in the upstream. The riverbank landslide area from 2012 to 2013 in the upstream and midstream watersheds are obvious comparisons for the difference in landslide recovery. The upstream watershed had suffered two heavy rainfall events on the same date, but the 3-day accumulated rainfall of Xingaokou station from August 21 to 23 and August 29 to 31 were only 449.5 mm and 353.5 mm, respectively. The riverbank landslide area in the upstream watershed in 2013 increased by 1.63 times of that in 2012, and the non riverbank landslide area also increased by 1.66 times.

A decade analysis of landslide distribution in the dense-landslide watersheds in Taiwan

*Chengyi Lin[1], Chunuhng WU[1]

1. Feng Chia University

The research focuses on using the multi-annual landslide inventories to observe the characteristic evolution of landslide after 2009 Typhoon Morkot in Taiwan. The research area includes Chengyulan river watershed (abbreviated as CRW) in the Central Taiwan, the Ailiao river watershed (abbreviated as ARW) in the South Taiwan and the Taimali river watershed (abbreviated as TRW) in the East Taiwan. Typhoon Morakot dumped more than 2000 mm rainfall during 2 days in southern Taiwan. After that, long-term evolution of landscape is developed from large area of landslides which are associated with specific typhoon events in landslide-prone sub-watersheds. The landslide ratio, i.e. the ratio of landslide area to the watershed area, in the three watersheds achieves the historical peak in 2009 or 2010, and that was 3.03% in CRW, 7.76% in ARW and 10.7% in TRW. This data means long-term evolution of landscape is related to the event-based large area landslide after few years, and the drop in three watersheds are determined to be that 1.87% to 3.03% higher than 1.21% to 1.73% in CRW, 3.27% to 7.76% higher than 1.41% to 2.23% in ARW and 3.96% to 10.7% higher than 1.98% to 2.73% in TRW. According to the above-mentioned data, the spatial and temporal characteristics of landscape is the point of the current study. Separate landslide ratio also appear in different sub-watersheds in the three watersheds, the landslide ratio are 11.16% to 24.17% of north-south flow direction sub-watersheds higher than the east-west flow direction sub-watersheds (2% to 5.24%) in ARW. The landslide ratio in some specific sub-watersheds has a dramatic increasing due to 2009 Typhoon Morakot. For example, the landslide ratio in the Heshe river watershed, i.e. a sub-watershed in CRW, after 2009 Typhoon Morakot was estimated as 2.76% to 6.53%, i.e. 3.6 to 4.3 times larger than that before 2009 Typhoon Morakot. Another obvious cases are the sub-watersheds in TRW, i.e. the Douli-douli river sub-watershed. The landslide ratio in the Douli-douli river sub-watershed after 2009 Typhoon Morakot was estimated as 7.3% to 24.5%, and that was around 2.9 to 6.3 times larger than that before 2009 Typhoon Morakot. The decade analysis from the landslide distribution data shows that the landslide ratio was hard to decrease as the landslide-prone sub-watersheds gather in the neighborhood.

Study of Seeding Amount of Vegetation Pellets

*Hung-Yen Hu[1], Guo-Zhang Michael Song[1], Shin-Hwei Lin[1], Kai-Chi Hsu[1]

1. National Chung-Hsing university, department of soil and water conservation

Vegetation pellets are spheroids made of a mixture of seeds, soil, fertilizers and growth material, which can be dropped by unmanned aerial vehicles (UAV)into unreachable places where engineering machinery is difficult to reach. If a small vegetation pellet contains too many seeds, excessive seeding can cause high plant density, problems such as intraspecific competition or pests and diseases, which will reduce revegetation effects and increase cast costs. In contrast, a vegetation pellet contains too few seeds, the plant density on the slope will be too low to effectively protect the slope. To achieve the best revegetation effects, there must be an optimal seeding amount. Therefore, the present study aimed to identify the optimal seeding amount with which the germination and survival of seeds in vegetation pellets can be maximized. The seed materials were two common plants for vegetation engineering, including Tall Fescue (*Festuca arundinacea*Schreb.)and Taiwan Acacia(*Acacia confusa* Merr.). The seeding amount used for hydroseeding was set as 100%. The other five seeding amounts included120%, 100%, 80%, 60%, 40%, and 20%. For germination tests, these pellets were then placed on three kinds of soils (laterite, colluvial soil, and mudstone) commonly found in landslide areas of Taiwan. During the tests, the temperature inside the plant growth chamber was set to 25˚C, the humidity was 70%, and the sunshine duration was 12 hours. And provided a fixed amount of water to reduce environmental differences for a period of 50 days. For Taiwan Acacia, although the germination rate varied considerably seeding amounts and soil environments, less than 25% of seedlings survived at the end of tests due to high seedling mortality rates. Taiwan Acacia is not suitable for the revegetation of mudstone areas, because the survival rates of this tree species on mudstone were zero at the end of tests regardless of seeding amount. Regardless of soil types, it was found that the germination rate of Tall Fescue was highest if the seeding amount was 20%. When the seeding amount was controlled, the germination rate of Tall Fescue was the highest on laterite soil, followed by colluvial and mudstone. However, in terms of cost efficiency(to achieve the same plant stem density with the minimum material cost of pellets) for Tall Fescus, the seeding amount should be 100% or even more. Further studies should examine whether seeding mount higher than 120% can even increase cost efficiency.

[H-DS10] Natural hazard impacts on human society, economics and technological systems

convener:ELENA PETROVA(Lomonosov Moscow State University, Faculty of Geography), Hajime Matsushima(Research Faculty of Agriculture, Hokkaido University)

The last decade set a record for the number and scale of natural disasters and demonstrates high vulnerability of human society, economics and ecosystems to their impacts. The most serious consequences have the so-called natural-technological disasters in which natural hazards trigger accidents at technology and infrastructure such as nuclear power and chemical plants, oil refineries and pipelines, power supply systems, buildings, roads, and railways. A distinctive feature of natural-technological events, such as of the 2011 Tohoku earthquake, is their multi-hazard and synergistic nature, which creates cascading impacts, resulting in simultaneous occurrences of myriad catastrophes. The main goal of this multidisciplinary session is to summarize case studies of relationships between natural hazards and technological disasters, their social and economic consequences; and to encourage a discussion about tools and methods to prevent disasters and to minimize their consequences, disaster reconstruction, and tourism for reconstruction, Eco-DRR, and green infrastructure.

Strong explosive eruptions of volcanoes are the most dangerous for aircraft because they can produce in a few hours or days to the atmosphere and the stratosphere till several cubic kilometers of volcanic ash and aerosols. Ash plumes and the clouds, depending on the power of the eruption, the strength and wind speed, can travel thousands of kilometers from the volcano for several days, remaining hazardous to aircraft, as the melting temperature of small particles of ash below the operating temperature of jet engines.
There are 68 active volcanoes in the Kamchatka and the Kurile Islands, and several of them are continuously active. Scientists of KVERT monitor Kamchatkan volcanoes since 1993, and Kurile Islands volcanoes since 2003. In 2019, six of the volcanoes (Sheveluch, Klyuchevskoy, Bezymianny, Karymsky, Ebeko, and Raikoke) had strong and moderate explosive eruptions.
The eruptive activity of Sheveluch volcano began since 1980 (growth of the lava dome) and it is continuing at present. In 2019, strong explosions sent ash up to 10-11.5 km a.s.l. on 09 March, 10 April, 29 August, 02 and 06 October, 03 and 11 November; and up to 6-8 km a.s.l. –in April, and August-November; ash plumes extended more 1300 km to different directions of the volcano. A resuspended ash was observed on April, May, September, and October: ash plumes extended for 250 km to the southeast of the volcano. Satellite data showed a thermal anomaly over the volcano all year. Activity of the volcano was dangerous to international and local aviation. The moderate explosive events (ash up to 5-6 km a.s.l.) of Klyuchevskoy volcano were observing on 21-22 April, 12 and 26 June, 01-02 July, 23-24 October, 29-30 December. Ash plumes extended for 200 km to different directions of the volcano. Explosive eruption of Strombolian type began on 01 November and continues in 2020. Satellite data sometimes showed a thermal anomaly over the volcano. Activity of the volcano was dangerous to local aviation. Two strong explosive eruptions occurred on Bezymianny volcano in 2019. 20 January explosions sent ash up to 10-12 km a.s.l., ash plumes extended for 900 km to the northwest of the volcano. 15 March explosions rose ash up to 15 km a.s.l., ash plumes extended for 1000 km to the east of the volcano. The eruption of 15 March was predicted by scientist of KVERT for 6.5 hours before this strong explosive event: www.kscnet.ru/ivs/kvert/ Activity of the volcano was dangerous to international and local aviation. The thermal anomaly over Karymsky volcano was noted on satellite images from time to time. According to visual and satellite data, explosions rose ash up to 6 km a.s.l. (21 August), ash plumes and clouds drifted for 500 km to the different directions from the volcano. The most intense eruptive activity of the volcano was observed in February, March, April, May, July, and August. Activity of the volcano was dangerous to local aviation. Moderate explosive eruption of Ebeko volcano began on October, 2016, and it is continuing at present. Daily occurred from one till eight-nine (27 April and 27 May) explosions, that raised ash up to 4.5 km a.s.l. Ash clouds drifted mainly to the eastern directions from the volcano. Ashfalls were noted at Severo-Kurilsk on January, February, and August-December. Activity of the volcano was dangerous to local aviation. The strong explosive eruption of Raikoke volcano occurred on 21-26 June. Paroxysmal phase of eruption continued for 15 hours. Explosions send ash up to 13.5 km a.s.l., a large ash cloud 750-800 km wide extended more 2500 km to the east from the volcano. Aerosol clouds were noting till 31 June from Baikal Lake till Arctic. A thermal anomaly was registered over the volcano from 21 June till end of year. Activity of the volcano was dangerous to international and local aviation.

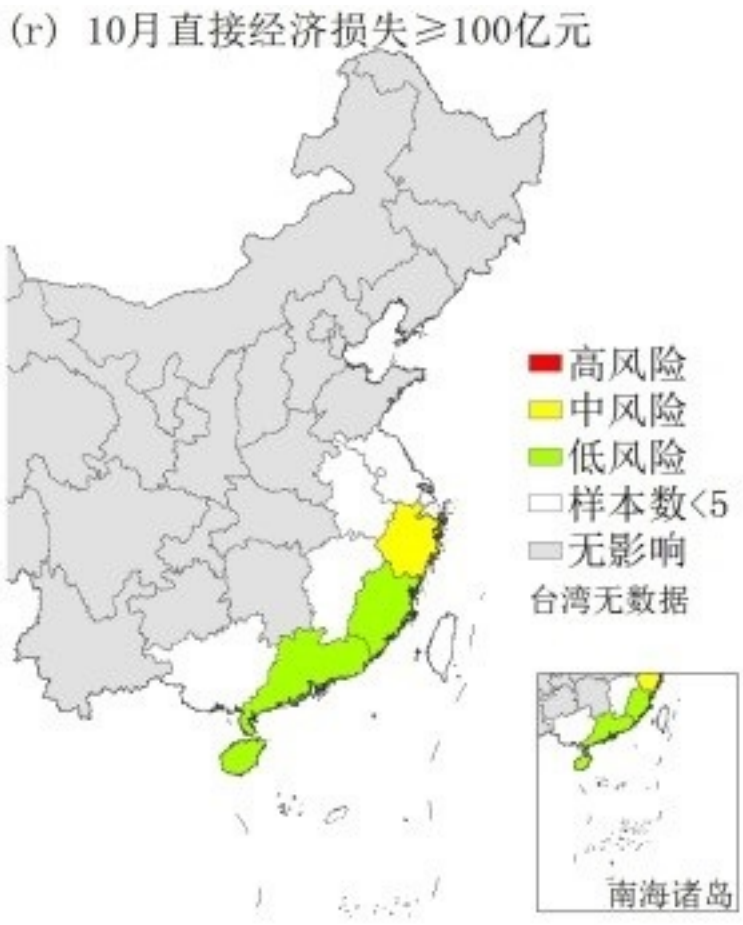
Annual and monthly risk assessment of typhoon disasters in China based on the information diffusion method.



*ge GAO[1], Dapeng Huang[1], Shanshan Zhao[1]

1. NCC, China

In the context of typhoon disasters information, social and economic data of China during 1985 and 2014, temporal and spatial characteristics of annual and monthly typhoon direct economic losses are analyzed in China and on provincial scale. Risk assessments are carried out by the information diffusion method as the references for improving the capabilities of typhoon disaster risk management. The results are showed as following. Annual and monthly typhoon-caused direct economic losses from July to September of China show slightly increasing trends during 1985 and 2014.The monthly variation of direct economic losses are obvious, particularly in August, with the most number of disaster-caused typhoon and the most serious losses in a year. Comparing to the period during 1985-1994, the range of monthly variations became greater and total economic losses of September and October are greater than that of June and July in recent two ten-years periods: 1995-2004 and 2005-2014. Along with the increasing of direct economic losses levels, the numbers of province with middle and high risk level are all decreased gradually. Under the condition with annual direct economic losses greater than and equal to 5 or 10 billion RMB, the risk probability in Zhejiang is the most of China. Under the three risk levels(returning period=10,20,30years), annual direct economic losses of Zhejiang, Guangdong, Fujian and Guangxi kept in the special serious degree. Under the risk levels with 20, 30 years returning periods, annual and monthly direct economic losses of Shandong and Liaoning and annual losses of Hebei also reached the special serious degree, the defense response to typhoon should not be neglected in these areas.

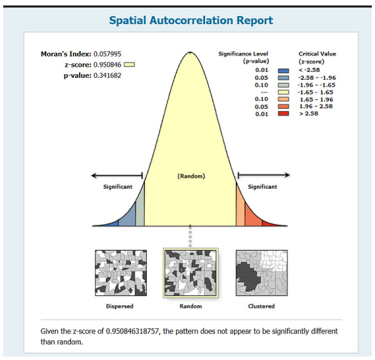
Study on the state of damage and the geographic distribution of flood damages in Japan from 2008 to 2017

*fumeng Zhang[1], Katsunori Furuya[1]

1. Chiba Univercity



In recent years, under the influence of climate factors such as global warming, Japan has also suffered heavy rains year after year, causing serious losses.
Through the study of the flood disaster losses in the 10 years from 2008 to 2017, it was found that the severely affected areas tended to be concentrated in recent years. In addition, in the research, I divided the damaged assets into three types according to their ownership and use, and found that in the same disaster, the distribution patterns of these three types of asset losses are also different.

A Research about the role of Eco-DRR: Ecosystem-based Disaster Risk Reduction in landscape design in Asian Cities

*Minghui Tang[1], Naoko Fujita[1]

1. University of Tsukuba

Introduction

When compared with other countries in a global point of view, Asia is a large area and the climate is diverse. In recent years, extreme natural phenomena affected by global warming have caused major natural disasters are frequent. There is a huge number of researches on the eco-application of proceeding in various countries and it is vitally important to verify their validity. There are some signs of adopting the Eco DRR concept in Asia. The scope and methods are limited, such as replacement and rainwater infiltration technology. Above all, the delay in research on planning and design is remarkable. Under these circumstances, landscapes are expected to be designed for gardens, parks, green spaces, etc. for simple beauty.

This research focuses on the analysis of the changes of the land cover on area-unit level with Mashiki-machi, the epicenter, as the target. By this research, the current disaster histories, disaster prevention policies, and urban plans of major Asian cities will be organized, analyzed, and evaluated. In addition, Asian economies expanding from the perspective of Eco DRR a new landscape design of the city will be presented, and it will show how a city coexists with frequent natural disasters.

Methods

In this study, to summarize the natural disasters and damage situation in Asian countries, and to identify the major cities most frequently affected in particular, organize the disaster prevention policies and city plans of each city and clarify the relationship with the disaster situation.Main research regarding the research method used in the above, evaluation of ecosystem services uses InVEST. Data will be collected using satellite data and UAV and organized as GIS data.

Results

After the earthquake, Mashiki town suffered 3278 completely destroyed houses and 926 partially destroyed houses. Residential areas in the reconstruction plan have increased the area of buildings in the city. Due to land cover change, collapsed residential land became a waste land among the building lands that caused environmental degradation in Mashiki town after the earthquake, and their environmental degradation sensitivity became more sensitive. The distribution of environmentally degraded areas in Mashiki Town after heavy rains remained the same mainly around urban building sites and road sites, and rice fields along the river changed to rough lands, but their sensitivity to environmental deterioration almost changed. The distribution of the environmentally degraded areas after the reconstruction project in Mashiki-cho the environmentally degraded area around the urban building site became wider. However, it was found that the high area became large. From the viewpoint of Eco-DRR, the change in

©2020. Japan Geoscience Union. All Right Reserved.

habitat quality was found to be large along the river because the habitat quality of some of the rice fields along the river was high. From the perspective of ecosystem disaster prevention, in the event of a heavy rain disaster after an earthquake, it is expected that designating green areas along the river, rice fields, and other agricultural lands as disaster prevention areas will have the effect of reducing disasters. In the Mashiki Reconstruction Plan, residential areas that contribute to reconstruction in response to the earthquake disaster have been set up, but the surrounding fields and other agricultural lands have been converted to building lands, and the surrounding habitat quality has deteriorated. From the perspective of ecosystem disaster prevention, it is desirable to formulate a reconstruction plan that does not cause a reduction in habitat quality in Mashiki town.

Impact of Climate Change on Socio-Economically Weaker Section in India

*Ruhma Khan[1], Jahangeer -[2]

1. Jamia Millia Islamia University, New Delhi , India, 2. University of Nebraska Lincoln USA

The recent years have observed an increase in the temperatures globally which poses serious concern to the environment. India, being a developing country is already suffering from various chronic stresses like traffic congestion, pollution, poverty, improper sanitation facilities, non-renewable wastes and increasing informal settlements. Above all these pressures, extreme weather events like sea level rise, heat waves, flooding, cyclone etc occurring due to climate change only add to the miseries of urban problems and make development difficult to achieve. These disasters result in loss of infrastructure, lives, property, and livelihood and also leave a psychological impact on the survivors for a long period of time. The socio-economically weaker sections with lack of resources and skills are usually the ones severely affected due to the adverse affects of climate change. This paper intends to outline the impact of climate change on socio economic sector of the society in Indian cities and find out some mitigation measures at local level to reduce the impact of climate change.

Cultural ecosystem services of green infrastructure: the comparison between Russia and Japan

*ELENA PETROVA[1], Hajime Matsushima[2], Anastasia Petrova[3], Yury Semenov[4]

1. Lomonosov Moscow State University, Faculty of Geography, 2. Hokkaido University, 3. Institute of Oriental Sudies of the Russian Academy of Sciences, 4. Sochava Institute of Geography, Siberian Branch of the Russian Academy of Sciences

Over the past decades, ecosystems of the Earth at all levels from local to global have undergone significant changes due to the increasing in all types of anthropogenic pressure on the environment. The anthropogenic pressure has led to significant degradation of many ecosystem services. Ecosystem services are all those benefits that people receive from ecosystems. Four types of ecosystem services are distinguished: providing, such as the production of food and water; regulatory, such as the control of climate and natural disasters; cultural services, as well as supporting services that are necessary for the production of all other ecosystem services. Due to degradation of ecosystems, the task of protection and rational use of ecosystem services is particularly relevant. For the solution of this task, we propose to use the concept of "green infrastructure". The green infrastructure includes both natural areas (such as forests, grasslands, wetlands, sea costs, river banks, and others), as well as green spaces (parks, and other elements) that perform the functions of regulating runoff and protecting against floods and other natural disasters, purifying air and water, providing habitats for animals and birds, recreational use, and others. We apply an approach that takes into account the complex pattern of the green infrastructure. We pay special attention to the multifunctionality of the green infrastructure, its implementation of a whole complex of various ecosystem services, including regulating and cultural services. A comparative analysis of the usage and recognition of green infrastructure in Japan and Russia with varying economic, social and environmental conditions and with long-standing traditions of environmental management is carried out in this study. We take into consideration landscape differences and local cultural features of both countries. This ethno cultural cross-analysis is very important not only from a scientific, but also from a humanitarian point of view, since it contributes to a better understanding of each other by representatives of these territorially close, but simultaneously very different and for a long time isolated cultures.

Keywords: ecosystem services, green infrastructure, cultural ecosystem services, landscape and ethno cultural differences, natural disasters, multifunctionality

The Reconstruction Assistance from Kumamoto Earthquake by the Grassland Conservation Volunteers in the Aso National Park

*REIKO MACHIDA[1]

1. TOKYO UNIVERSITY OF AGRICULTURE

The Kumamoto Earthquake struck the Aso Area of Kumamoto Prefecture on April, 14 and April 16 in 2016, killing at least 24 people. The earthquake (The A magnitude-7.3) caused by the sediment disaster in the mountain slope. Regarding the damage to agriculture, the surface ruptures, landslides across the grasslands and damages to barns posed severe challenges to the continuation of the livestock industry. However, due to the assistance of volunteers such as Green Stock and the efforts of the Grassland Restoration Committee, local residents were able to overcome the destruction. This study analyzed the recovery efforts of the grassland conservation volunteers in a chronological order using the following time frames. The time to secure survival, the time to secure living conditions, the time to secure livelihood, and the time until the resumption of business activities. The study applied various research methods. Interviews were conducted with the members of Aso Green Stock and the Grassland Restoration Committee. The question topics were as follows: the reconstruction assistance and the implementation periods following the Kumamoto Earthquake, the support activities, and methods of information distribution. The interview surveys were conducted on May 4, 2017, September 12, and September 13, 2017, and September 8, 2018.Therefore, the Grassland Restoration Committee conducted an emergency questionnaire to the livestock farmers on the disaster support, immediately after the Kumamoto Earthquake. On June 15, about two months after the earthquake the Grassland Restoration Committee has restored a pasturage road, which was damaged by surface ruptures. On June 17 damaged water wells, feeders and farm fences were repaired or replaced. Three months after the Kumamoto Earthquake, on July 19 new water tanks were installed in the grasslands of Minami-Aso Village.Also, 11 months after the Kumamoto Earthquake, the Grassland Restoration Committee carried out supporting activities in order to restart the fire controlled burning for the livestock farmers on the grasslands where the land had been damaged by surface ruptures.3 days after the Kumamoto Earthquake, on April 19th, Aso Green Stock surveyed the area struck by the disaster and assessed the extent of damage to the grasslands. 11 days after Kumamoto Earthquake, the Aso Green Stock started raising funds for the affected livestock farmers. The donations have reached approximately 2.8 million yen in four months. So Green Stock implemented three projects as emergency support for the livestock farmers. Firstly, it supported the resumption of the fire controlled burning in the ruptured grassland areas. Secondly, it repaired the grassland roads that were damaged by the earthquake. Thirdly, it raised fences for preventing cattle and horses from slipping into the cracks across the grasslands. It also repaired the barns and cattle sheds damaged by the earthquake. Aso Green Stock organized sightseeing tours and exchange opportunities in order to facilitate constructive participation efforts. These tours included grassland management experiences, barbecues and visits to the local hot springs. The tours began in Oct, 2016; buses departed from the cities of Fukuoka and Kumamoto in Kyushu. In total, 119people have participated in these events. As a result of the aforementioned efforts, the partnerships with the volunteers of the grassland preservation before the Kumamoto Earthquake have led to the swift recovery of the livestock farmers following the earthquake. After 6 months, the disaster support activities of the grassland volunteers have successfully developed into various tourist and exchange projects.

Drought, War, and Cannibalism in Northern China in History

*Harry F Lee[1]

1. The Chinese University of Hong Kong

Despite the effort made by historians and archaeologists to investigate cannibalism in human societies, large-N statistical analysis of cannibalism and its triggering factors in pre-industrial societies is still missing in the literature. In this study, I base on 1194 cannibalism incidents in northern China in 1470–1911, together with other fine-grained paleo-climate and historical war datasets, to verify quantitatively the driving factors of cannibalism in pre-industrial societies. Granger causality, wavelet coherence, and phase analyses are employed. The key findings are that in historical northern China, cannibalism was primarily caused by drought and war, but their relationship is non-stationary and is mediated by environmental and socio-political contexts. The positive feedback between war and cannibalism is also revealed, indicating that they are mutually reinforced. The above findings supplement Malthusian theory with empirical evidence of the non-stationary influence of natural disasters on positive checks and how positive checks interact with and reinforce each other. The results also refine our knowledge about the regional environment-human nexus in northern China.

Design and evaluation of effective methods of green infrastructure for municipalities

*Shan Liu[1], Naoko Fujita[1]

1. University of Tsukuba

The purpose of this study is to evaluate the effective method of green infrastructure in the level of municipalities. The research area is river basins and surrounding areas in Tsukuba, Ibaraki, Japan. According to analysis the data of local green areas, farmland, etc., and using PPGIS (Public participation geographic information system) and Hydrological modeling to select the locations of potent/effective functions of green infrastructure. Through the above analysis to clarify the ideal combination of river green infrastructure and regional landscape regeneration.
In 2013, the European Commission formulated a solution called "green infrastructure", and the concept of "Eco-Disaster Risk Reduction (Eco-DRR)" was submitted. In Japan, the introduction of "green infrastructure" was clearly stated in the national land formation plan decided by the Cabinet in August 2015 and the social capital development priority plan in December 2015, as an important direction in future infrastructure development.
Due to the heavy rains in the Kanto Tohoku region in September 2015 and the heavy rainfall from typhoon No. 19 in October 2019, flooding in areas such as Tsuchiura City and Tsukuba City in Ibaraki Prefecture, causing serious losses in residential areas and fields. Based on this situation, it is necessary to promote the rebuilding of a water disaster prevention awareness society. that works on disaster prevention and mitigation measures that integrate hardware and software throughout society.
During these five years from 2014 to 2018, The number of rivers that exceed the target discharge of the river improvement plan and the flood risk water level is increasing year by year. As a result, the countermeasures against urban floods such as external and inland water floods are required in each region.
Green infrastructure is not only a green and "green" infrastructure but also an infrastructure that intelligently uses the resources and mechanisms provided by the natural environment and various living things. It is a means to solve various environmental problems by making good use of the various functions of nature. Depending on the cases in Europe and the United States, green infrastructure is mainly of three types: basin size (river), site size (street), and neighborhood size (park). The scale of site size (street) and neighborhood size green infrastructure are mainly prevented for storing rainwater and mitigating flood risk by rain seepage. However, those types of green infrastructure are not limited, in some cases, there are also adopt a combination of parks and rivers to simultaneously prevent external and internal water inundation. The remaining four and five are acting on rainwater storage and flood mitigation.
By the above, not only the river scale but also the street and park scale green infrastructure is equally important. Therefore, the three elements of basin size (river), site size (street), and neighborhood size (park) are important in the formulation of a green infrastructure plan. Besides, as the population and land use rate is decreasing in Japan, there is a possibility that such green infrastructure means can be introduced by utilizing the open spaces, waste green spaces, and low unused land in urban areas.

[H-DS11] Subaqueous Landslides and Their Anthropogenic Impact for Coastal Regions

convener:Yujin Kitamura(Department of Earth and Environmental Sciences, Graduate School of Science and Engineering, Kagoshima University), Kiichiro Kawamura(Yamaguchi University)

A large number of people inhabit coastal areas around the world that are susceptible to natural catastrophes and subaqueous landslides are one of such hazards as demostrated recently. The risk associated with the occurrence of subaqueous landslides is not only constrained to passive margins or subduction zones but any of water areas is also susceptible to their occurrence since subaqueous failures can be triggered at very low slope angles. This realization poses a significant challenge that requires the collection of vast amounts of information and data to unravel the true nature of these events and their potential risk to coastal communities. Despite these challenges, recent technical and engineering advances in the acquisition and processing of sea floor and shallow subsurface data are encouraging. There has also been a concerted effort by scientists from different earth-science disciplines to increase interdisciplinary cooperation at an international level to advance our collective understanding of subaqueous landslides and their consequences.
This session calls for technical contributions covering all aspects of subaqueous landslide research including but not limited to: physical properties of deformed sediments (pre- and post- deformation), role of interstitial fluids in subaqueous landslide development, slope stability and risk assessments, geomorphological and sedimentological/stratigraphic descriptions, tsunamigenic risk and modeling, description of ancient subaqueous landslides, sand-box models and numerical simulations of subaqueous landslides. Case studies from lacustrine landslides and subaerial coastal landslides transitioning into the marine realm are also welcome. Case studies associated with the broader topic of subaqueous gravity-driven flows (e.g.: turbidites and transitional flows) and their relationship with seafloor faulting are also of interest to this session. Participants of IUGS project S4SLIDE IGCP-640 sponsor this session.

Numerical Simulation of Submarine Landslide Tsunami due to the 1929 Grand Banks Earthquake

*Tatsuya Nakagaki[1], Yuichiro Tanioka[1]

1. Hokkaido University

On Nov 18th, 1929, The Grand Banks earthquake (Mw7.2) occurred off the southern coast of Burin Peninsula in Newfoundland, Canada. At the same time and few hours after, twelve Telegraph cables installed on the seafloor were cut, and several meter height tsunami hit the southern coast of Burin Peninsula and 28 people were killed. It is suggested that the earthquake generated the large submarine landslide and turbidity current (Doxsee, 1948; Heezen and Ewing, 1952) and this landslide cut the cables and generated this tsunami. The tsunami waveform was recorded at the tide gauge at Halifax, Canada. We numerically computed this submarine landslide using ‘Tsunami squares’ cord (Xiao et al., 2015; Yamanaka and Tanioka, 2017; Wang et al., 2019). This cord is a time-dependent landslide model. The area of the landslide is consistent with the previous study (Fine et al., 2005). Tsunami propagation was numerically calculated with JAGURS tsunami simulation code (Baba et al., 2017). As the ocean surface deformation input is calculated from the result of the time-dependent landslide simulation. Mass volume of the landslide is estimated by comparing the calculation result and observed tsunami waveform at Halifax. The result shows that, at least, in terms of arrival time and peak height, the first pulse of the observed tsunami is explained well by the computed one. The amount of landslide is estimated to be about 100 cubic km.

Trial and error estimation of the initial sea surface deformation of the tsunami caused by the 2009 Suruga Bay earthquake

*Masahiro Kurozumi[1], Toshitaka Baba[2]

1. Tokushima University Graduate School of Frontier Sciences, 2. Tokushima University Graduate School of Industrial Science and Engineering

Tsunamis are caused by not only submarine earthquakes but also by submarine landslides. Because tsunami caused by earthquakes that simultaneously generate seismic waves can be expected due to precursory shaking. However, a submarine landslide would not generate strong seismic waves, so we would underestimate a coastal risk of submarine landslide tsunami. During the 2009 Suruga Bay earthquake, a tide gauge (Yaizu) recorded tsunami much larger than we expected from the magnitude of the earthquake. Bathymetric traces of submarine landslides were observed by post-event surveys (Matsumoto et al., 2012). A tsunami modeling based on the topographic change between before and after the event could not simulate the observed tsunami waveforms (Baba et al., 2012). In this study, the source of the tsunami was estimated by a trial and error method neglecting the topographic changes. For estimations of the initial sea surface deformation, we used a method proposed by Watts et al. (2005) and combination of multi Gaussian distributions. In tsunami propagations, the nonlinear long wave equations were solved by a finite difference method. Also, the volume and location of the submarine landslide body were estimated using a two-layer flow model.

In the model of Watts et al., the six parameters of landslide length, width, collapse depth, slope gradient, moving distance and thickness of sediment deposit, were changed in ranges between 130 to 1750 m, 115 to 660 m, 15 to 250 m, 2 to 10 ˚, 500 to 8000 m, 3 to 45 m, respectively, while parameters of landslide position, strike, depth, specific gravity, added mass coefficient, and shape were fixed. In the use of Gaussian distributions, three parameters of standard deviation, amplitude, and position were changed ranges between -15 to 6m, 8 to 19.2m, (x,y)=([BT1] 205 to 379, 81 to 183), respectively, where (x, y) is index number of 90m mesh grid of the calculated region. It is about 3 to 18km off Yaizu. For the two-layer flow model, the location of initial dirt mass was fixed at a position of about 5km off Yaizu. The dirt mass was given in a circular shape with radius, height, and seabed friction changing ranges between 2000 to 4000 m, 10 to 30 m, and 0 to 0.5 $sm^{-1/3}$, respectively. Tsunami calculations were repeated varying these models and parameters to find the best model that fits with the observed tsunami waveforms.

However, all examinations could not simulate the observations. In the Yaizu tide gauge record, the amplitude of the first drawn wave was observed by -0.62 m at about 720 seconds since the occurrence of the earthquake. The maximum wave of about 0.33 m appeared at about 1080 seconds. The best Watts model provided an amplitude of -0.63 m at 302 seconds for the first drawn wave, the amplitude of 0.55 m at 438 seconds for the maximum wave. In the best Gaussian model, these were -0.61 m at 427 seconds and 0.91 m at 709 seconds, respectively. In the two-layer flow model, these were -0.67 m at 350 seconds and 0.45 m at 504 seconds, respectively. To summarize, the amplitude of the maximum wave in the simulations was about 1.5 to 3 times larger than the observation even when the amplitude of the first drawn wave was close to the observation. The tsunamis in all simulations arrived at the Yaizu station earlier by 300-420 seconds.

Effect of cohesion between sedimentary layers on water film formation in submarine landslides

*Shogo Kawakita[1], Daisuke Asahina[2], Takato Takemura[3], Hinako Hosono[3], Keiji Kitajima[4]

1. Graduate School of Science and Technology, Nihon Univ., 2. National Institute of Advanced Industrial Science and Technology, 3. College of Humanities and Sciences, Nihon Univ., 4. College of Science and Technology, Nihon Univ.

Over the past decades, submarine landslides have been reported in various sea areas. Submarine landslides can be larger in scale than landslides on land. Physical measurements of submarine landslides at the seafloor are not easy to conduct, largely because of the relevant scales and locations. This makes it difficult to understand the mechanism of seafloor destabilization. A possible triggering mechanism to destabilize the submarine sediments is the elevated pore-fluid pressure which is formed at sediment layer interfaces and can reduce their shear strength. Kokusho et al. (2000) proposed a water film effect and its mechanism on lateral flow with less frictional resistance to explain large-scale submarine landslides. Elger et al. (2018) discuss the relationship between submarine landslides due to the elevated pore pressure and gas hydrate system. Their study showed that the reduced permeability due to gas hydrate increases pore pressure, and it transfers to the shallower layer interface through the pipe structure. In both studies, elevated-pore pressure is formed at sedimentary interface where there is a permeability contrast. However, although the actual submarine ground may have been consolidated by compaction and diagenesis, limited studies have been conducted to investigate the effect of the degree of consolidation at the sediment layer interface on the formation of water films.

In this study, we conducted a series of experimental tests to observe the effect of a cohesion between layers on water film formation. Portland cement was used to change the cohesion of the sediment interface. We observed a clear relationship between the amount of Portland cement and pore pressure at which the water film was formed. This indicates that the degree of solidification (consolidation/ diagenesis) of sedimentary layers may have a significant effect on the occurrence of submarine landslides.

Evaluation of seismic wave amplifications in the mountainous area with a temporary seismic network in Totsukawa Village

*Chi-Wen Chen[1,2], Masato Sato[1], Ryuji Yamada[1], Tomoyuki Iida[1,2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. The University of Tokyo

Seismic wave is one of the most important triggering factors of landslides. Amplification effect of seismic waves transmitted from bedrock to ground surface has been confirmed by many observations. However, very few seismic stations are located in mountain areas, so it is impossible to assess the amplification effect of seismic waves using pre-existing measured data. In addition, the fact that most earthquake-induced landslides initiate from the ridge indicates that the magnification of seismic waves may vary in different parts of a mountain. In this study, we installed a temporary seismic network in the mountainous area of the Totsukawa Village, Nara Prefecture, Japan, having four station sites at different parts of a mountain with an EW trending topography: a ridge, a valley, a north-south slope, and an east-west slope. The monitoring period of the temporary network is approximately two years from November 15, 2017 to December 10, 2019, and we selected 25 earthquakes that occurred during the period for further analyses of the seismic waves. The fast Fourier transform (FFT) was applied to each seismic wave with a duration of 81.92 s and a Parzen window of 0.2 Hz bandwidth. We obtained the EW and NS horizontal components and the UD vertical component of the observed Fourier spectrum for each earthquake at each site. The relative position of an earthquake epicenter was interpreted as the direction of the seismic wave transmitted to each station. It is found that the difference in magnitudes of seismic wave amplification seems to be related to the parts of a mountain and the seismic wave direction. This would be helpful to identify locations susceptible to earthquake-induced landslides.

Landslide Detection from Remote Sensing Imagery Based on SPP-PCANet

*Yimei Wei[1], Takashi Oguchi[2]

1. The University of Tokyo, 2. Center for Spatial Information Science, The University of Tokyo

Landslides are complex geological phenomena that can cause serious damage to the natural and social environments and may result in a significant loss of lives and properties. Therefore, it is crucial to conduct a timely post-disaster investigation. Landslide detection is an important step of landslide studies such as mapping, inventory preparation, and specific analyses for the coordination of practical actions including rapid disaster responses. Remote sensing images have been widely used in disaster research with the aid of image feature analysis based on computer vision. Traditional feature extraction methods depend on visual interpretation of feature characteristics such as color, gradient, and corners. However, such methods usually require a large amount of prior knowledge and tedious work. They also tend to be subjective and are only applicable to some specific environments, meaning that generalization ability is low. In recent years, the increasing maturity of machine learning, especially deep learning, enables features to be automatically detected from images, providing more robust analysis and interpretation of remote sensing images. This study explores a landslide detection method that uses a simple and effective image feature descriptor based on a highly simplified network designated as Spatial Pyramid Pooling Principal Component Analysis Network (SPP-PCANet) combined with the SVM classifier. We analyzed landslides due to the 2018 Hokkaido Eastern Iburi earthquake, using vertical aerial photographs and orthophotographs provided by the Geospatial Information Authority of Japan (GSI) for model training and hyperparameters optimization. Then we performed landslide detection using Google Earth imagery. Experimental results show that the proposed landslide detection method has promising performance and may contribute to future rapid responses to landslide hazards.

GIS-based frequency ratio, logistic regression and artificial neural network models for landslide susceptibility analysis in central Shenzhen, South China

*DI LU[2], Takashi Oguchi[1]

1. Center for Spatial Information Science, The University of Tokyo, 2. The University of Tokyo

As major geological hazards, landslides account for a great number of human casualties and an enormous amount of property loss, and cause significant damage to natural ecosystems and human-built infrastructures, especially in urban areas. Landslide susceptibility analysis is regarded as a semi-quantitative risk assessment and has become an important part in landslide studies and risk management engineering. This study investigates landslide susceptibility in the new district of Shenzhen, South China. Shenzhen is a mountainous area, lying in the East Asia monsoon region, with a subtropical monsoon climate. The district has been rapidly developing so that there are broad construction areas and lots of living people. Some previous studies have shown the results of landslide susceptibility analyses for this area. This study aims to further develop such studies by analyzing landslide susceptibility using three different methods: frequency ratio, logistic regression, and artificial neural network (ANNs) models. The latter includes Back Propagation ANNs and Radial Basis Function ANNs. These models were established using elevation, slope, aspect, lithology, human activities, vegetation, and precipitation as independent variables. Land use data are utilized to represent human activities, and the Normalized Difference Vegetation Index (NDVI) is employed to indicate the level of vegetation coverage. Landslide susceptibility maps of the study area are created based on the three methods to show the relative risk of landslides. There are 429 landslide points and 400 points without landslides in the sample data. For the logistic regression model, the overall accuracy is 0.743, the recall is 0.799, and AUC (area under the receiver operating characteristic curve) is 0.790. For the BPANNs model, the overall accuracy is 0.724, the recall is 0.762, indicating that the two methods have similar high performances. The performance of the frequency ratio model is lower.

Analysis of Morphometric Parameters and Precipitation Characteristics for Landslides Using GIS

*Toshikazu Fukuba[1], Takashi Oguchi[2]

1. Department of Earth and Planetary Environmental Science, The University of Tokyo, 2. Center for Spatial Information Science

Morphometric parameters calculated from DEMs have been used for producing landslide hazard maps. This study investigates morphometric parameters of areas affected by landslides due to the August 2014 heavy rain in Hiroshima and the July 2018 heavy rain in western Japan. Altitude, slope angle, slope aspect, slope curvature and geology are chosen for morphometric parameters to be investigated. In addition, precipitation distribution data are used for investigating the relationship among landslides, topography and rainfall amount.

Most landslides caused by the July 2018 heavy rain occurred on slopes gentler than 30 degrees with concave topography in plan curvature. In contrast, most landslides caused by the August 2014 heavy rain are located on slopes steeper than 30 degrees with convex topography in plan curvature. This result indicates locational differences in landslide distribution depending on precipitation characteristics.

Landslides caused by the July 2018 heavy rain in areas underlain by plutonic and volcanic rocks mostly occurred on slopes slightly steeper than 25 degrees, whereas landslides in areas with lithosol and regosol tended to take place on slopes slightly gentler than 25 degrees. This observation suggests that differences in surficial geology should be considered to estimate the threshold slope angle for landsliding.

Keywords: GIS, landslide, morphometric parameters

GIS and remote sensing applied to topographic analyses of hilly and mountainous communities, Nishi-Awa, Japan

*Roxanne Lai[1], Takashi Oguchi[1]

1. University of Tokyo

Quantifying topographic characteristics of hilly and mountainous settlements is important to fully understand the drivers of issues such as depopulation, as well as the implications of topographic characteristics in the face of future human development or climate change. These settlements are located on remote and difficult terrain such as steep slopes and thin soils. Consequently, these settlements are particularly vulnerable to environmental and social threats such as landslides from rainstorms, food insecurity, and political marginalization. Mountain topography plays a large role in defining multiple characteristics of hilly and mountainous settlements, and is also therefore important to understand within the context of the sustainability of these settlements.

While topographic studies have been conducted for individual settlements or on large country-scales, few regional studies have focused on the distribution of topographic characteristics across multiple settlements due to difficulties in obtaining multiple accurate settlement-level data. Regional or national-scale topographic studies in Japan tend to apply administrative boundary shapefile data freely offered by the government. However, these boundaries fail to distinguish the much smaller agriculture settlements.

To clarify the differences of using topographical characteristics at different scales (i.e., whether at settlement or at municipal scales) and better characterize hilly and mountainous settlements, this study applies medium-resolution topographic data and geospatial analysis. This study firstly identifies and quantifies the topographic characteristics (slope, profile curvature, elevation, and aspect) of agriculture settlements in the Nishi-Awa area, Shikoku, Japan, and secondly compares their topographical characteristics with the characteristics calculated from government-designated boundaries. Thereafter, correlation calculations are performed using the calculated topographical characteristics and other geographic variables to explore the relationship their relationship with depopulation.

The results show that aspects and profile curvatures of the settlements indicate directional tendencies most likely based on preferential agriculture conditions. Significant heterogeneity of topographical characteristics within the Nishi-Awa administrative area implies governance needs to account for the variety of environmental and social risks occurring. Furthermore, slope angle calculated from broader boundaries tends to overestimate actual mean slope angle of the settlements, resulting in exaggerated relationships between topography and depopulation. However, results also emphasize that even within mountainous settlements, slope remains a major driver of depopulation, compared to other topographical variables. This implies that other factors such as aging population may exacerbate slope influence on depopulation.

Development of e-learning materials for high school education on topography using GIS

*Hiroyuki Yamauchi[1], Takashi Oguchi[2]

1. Department of Natural Environmental Studies, Graduate School of Frontier Sciences, The University of Tokyo, 2. Center for Spatial information Science, The University of Tokyo

Geomorphology education concerning characteristics of topography is important for learning the basic elements of natural environment and disaster prevention. However, geography education on topography in Japanese high schools faces difficulties in various aspects such as reading contour lines and understanding the development processes of landforms. A reason for this is that most high school teachers who teach topography did not learn a lot about geomorphology in universities. In Japanese high schools, a new geography course will become compulsory in 2022, and in the course GIS (Geographic Information Systems) have to be taught to all students. Therefore we started developing e-learning materials for geomorphology education in high schools using GIS. The materials under development consist of three components: 1) online text explaining geomorphology using digital maps, 2) utilization of 3D-printed topographic models and VR viewing, and 3) utilization of GIS software to analyze DEMs (Digital Elevation Models). In this presentation, we introduce the construction processes of the materials.

An Improved Mosaicking Algorithm for UAV Photographs of Vegetated Areas

*Zijin Wang[1], Takashi Oguchi[2]

1. Department of Natural Environmental Studies, Graduate School of Frontier Science, The University of Tokyo, 2. Center for Spatial Information Science, The University of Tokyo

Unmanned Aerial Vehicle (UAV) photogrammetry is widely used for vegetation research because of its high resolution and superior cost efficiency. However, photographs taken by a UAV at one time are not consistent over the whole study area in terms of geometry, distortion, and color tone. In addition, high resolution aerial images of vegetation usually contain numerous similar features and illumination changes, which consequently brings a huge challenge to mosaicking and processing images using tie points efficiently and accurately. This study aims to propose an improved algorithm to mosaic aerial photographs of a vegetated area efficiently under various situations. The steps for mosaicking images include feature point extraction, point matching, elimination of mismatching points, fusion, and mosaicking. Among them, detecting and matching the feature points of images are the most important part for image mosaicking. In this research we analyzed traditional algorithms for feature point detection including the Scale Invariant Feature Transform (SIFT) and Speed up Robust Feature (SURF) algorithms, and found that both do not perform well. Then we adjusted parameters and used 128-element descriptors inside of 64-element descriptors without computing the orientation, to improve the SURF algorithm in terms of efficiency and accuracy. The improved mosaicking algorithm is expected to be applied in vegetation studies to provide better information with high efficiency.

Surge event of Alakesayi Glacier, West Kunlun Shan, based on remote sensing data

*Qiqi MA[1], Takashi OGUCHI[2,1]

1. Dept. of Natural Environmental Studies, Graduate School of Frontier Sciences, The University of Tokyo, 2. Center for Spatial Information Science, Division of Spatial Information Analysis, The University of Tokyo

Surging glaciers are glaciers that move periodically and rapidly. During a surge event, a glacier advances rapidly in a short time. The velocity is several times larger than usual, and glacier thickening at the terminus may be induced. After a surge, a compensatory glacier retreat may occur. These processes lead to potentially dangerous consequences, especially the outburst flood of a glacial lake. Although surging glaciers in Alaska and Svalbard Islands have been studied in detail, there are few studies on a large number of surging glaciers in the High Mountain Asia (HMA) including Kunlun. A better understanding of the dynamics of glacial surges in this region will help to predict future glacial behavior and assess potential disasters.
Alakesayi Glacier lies in West Kunlun Shan (WKS), northwestern Tibetan Plateau, China. A surge event was observed to have started in 2014. By utilizing more than 50 frames of Sentinel 1 and Landsat satellite images, we estimated the change in surface velocity (seasonal and inter-annul) and terminus morphology. Changes in surface elevation were also obtained using DEMs for different periods. The data analysis shows that, the surface velocity continued to increase during 2014-2015, reaching a maximum of more than 1,000 m/yr. Then the velocity gradually decreased but was still greater than other glaciers in the same region. During the surge, Alakesayi Glacier advanced by 1.3 km. Although the glacier continued to retreat during the 1980s and 1990s, the current terminus is close to that before the retreat because of the surge. Surge events similar to this time may have occurred also in the past. The elevation change of the glacial surface reflects the mass transport process during the surge, i.e., the mass lost in the midstream but increased in the downstream including the terminus. These results from remote sensing data provide an insight into the surge dynamics of Alakesayi Glacier and will be useful for understanding the glacier mass balance in this area.

Remote Sensing-Based Urban Heat Risk Assessment in Philippine Cities

*Ronald C. Estoque[1], Makoto Ooba[1], Xerxes T. Seposo[2], Takuya Togawa[1], Yasuaki Hijioka[1], Kiyoshi Takahashi[1], Shogo Nakamura[1]

1. National Institute for Environmental Studies, Japan, 2. Nagasaki University, Japan

More than half of the world’ s population today live in urban areas and are particularly at risk from the combined effects of the urban heat island phenomenon and heat increases due to climate change. Advances in remote sensing technology, including the increasing availability of remotely sensed thermal data, have been helpful in urban ecological studies, including the study of the urban heat island phenomenon. In this study, focusing on the dry season, we examined the potential of remotely sensed surface temperature as a proxy indicator for heat hazard as we assessed the current heat health risk in Philippine cities, whose population accounts for over 40% of the country’ s total population. The assessment was based on the risk framework of the Intergovernmental Panel on Climate Change, in which risk is expressed as a function of hazard, exposure and vulnerability. The assessment produced an overall heat health risk index which was validated by comparing it with heat-related mortality data. Results revealed that the overall heat health risk index had a positive and statistically significant relationship with heat-related mortality, indicative of the potential of remotely sensed surface temperature as a proxy indicator for heat hazard. This is important especially for the developing regions where data on air temperature is scarce. Empirically, the assessment revealed that the cities that were at high and very high risk were found in Metro Manila where levels of heat hazard and exposure were higher. The most vulnerable cities were, however, found mainly outside the national capital region where sensitivity was higher and capacity to cope and adapt was lower. The cities with high levels of vulnerability and exposure to heat need to be prioritized for adaptation. The results contribute to the risk profiling endeavor in the country and to the understanding of city-level heat health risks in the developing region of the Asia-Pacific.

Keywords: heat risk, land surface temperature, remote sensing, heat health risk index, urban heat island, adaptation

[E] Poster | H (Human Geosciences)：H-TT Technology & Techniques

[H-TT15] Environmental Remote Sensing

convener:Wei Yang(Chiba University), Akihiko Kondoh(Center for Environmental Remote Sensing, Chiba University), Carolynne Hultquist(Columbia University), Elena Sava(US Army Corps of Engineers Geospatial Research Laboratory), Guido Cervone(Pennsylvania State University Main Campus)

Our human beings are encountering various environmental issues on the Earth, and it is urgent to find out the solutions based on corresponding observations and models. Remote sensing is currently the only feasible means to observe the Earth environment at regional/continental /global scales over long periods, and consequently detects the environmental changes occurred all over the world. Although remote sensing has been extensively applied in numerous environmental studies, there are still many challenges for data analysis and applications. Consequently, this session invites presentations on theory, science, technology, and applications of remote sensing to study the Earth environment from local, regional to global scales. Both oral and poster presentations are sincerely welcome.(TBD)

Impacts of urbanization on the local thermal environment in Central America

*Son Thanh Nguyen[1], Chi-Farn Chen[1], Cheng-Ru Chen[1]

1. Center for Space and Remote Sensing Research, National Central University, Zhongli District, Taoyuan City 32001, TAIWAN

Central America is recognized as the second-fastest urbanizing region in the world. Today, at least 60.5% of the region’ s population (30.7 million people) lives in urban areas, and is expected to double in size by 2050. The rapid urbanization has brought both employment opportunities and negative impacts, including heat island effect that is a phenomenon, where higher temperature is observed in urban areas due to changes in properties of land surface. Such effects coupled with congestion of population can trigger severe influences on the local thermal environment, consequently decreasing the health-related quality of life. Information on urbanization and its impacts on the local thermal environment is thus important for urban planning process. The objective of this study is to investigate impacts of urbanization on the local thermal environment in El Salvador, Central America using multi-temporal Landsat data. The data were processed for the period 1986–2016, following four main steps: (1) data pre-processing to account for atmospheric effects and geometric errors; (2) urban image classification using random forests; (3) retrieval of land surface temperature (LST); and (4) hotspot detection, and analysis of impacts of land-cover change on local surface temperature. The results of urban classification, verified with the ground reference data, revealed close agreement between these two datasets, with the overall accuracies and Kappa coefficients, achieved for 1986 and 2016, were respectively 89.8% and 0.8, and 91.4% and 0.84. From 1986 to 2016, the urban area had increased 2,654.7 ha, and the city had expanded into various directions, especially in the northern and eastern parts, owing to advantages of existing and newly developed infrastructures. Due to such a rapid urbanization, the proportion of hotspots (areas of elevated temperature) had also increased from 32% in 1986 to 39.9% in 2016, respectively. The results of decadal analysis of impacts of land-cover change on the local thermal environment also confirmed the significant association between the LST and Normalized Difference Vegetation Index (NDVI), and Normalized Difference Built-up Area Index (NDBI) ($R^2 > 0.72$). The research findings, achieved from this study, highlighted the importance of urban sprawls in conjunction with changes of vegetation cover and temperature. Such information would be valuable to urban planners to successfully devise strategies to regulate effects of urban heats on the city's liveability.

Generation of the GCOM-C land surface phenology product: Algorithm development and performance evaluation

*MENGYU LI[1], Wei Yang[2], Akihiko Kondoh[2]

1. Graduate School of Science and Engineering, Chiba University, 2. Center for Environmental Remote Sensing, Chiba University

The satellite Global Change Observation Mission –Climate (GCOM-C) carrying the optical sensor, Second Generation Global Imager (SGLI) with 250 m spatial resolution, was launched on December 23, 2017. One of the major goals of the GCOM-C mission is to monitor global climate changes. Vegetation phenology not only describes the life cycle events of periodic plants in the growing season but also is an indicator of the sensitivity of the ecosystem to climate change. The long-term study of phenological records on the surface of vegetation is very important for exploring regional and global scale biological responses to environmental changes. Land surface phenology from satellite monitoring has been shown to capture the spatial patterns of vegetation dynamics at global scales. In this study, we will present a newly proposed algorithm to produce the Global Land Surface Phenology (GLSP) product based on the GCOM-C/SGLI data. The GCOM-C GLSP algorithm uses GCOM-C Atmospheric Corrected Reflectance (RSRF) data as the input to calculate the normalized difference greenness index (NDGI). The temporal NDGI trajectory is reconstructed using the iterative Savitzky-Golay filter and modeled using a hybrid piecewise logistic function to retrieve the state of seasonal vegetation development, detect phenological transition dates and characterize the confidence of phenology detections on an annual basis. The GCOM-C GLSP algorithm has been verified by the field phenology observations of specific species at multiple observation sites (i.e., Penological Eye Network, PhenoCam Network), and compared with the VIIRS and MODIS GLSP products to evaluate the resulting phenological metrics. The evaluations results demonstrated satisfactory agreements between the satellite-estimated and field-observed phenological metrics, indicating that the GCOM-C/SGLI data can be used to generate a new generation of the GLSP product at 250 m resolution.

Monitoring macrophyte phenology in Lake Inba-numa, Japan based on Sentinel-2 images

*HU LIANG[1]

1. Chiba University, Graduate School of Science and Engineering, Center for Environmental Remote Sensing

Recently, the floating-leaved plants, especially Trapa spp., have been increased in eutrophic lake Inba-numa, Japan. The Trapa spp. can reduce phytoplankton blooms and stabilize a clear water state by storing nutrients. On the other hand, they can also block the water way and cause low dissolved oxygen concentration. In order to understand the processes of growth, senescence and reproduction of Trapa spp., it is necessary to monitor the phenology of Trapa spp. The improved spatial and temporal resolution of latest-generation Earth Observation missions, such as Sentinel-2, has provided new opportunity of remote sensing for mapping land surface phenology in small inland water systems like Lake Inba-numa, however the driving force for the spatial variation of Trapa spp. phenology is still unclear. The aim of this study was first to estimate the Trapa spp. phenology with sentinel-2A,B in years of 2018 and 2019, and then to analyze the mechanism for the spatial variation of Trapa spp. phenology. Phenology metrics including start and end of the growing season (SOS and EOS) were computed from NDVI time series using the software TIMESAT. The SOS in 2018 North Inba-numa and West Inba-numa was ranging from DOY110 to DOY130 and DOY100 to DOY120, the EOS of North Inba-numa and West Inba-numa was ranging from DOY265 to DOY275 and DOY250 to DOY300. Noticeable spatial variations of phenology were observed in Inba-numa. The relationship between the phenology variation, water depth and $K_{d(PAR)}$ (downwelling attenuation coefficient of photosynthetically active radiation) was also analyzed. The water depth data is provided by Geospatial Information Authority of Japan and the $K_{d(PAR)}$ was calculated from Sentinel-2A,B in years of 2018 and 2019 based on the semi-analytical approach for K_d retrieval which was presented by Lee et al. (2013). In general, for water depths up to 2 m, there is no obvious relationship between the phenology spatial variation and water depth, the phenology spatial variation was directly influenced by the $K_{d(PAR)}$. In conclusion, this study is helpful to improve our understanding of seasonal changes in macrophyte growth and help to manage the macrophyte to have a positive effect on water quality.

Detecting Urban Growth Using Remote Sensing and GIS Techniques in Taoyuan City, Taiwan

*Cheng-Ru Chen[1,2], Chi-Farn Chen[1], Thanh-Son Nguyen[1]

1. CSRSR,NCU, 2. CLVSC

Understanding spatio-temporal dimensions of land-use changes that shape the urbanization is critical to the process of urban planning. In the recent years, remote sensing data and GIS techniques are widely being used for mapping the urban growth, land-use/land-cover, and sprawl. The aim of this study is to produce land use and cover map for the studied area at varied periods to monitor possible changes that may occurred, particularly in the urban areas and agriculture and subsequently predict likely changes. We explore the urban growth in Taoyuan city through remote sening data for each 10-year period form 1970 to 2019 using the ISODATA (Iterative Selforganizing Data Analysis Techniques Algorithm) classification to assess the changes of agricultural lands, urban encroachment and water areas during this period with integration by GIS. The data are processed through four steps: (1) data pre-processing, (2) image classification by regional ISODATA, (3) accuracy assessment of the classification results using field verification data, and (4) urban growth analysis to understand the spatial changes of land cover. The results achieved by comparisons between the classification results and ground reference data indicate that the overall accuracy and Kappa coefficient in five periods were all higher than 82.5% and 0.76, respectively. The results of urban growth analysis indicate that the growth rate of built-up areas has a highest value of 26% in 1980s, while the growth rate in other follwing periods are between 2.3% and 5.7%. Referancing to the development of public works in Taoyuan city, it reveals that urban growth of Taoyuan city was dominated initially by large-scale public work, such as the contruction of Taoyuan Airport and Industrial parks and then was subsequently affected by the demand of dwelling space of immgration from Taipei and its immediate vicinity.

Evaluation and comparison of *Karenia mikimotoi* detection in the Seto-Inland Sea by remote sensing

*Zhenjia Zhou[1], Joji Ishizaka[2]

1. GSES, Nagoya Univ., 2. ISEE, Nagoya Univ.

Harmful Algae Blooms (HABs) is a worldwide problem in coastal marine systems. Seto-Inland Sea is a semi-enclosed coastal area in Japan that suffered from HABs. Dinoflagellate *Karenia mikimotoi* is one of the most common species that form HABs in the Seto-Inland Sea. It could increase fish mortality, thereby causing economic losses for coastal aquaculture. A detection method based on the spectral difference in short wavelength was developed by limited field observation in the western part of the Seto-Inland Sea (Siswanto *et al.*, 2013). But the spectra in the short wavelength are always influenced by colored dissolved organic matters and non-algal particles as well as the error of atmospheric correction. Thus, it is necessary to evaluate the method with more filed observation data. Meanwhile, several methods for the detection of *Karenia brevis*, a HABs species belongs to the same genus and has similar optical properties with *Karenia mikimotoi*, were developed in the West Florida Shelf. These methods could be divided into chlorophyll-a based, apparent optical property based, inherent optical property based approach, etc. This research aims to compare results of different detection methods in the Seto-Inland Sea and evaluate them with the recent filed observation data.

Spectro-polarimetric BRF measurements of the desert sand with multispectral LCTF camera

*Begzsuren Tumendemberel[1], Yukihiro Takahashi[1], Junichi Kurihara[1], Tetsuro Ishida, Nobuyasu Naruse[2], Ahmad Shaqeer[1]

1. Hokkaido University, Department of Cosmosciences, Graduate School of Science, Kita 10-Nishi 8, Kita-ku, Sapporo, Hokkaido 060-0810, 2. Division of Physics Dept. of Fundamental Bioscience, Faculty of Medicine, Shiga University of Medical Science ZIP: 520-2192 Seta, Tsukinowa-cho, Otsu, Shiga, JAPAN

Earth observation satellites have the ability to calibrate their radiometric characteristics of space-borne cameras and optical sensors on-orbit when traveling on Pseudo Invariant Calibration Sites (PICS). PICS are located mostly in deserts with high spatial homogeneity and high time-related stability of canopy optical properties. On the other hand, modern satellites are able to take images to alongside using attitude control. The light reflected from the sand is not only indicated by the intensity, but also by the phenomenon of polarization of light. The polarized light reflection of the earth’ s canopy begins to be a new strong method of earth observation. A polarization camera can be on flight devices or satellites to explore atmospheric chemistry or to detect hidden objects. If we study further efficiently the spectral signature of sand as well as the light reflection and polarization, we can do more precise calibration on polarization camera in space. This study aims to investigate the polarization properties and spectral relations of the sand Bidirectional Reflectance Distribution Function (BRDF) by separating specular and diffuse reflectance. For this purpose, the sands BRDF was measured in a laboratory by Liquid Crystal Tunable Filter (LCTF) camera in the wavelength range of 460-780 nm with a polarization intensity. The imaging with the multispectral LCTF camera has a great advantage that an arbitrary angle of the field of view can be selected in a specific area. Hundreds of combinations of light illumination and camera view direction are considered in this study, due for this reason we built a fully automatic goniometer with LCTF camera at Hokkaido University. The room window is closed by a dark curtain and the darkroom has built inside the room, which means it’ s ideal entirely dark. The laboratory and its equipment, including the automatic goniometer, control system, and sensor instruments covered with black absorbing materials for minimizing diffuse irradiance scattering. We have classified sand by grain size, and its properties are more accurate than in previous studies.

Mirror Reflection Measurement of Leaves from Different Environmental Stresses

*Garid Zorigoo[1], Begzsuren Tumendemberel[1], Yukihiro Takahashi[1]

1. Department of Cosmosciences, Graduate School of Science, Hokkaido University

Plants have a waxy-cuticle layer on their leaves to protect from dehydration. Different plant species have different waxy-cuticle layer thickness. The previous study suggests that one can estimate this waxy-cuticle layer thickness in the leaf with mirror reflection measurement with a polarizer.
In this work, some theoretical explanations are formulated for the previous study measurement. Yet, it did not match with new measurements. Theoretical explanations are still in development. Furthermore, we anticipate that within a single species, waxy-cuticle layers can be distinct depending on the environmental stresses. Especially by increasing its waxy-cuticle layer, plants may protect itself from losing more water in a dry environment. In this study, we investigated such occurrence of a change in thickness (or mirror reflection measurement output) of coffee-plants in 2-different environmental stresses: A healthy group (normal watered) and an Unhealthy group (dehydrated). This could lead to the possibility of detecting the leaf's health-status with a different approach. As a result of the measurement, a slight difference between the two groups is observed.

[H-CG21] International Comparison of Landscape Appreciation

convener:yoji aoki(Open University of Japan)

Evaluation of landscape has been developed in a variety of fields, such as geography, landscape architecture, nature protection, and some others. Landscape appreciation is a complex and sophisticated psychological phenomenon. There is no consensus among researchers on what the phenomenon of "landscape" truly is, how people physiologically and mentally experience it, which human attributes affect the perception of it, and why it is apprehended the way it is. The concept of landscape appreciation has yet to be clearly defined and there is a lack of agreement on evaluation methods, the factors that determine landscape preferences, the steps in appreciation, and so forth. This session aims to discuss the research findings of landscape evaluation in various fields, including geography, geomorphology, landscape planning, architecture, engineering, social sciences, environmental psychology, meteorology, phenology, and so on.

Upon the implementation of Japan's tourism policy, more and more foreigners are coming to Japan. According to data from the Japan National Tourism Organization, the number of foreigners visiting Japan in 2018 reached 31.19 million. Asakusais one of the tourist attractions in Tokyo, Japan.Despite the temple as the main attraction, tons of attractions are also available surrounding this Asakusa area, not only for the cultural and historical aspect. Foreign tourists often visit this area for the whole area, Asakusa, not only for Sensoji temple. In order to contribute and promote tourism growth in Japan, especially Asakusa,.This research uses the visitor-employed photography (VEP)method, which invites volunteers to photograph their liked scenes and then captures the visitors' landscape attitudes by deriving their intentions behind the photographs, was designed for capturing visitors' on-site and real-time perception while visiting (Cherem and Traweek 1977). The total participants in this research are 36 people, with 740 photographs that use as data. The photographs classify in Google Vision API to classify the attraction based on image character (information about entities in an image, across a broad group of categories) and landmark image (popular natural and man-made structures). The data later use for mapping the scenic attraction in the Asakusa area. The result shows that most attraction is still around the Sensoji Temple, but this research also identifies another potential sightseeing image. In conclusion, even if Sensoji temple is the main attraction, the other Asakusa area also have high potential to develop as a sightseeing attraction, not only perform as a tourism service area (souvenir shop and restaurant).

Abstract

Upon the implementation of Japan's tourism policy, more and more foreigners are coming to Japan. According to data from the Japan National Tourism Organization, the number of foreigners visiting Japan in 2018 reached 31.19 million. Asakusa is one of the tourist attractions in Tokyo, Japan, with Sensoji Temple as one of its main attractions. It is a popular tourist destination that attracts people from all over the world. Based on its history, Sensoji is the oldest temple in Tokyo built in 628 AD.

Despite the temple as the main attraction, tons of attractions are also available surrounding this Asakusa area, not only for the cultural and historical aspect. Foreign tourists often visit this area for the whole area, Asakusa, not only for Sensoji temple. In order to contribute and promote tourism growth in Japan, especially Asakusa, research about foreign tourism is needed to understand the sightseeing image of Asakusa better based on their preferences. Tourist preference reflects the ability of different destinations to attract tourists and win the tourist market shares by utilizing tourism resources effectively.

This research uses the visitor-employed photography (VEP) method, which invites volunteers to photograph their liked scenes and then captures the visitors' landscape attitudes by deriving their intentions behind the photographs, was designed for capturing visitors' on-site and real-time perception while visiting (Cherem and Traweek 1977). The total participants in this research are 36 people, with 740 photographs that use as data. The photographs classify in Google Vision API to classify the attraction based on image character (information about entities in an image, across a broad group of categories) and landmark image (popular natural and man-made structures). The data later use for mapping the scenic attraction in the Asakusa area. The result shows that most attraction is still around the Sensoji Temple, but this research also identifies another potential sightseeing image. In conclusion, even if Sensoji temple is the main attraction, the other Asakusa area also have high potential to develop as a sightseeing attraction, not only perform as a tourism service area (souvenir shop and restaurant).

Study on the Influence of Japanese Traditional Garden and Culture on Japanese People’s Perception of Residential Garden

*Zhendong Liu[1], Tingyu Lu[1], Heyan Jiang[1], Junhei Watanabe[2], Fumeng Zhang[1], Zhi Li[1], Yingming Mao[1], Dibyanti Dibyanti Danniswari[1], Pratiwi Prita Indah[1], Katsunori Furuya[1]

1. Graduate School of Horticulture, Chiba University, 2. Faculty of Horticulture, Chiba University

Background

Japan has a relatively small capita housing area, but many residents live in detached houses and have private gardens. For such choices, we believe that, besides economic considerations, we believe that Japanese are carrying on the tradition of their ethnic culture and customs.

A Japanese detached house has a total area of about 126 square meters per house. In addition, it is defined by the Urban Planning Act to protect the environment as a residential area and differs depending on the area. In the case of residential areas, the building coverage is about 60%, and 40% in the lower areas. A single-family house with a total area of 126 square meters stands on the second floor with a building coverage of 60% and has a garden of 42 square meters. Therefore, we think that houses with private gardens are not uncommon in Japan.

Japanese-style private gardens are handed down to the present age with the flow of history, but there are many private gardens such as Scandinavian, American and modern styles. Private gardens are usually designed in the style of a building but may be decided by the person. However, compared with other countries, we can feel small but Japanese design aesthetic in private gardens. We think this difference is related to Japanese culture.

So, our research purpose is to explore the influence of Japanese culture in private garden of Japanese residents and analyze the characteristics of landscape and culture in Japanese gardens under the background of global cultural blending.

Study Method

This research is a group cooperation study in method of questionnaire survey. Questionnaire includes three aspects, personal information, residential condition and landscape factors grading of residential garden. Fifty questionnaires were collected from volunteers of Japanese nationality.

In order to find out how much influence have Japanese traditional garden and culture put on modern residential garden, we selected eighteen landscape factors for volunteers to grade, six of them are typical elements in Japanese traditional garden. Each factor has five options of different degrees in importance, then we digitalized options into numbers from 1 to 5, 1 is negative elements, 2 is not important, 3 is normal, 4 is important and 5 is strongly important. The collected data was analyzed by software excel and SPSS.

Results

The results of questionnaire survey show that 54% of volunteers live or once lived in a house with garden

©2020. Japan Geoscience Union. All Right Reserved.

and Japanese style is most common, 33.3% of those gardens are Japanese style.

However, each factor with strong Japanese garden’ s characteristic gets an average point low than 3 except garden pine of 3.02. We also find that all six Japanese garden factors are highly associated, which means if one individual volunteer gives one factor a low point, it’ s more possible that he gives other five factors low points.

In result, although Japanese garden style is most common style now, volunteers didn’ t give positive assessment on traditional garden’ s elements. Some volunteers gave all six Japanese garden factors 1 or 2 point. Traditional garden doesn’ t meet people’ s demand in modern times.

An attempt to manage both rural landscape conservation and tourism development

*Kojima Shusaku[1], Megumi Aso[2]

1. Graduate School of Tokyo University of Agriculture, 2. Community-reactivating cooperator squard of Miyaki town

1. Introduction

As the number of farmers has been decreasing in the rural areas of Japan, the cultivation of some farmland and forest areas has been abandoned. Therefore, a recent trend involves developing tourism as one method for solving these problems. However, some practices have spoiled the rural landscape because of the promotion of tourism development. Hence, it is necessary to develop planning methods that manage both rural landscape conservation and tourism development sustainably. This study implemented and evaluated a new planning method to assess its future feasibility.

The Yamada area in Miyaki town was selected as a case study. Yamada Sunflower Farm (YSF), which has been managed by local farmers' union, is the main tourist attraction in Miyaki town. These days, over 20,000 tourists visit during the sunflowers' blooming season from October to November. Therefore, traffic jams sometimes happen and the local farmers have planned to develop new parking lots on other farmlands.

2. Methods

The fundamental policy for managing both rural landscape conservation and developing new parking lots as tourism infrastructure involved estimating the demand and the available supply of parking lots in Yamada area, then comparing the two data sets.

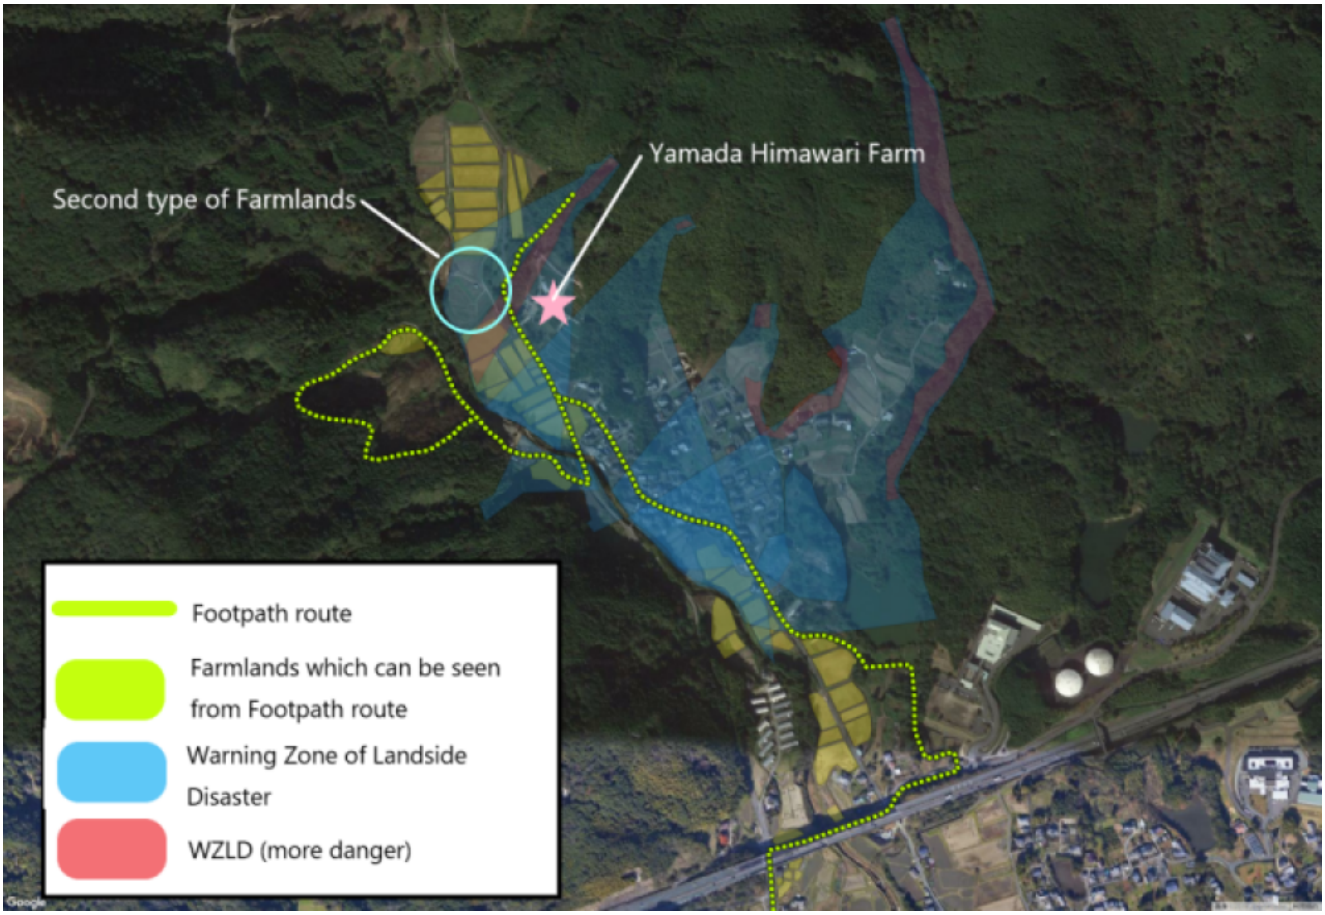
The demand for parking lots on YSF was estimated using data provided by a local farmer that indicated the number of visitors. Additionally, oral information about conditions when the maximum number of visitors arrived in the past was used to estimate the maximum demand.

When we tried to calculate the available supply of parking lots, our research team developed a footpath route with the cooperation of residents. The purpose was to invite visitors to look at the beautiful rural landscape. Second, we identified which farms were visible from the footpath route using a field survey. These farms were considered what most visitors would regard as a beautiful rural landscape that should not be developed. These farms were transformed into shapefiles for analysis by QGIS. Third, Warning Zone of Landside Disaster (WZLD) was added to QGIS because the development of parking lots on WZLD should be avoided. Fourth, the farms visible from the footpath and the WZLD were overlaid and we estimated the available supply of parking lots.

Finally, We held a workshop to explain the results to local residents and evaluated the proposed planning method by listening to their responses.

3. Results

At first, 452 cars per day was the estimated maximum figure according to the data on the number of visitors. Furthermore, the estimated maximum figure was 250 cars per hour according to residents' oral information. Therefore, 4508 m^2 would be needed to park 250 cars.



When both the farms visible from the footpath and WZLD was overlaid, four types of farmland were confirmed. The first type of farm was both visible from the footpath route and located on the WZLD. The second was only located on the WZLD. This type was located east of the YSF. The third was visible from the footpath route only. the fourth was not visible from the footpath route nor located on the WZLD.

Both the second and fourth types were suitable for parking lot development in rural landscape conservation terms and were bigger than 4508 m^2. However, the fourth, the most suited in terms of disaster prevention, was quite far from YSF so we decided that the new parking lots should be developed

©2020. Japan Geoscience Union. All Right Reserved.

on the second type of farm.
Finally, we explained the aforementioned results to local residents who provided the following responses. First, although residents understood that farmlands visible from the footpath route should be protected, they tended to hope that parking lots would be developed on farmlands near the YSF, or lands not suited for cultivation. Second, the ownership of farmlands in the Yamada area is finely differentiated so that there are various conflicting environment. This may make reaching agreement about parking lots among the people concerned difficult.

Appreciations of Japanese landscapes by the western visitors arrived (1549-1858)

*yoji aoki[1], Fumihiro Konta[2]

Appreciations of Japanese landscapes by the western visitors arrived (1549-1858)

Introduction

This report listed and summarized the descriptions of Western visitors about "Fukei" of Japan since the first arrival on Tanegashima Island in 1549 (Table 1). We could define 'Fukei' as similar to the concept as the appreciation of landscape or the impression of scenery. Japanese appreciation of scenery had been affected by Chinese culture since ancient times. For example, the idea of "Eight Scenery", which evolved in the 10th century in old China, was introduced in the 14th century to Japan, has affected more than five centuries of the appreciation of Japanese landscape (Aoki, et al. 2003). Because Japan was closed to western foreigners until the end of the Edo era, i.e., the 19th century, those effects continued until the opening of the country. And the educated Japanese used the Chinese method for the sophisticated way of landscape observation as Chinese poetry. After the opening of the country, Japanese began to accept Western culture and its way of landscape appreciation. The educated Japanese began to understand the natural phenomena by the natural sciences developed in western countries. Although the western countries had experienced the period of Landscape Painting from the 16th to the 19th centuries and they sometimes described Japanese landscape to belong the similar kind of beauty, most Japanese never understand their appreciation. So by studying the descriptions of Western visitors to Japan, we find how they understood and appreciated Japanese landscapes and what the landscape beauty of Japan was existed in those times.

Summary of the focal objects appreciated were listed in table 2.
(1) Until open the country, 1853
The first period began with the arrival of the first Portuguese, Mendes Pinto, to Tanegashima Island in 1549 and ended at the time of opening the country by negotiation with Perry in 1853. During the period, Portuguese and Spaniards visited and mostly engaged in missionary work and obtained many believers in western Japan. Although the domestic warfare sometimes threatened not only Japanese lives but also Westerners' lives, they, established many churches as the result of their activities. But the Japanese government since the 17th century excluded them, because the government feared the country's stability. In that period, westerners were not yet accustomed to the plant taxonomy or landscape paintings. They never describe the natural landscape or vegetation in Japan, the outstanding features of Japanese landscape. During the closed country, i.e. the Edo era, the Dutch including German or Sweden visitors traveled from Nagasaki to Edo. Some of them knew plant taxonomy and found the features of Japanese landscape to be endowed with a diversity of plants. In this period, Russia also investigated Japanese landscape from the coasts and found pleasant impressions. Unfortunately, the Japanese government sometimes met them and arrested some Russians as prisoners unfortunately. They also reported the landscape beauty of Japan.

(2) Until diplomat residence, 1858

©2020. Japan Geoscience Union. All Right Reserved.

U. S. A. and Russia visited to negotiate the opening the country of Japan in 1853. Some members of the troop could understand Japanese and some had known plant taxonomy. They could describe the landscape and vegetation more precisely. Moreover the troops came accompanied with landscape painters, so they could report in detail the vegetation of Japan. Some enjoyed familiar vegetation at Hokkaido Island and some admired the beauty of topographic features of Japanese landscapes. Vysheslavtsov appreciated rice terraces at mountainside.

Acknowledgements

We express our gratitude's to Prof. Jay Appleton of Hull University for his kind explanation of the importance of "Experience of Landscape", and Prof. Takasuke Watanabe of Tokyokogyo University for his instruction of the description of western travelers. We thank Mr. Motoh Shoda and many other translators for their detailed information of travelers and hard efforts of their works.

Trends of the methods of landscape presentation in the landscape appreciation test from 1967 to 1987

*yoji aoki[1]

1. Open University of Japan

Trends of landscape presentation method until 1987

Peterson (1967), who used psychometric measurements, evaluated 23 slides by projecting them onto a 50x50 cm screen. The slide evaluation method is an easy way to obtain data for many evaluators at once, and has since become widely used. Canter (1969) experimented with 20 black and white slides on a 2x2m screen. Carr and Schissler (1969) experimented with 10 scenes per second by video. Zube (1973) explored the effects of landscape changes using slides and line drawings. Law and Zube (1983) examined foreground effects in 19 pairs of slides. Hull, Buhyoff and Daniel (1984) conducted an evaluation experiment with a maximum of 134 slides.

Before using the slides, experts visited the site, scored it according to certain criteria, and decided on the quality of the landscape in the area (Fine1968). Although such a method is laborious and costly and there are not many studies have been carried out, but Penning-Rowsell (1977) reported two people evaluated 269 km2. Aoki (1981) conducted the field experiment at 21 sites with 40 subjects and Nasar et al. (1983) examined the effects of observations and widening and narrowing at four locations. Stewart et al. (1984) confirmed the association with 50 slides and field experiments. Nasar (1987) explored the observation directions at 20-point interview.

Carls (1974) began an experiment using photographs that were easier to experiment with than slides. He used 100 color photographs of 8x10 inches. Propst and Buhyoff (1980) performed 100 slide experiments. Schroeder (1982) rated the green on 35 5x7 inch photographs. Shuttleworth (1980) examined the differences between black-and-white and color photographs at six locations. Dearden (1984) conducted an evaluation experiment with 12x18 cm 30 color photographs. Benayas, Lucioto and Belnaldez (1987) gave an environmental assessment with 72 pairs of photographs.

However, it was immediately a matter of whether the photos matched the site evaluation. Dun (1974) examined the differences between the six-point rating and the photo rating. Although his experiments concluded that they were roughly the same, I examined the correlation analysis of the results and found no significant correlation. Dearinger (1979) examined the differences between the 20 slides and the field evaluation. Kane (1981) examined the difference between the site and the slide at 10 points and found a correlation of 0.96. However, Coeterier (1983) examined the five scenery sites and photographic evaluations and found a correlation of 0.39-0.68. Latimer et al. (1981) examined the effects of sky, morning, snow, and clouds. Malm et al. (1981) examined the effects of climatic conditions from 15-150km on 80 slides and on site. Kellomaki and Sabolainen (1984) conducted field and indoor evaluation

experiments at 34 locations. Shelby and Harris (1985) examined the relationship between a 5x7inch photograph and the description on the scene. Trent, Neumann and Kvashny (1987) examined differences between on-site and color photography at five locations.

Pogacnick (1976) experimented with a method of creating a montage photograph and evaluating the plan. He also used 20×30 cm black and white 36 photographs, and pointed out the project objects on the photographs (Pogacnick1979).

Myklestad and Wagar (1977) attempted to present landscapes with computer graphics. Killee and Buhyoff (1983) examined the difference between eight CP drawings and sketches with an 8-second presentation.

As for the panorama scenery, Banerjee (1977) tested a 360-degree coastal panoramic view on 16mm film. Clamp and Powell (1982) presented 40 panoramas with six slides. Nassauer (1983) examined the difference between a 140-degree panoramic view and a 65-degree wide-angle view on a 100 x147cm screen with 17 pairs of slides.

Ulrich (1984) examined the effect of the 182 x 122 cm window on postoperative recovery in a hospital.

Keywords: presentation of landscape, landscape appreciation, 1967-1987

Table1 List of interesting papers

Presentation tools	Name of authors	Year	Title of paper	Name of journal
50x50inches screen, 23 color slides	Peterson, G. L.,	1967	A predictive model of preference: Quantitative analysis of the perception of the visual appearance of residential neighborhoods,	J. of Regional Science, 7(1), 19-31.
on-site appreciation by responderits: 773 square miles, 90 days	Fine, K. D.,	1968	Landscape evaluation: a research project in East Sussex,	Regional Studies, 2, 41-55.
20 photos: 2x2m screen, b and w	Canter, D.	1969	An intergroup comparison of connotative dimensions in architecture,	Environment and Behavior, 1, 37-48.
observation by city trip: 10frames/s, 5 minutes, 40mph	Carr, S. and Schissler, D.	1969	The city as a trip: Perceptual Selection and Memory in the View from the Road,	Environment and Behavior, 1, 7-36.
landscape type: 15 slides, 3 min	Calvin, J.S., Dearinger, J.A. and Curtin, M.E.	1972	An attempt at assessing preferences for natural landscapes,	Environment and Behavior, 4(4), 447-470.
preference: 56 slides, 20seconds	Kaplan, S., Kaplan, R. and Wendt, J.S.	1972	Rated preference and complexity for natural and urban visual material,	Perception & Psychophysics 12(4), 354-356.
scaling: 15 slides, 50 slides	Acking, C.A. and Sorte, G.J.	1973	How do we verbalize what we see,	Landscape Architecture, 64, 470-475.
personality: 27 slides, 18 photo, 9 drawing	Zube, E.H.,	1973	Rating everyday rural landscapes of the Northeastern U. S.,	Landscape Architecture 63, 370-375.
predictive model: 100 color photos, 8x10inches	Carls, E.G.,	1974	The effects of people and Man-induced conditions on preferences for Outdoor recreation landscapes,	J. of Leisure Research, 6, 113-124.
comparison of on-site and photograph: 6 sites	Dunn, M.C.,	1974	Landscape evaluation: A further perspective,	The planner 60(10), 935-936.
personality: 2.25miles, 6 areas, car	Zube, E.H.,	1974	Cross-disciplinary and intermode agreement on the description and evaluation of landscape resources,	Environment and Behavior, 6(1), 69-89.
8 view on-site fields, 56 station photogrphed in color	Zube, E.H., Anderson, T. and Pitt, D.	1974	Measuring the landscape: Perceptual responses and physical dimensions	Landscape Research 1(6), no page
spatial sampling of landscape: survey line from avoiding major towns, 170 locations, 8 directions	Clamp P.,	1976	Evaluating English landscapes - some recent developments,	Environment and Planning A, 8, 79-92.
validation; b and w photos, 8 on-site	Dunn, M.C.,	1976	Landscape with photographs: Testing preference approach to landscape evaluation,	J. of Environmental Management 4, 15-26.
predictive model: 86 slides, label, imagery	Herzog, T.R., Kaplan, S. and Kaplan, R.	1976	The prediction preference for familiar urban places,	Environment and Behavior, 8(4), 627-645.
for planning; photo montage	Pogacnik, A.,	1976	Visual-aesthetic components in the cybernetics of urban planning,	Computer Aided Design, 8(1),41-48
video, 16mm sound film, 125 seconds, 360 panorama	Banerjee, T.	1977	Who Values What?, audience reaction to coastal scenery,	Landscape Architecture 67(3), 240-243.
presentation uses computer graphics	Mydestad, E. and Wagar, J.A.	1977	Preview: Computer assistance for visual management of forested landscapes,	Landscape Planning 4, 313-331.
predictive model: on-site evaluation, 8 man-days, 289km2, 2 people	Penning-Rowsell, E.C.,	1977	The 'Manchester' Landscape Evaluation Method: A Critical Appraisal,	Landscape Research 2(3), 6-11.
predictive model: b ad w photo, 8x10inch	Shafer Jr., E.L. and Brush, R.O.	1977	How to measure preferences for photographs of natural landscapes,	Landscape Planning 4, 237-256.
nationality: 53 photos, 30-40dgree alignment, b and w	Ulrich, R.S.,	1977	Visual landscape preference: A model and application,	Man-Environment Systems 7(5), 279-293.
effect of professional experience: 9 color slides, 36 pairs	Buhyoff, G.J., Wellman, J.D., Harvey, H. and Fraser, R.A.,	1978	Landscape architects' interpretations of people's landscape preference,	J. of Environmental Management 6, 255-262.
analysis: 20 slides, 5 sec	Ootendorp, A. and Berlyne, D.E.	1978	Dimensions in the perception of architecture: III. Multidimensional preference scaling,	Scandinavia Journal of Psychology 19, 145-
validation: 46 slides and color sketches, 0.74, 15 b and w sketches, color photo, 0.68	Schomaker, J.H.,	1979	Measurement of preferences for proposed landscape modifications,	Landscape Research 3(3), 5-9. College of Forestry, Idaho.
description: 8 photos	Byrne, S.M.	1979	Perception of the Landscape in the Lands End Peninsula	Landscape Research 5(1), 21-24.
difference between on-site and photograph: 20 slides, 2 min	Dearinger, J.A.,	1979	Measuring preferences for natural landscapes,	Journal of the Urban Planning and Development Division, ASCE, 63-80.
photointerpretation: 35 photos, 40x30cm, b and w	Pogacnik, A.,	1979	Environmental public preferences as obtained by the method of photointerpretation in the Ljubljana Region,	Urban Ecology 4, 45-51.
information: pre slide, after slide, 50slides	Ulrich, R.S.	1979	Visual Landscape and Psychological Well-Being	Landscape Research 4(1), 17-23.
information, label affected: 127x178mm photo, label 10x65mm	Hodgson, R.W. and Thayer Jr., R.L.	1980	Implied human influence reduces landscape beauty,	Landscape Planning 7, 171-179.
congestion: 360slides, 0.75x0.75m screen, 12sec, 1.15ha/boat	Pitt, D.G., et al.	1980	A Perceptually Based Definition of Valued Boating Environments on the Tributaries of Chesapeake Bay	Landscape Reseach 5(3), 19-21.
analysis: 100 color slides	Propst, D.B. and Buhyoff, G.J.	1980	Policy Capturing and Landscape Preference Quantification: A Methodological Study,	J. of Environmental Management, 11, 45-59
comparison of b-w and color photo: 6 sites	Shuttleworth, S.,	1980	The use of Photographs as an Environment Presentation Medium in Landscape Studies,	J. of Environmental Management 11, 61-76.
effects of regional familiarity: 11 slides, 5sec	Wellman, J.D. and Buhyoff, G.J.,	1980	Effects of regional familiarity on landscape preferences,	J. of Environmental Management 11, 105-110.
congruity: 48 slides, 90x75cm screen	Wohlwill, J.F. and Harris, G.	1980	Response to congruity or contrast for man-made features in natural-recreation setting,	Leisure Science 3(4), 349-365.
information: 90 color slides	Anderson, L.M.,	1981	Land Use Designations Affect Perception of Scenic Beauty in Forest Landscape,	Forest Science 27(2), 392-400.
on-site: 40 respondents, 21 sites	Aoki, Y.,	1981	A study of On-site Evaluation for Site Planning: Lake Kasumigaura,	Landscape Planning 8, 235-255.
SD method: 54 pairs b and w photo, 10sec	Bernaldez, F.G., Parra, F. and Garcia-Quintas, M.A.	1981	Environmental Preferences in Outdoor Recreation Area in Madrid(Spain),	J. of Environmental Management 13, 13-26.
on-site, 19 observers, minibus, 47 sites km2	Briggs, D.J. and France, J.	1981	Assessing Landscape Attractiveness: a South Yorkshire Study	Landscape Research 6(2), 2-5.
attributes: 19 pairs slides, pre and post, student, US Federal, BLM/Forest Service	Palmer, N.R. et al.	1981	Evaluating Effectiveness of Observer Based Visual Resurce and Impact Assessment Methods	Landscape Research 6(1), 12-16.
experienced: pre and post 30min hike; 24 photos, b and w	Hammitt, W.E.,	1981	The Familiarity-Preference Component of On-Site Recreation Experiences,	Leisure Science 4(2), 177-193.
Statistical test on-site to slide: 10 sites, 0.96 coefficient	Kaine, P.S.,	1981	Assessing landscape attractiveness: a comparative test of two new methods,	Applied Geography, 1, 77-98.
predictive model: percentage of sky, effect of morning, snow, clouds, 70 or 80 slides	Latimer, D.A., Hogo, H. and Daniel, T.C.	1981	The effects of atmospheric optical conditions on perceived scenic beauty,	Atmospheric Environment 15(10-11), 1885-1974.
meteorological; on-site and slides, 80 slides, 8 second, 15-150km	Malm, W., et al.	1981	Human Perception of Visual Air Quality (Uniform Haze),	Atmospheric Environment, 15(10/11), 1875-1890.
predictive model: sampling of photo points, 90 points	Schroeder, H. and Daniel, T.	1981	Progress in Predicting the Perceived Scenic Beauty of Forest Landscape,	Forest Science 27(1), 71-80.
other appraisals: 60 slides, 50x75cm screen	Ulrich, R.S.,	1981	Natural versus urban scenes, some Psychophysiological effects,	Environment and Behavior 13(5), 523-556.
effect of age: 20 slides	Balling, J.D. and Falk, J.H.,	1982	Development of visual preference for natural environments,	Environment and Behavior 14(1), 5-28.
on-site: twice, 37 sites	Beer, A.R.	1982	The Development Control Process and the Quality of the External Environment in Residential Areas	Landscape Research 7(3), 14-21.
40 color panoramic slide; 6 screens formed a circle, back-projected	Clamp, P. and Powell, M.	1982	Prospect-Refuge Theory under Test,	Landscape Research 7, 7-8.
information, 70 slides, 15s, 20ms, 10ms	Herzog, T.R., Kaplan, S. and Kaplan, R.	1982	The Prediction of preference for Unfamiliar Urban Places,	Population and Environment 5(1), 43-59.
greenery: 35photos, 5X7inch, slides	Schroeder, H.W.,	1982	Preferred features of urban parks and forests,	Journal of Arboriculture 8(12), 317-322.
difference of new residents and natives: 118x165mm photo	Aoki, Y.,	1983	An empirical study on the appraisals of landscape types by residential groups -Tsukuba Science City-,	Landscape Planning 10, 109-130.
validation: 5 scenes, field and photo, R=0.39-0.68	Coeterier, J.F.,	1983	A photo validity test,	Journal of Environmental Psychology 3, 315-323
distance: affect SBE: 38 slides, 4000-8000m	Hull IV, R.B. and Buhyoff, G.J.	1983	Distance and scenic beauty: A nonmonotonic Relationship,	Environment and Behavior 15(1), 77-91
other presentation: 8 slides, graphic, sketch, 8sec	Killeen, K. and Buhyoff, G.	1983	The relation of landscape preference and abstract topography,	J. of Environmental Management 17, 381-392

[H-CG22] Deltas and estuaries: multidisciplinary analyses of complex river-mouth systems

convener:Yoshiki Saito(Estuary Research Center, Shimane University), David L Dettman(University of Arizona), Kazuaki Hori(Department of Geography, Graduate School of Environmental Studies, Nagoya University)

This session examines deltas and estuaries from multiple points of view: morphodynamics, hydrodynamics, material cycling, ecosystem, human impacts, and sustainability. We invite contributions that advance research on deltas and estuaries as complex river-mouth systems from both modern and ancient examples, and that develop integrated frameworks for modeling delta & estuary dynamics on a broad range of temporal and spatial scales: from studies of coastal evolution over the Quaternary to small-scale sediment/material transport processes. We also invite physical processes studies based on field observations, numerical simulation, and flume experiments. Finally, the conveners encourage contributions that promote data collection and sharing for both advancing science and local problem solving, that consider policy and governance issues linked to the sustainable development of deltas and estuaries, and that use in-situ and satellite data for modeling and risk assessment.

Numerical estimation of Holocene paleowave changes in an estuarine environment: case of Tokyo Bay, central Japan

*Katsuto Uehara[1]

1. Kyushu University

During the Holocene, many estuaries and embayments has changed their shape due to shoreline transgressions caused by the sea-level rise and regressions due mainly to the sedimentation, which may have changed the condition of the wind-wave propagation and development within the area. In this study, a paleowave simulation of Tokyo Bay has been carried out by using SWAN model to estimate changes in the wave field and to evaluate the role of wind waves on the formation of the estuarine morphology taken place during the Holocene. Tokyo Bay was chosen as a study area due to the following three reasons: 1. paleoshorelines are well identified by a large number of geological and archeological proxies, 2. the head of the elongated bay has extended northward during the mid-Holocene transgression stage and the maximum length of the bay was estimated to be twice as large as that at present and the fetch within the area during the winter monsoon season and during typhoon events in summer are expected to have changed greatly, and 3. many erosive features are estimated to have formed by wave actions, such as erosive cliffs and underwater wave-cut platforms, indicating a strong relevance of waves on the formation of the present-day morphology.

Channel deformation of the lower Mississippi and Yangtze Rivers –Implications for future backwater zone studies

*Yi-Jun Xu[1], Maotian Li[2], Zhongyuan Chen[2], Bo Wang[1], Shuwei Zheng[3], Weiguo Zhang[2]

1. Louisiana State University, 2. East China Normal University, 3. Shandong Normal University

The lower reaches of many world’s large rivers serve as transportation hubs, commercial hotspots, and industry and population centers. This is especially the case of the Mississippi River in the United States and the Yangtze River in China. Draining a land surface of 3.2 and 1.8 million square kilometers, respectively, the lower Mississippi and lower Yangtze Rivers have become the world’s two most important shipping channels and their countries’ most vibrant economic corridors. However, as riverine sediment loads in the Mississippi and Yangtze have declined largely, these two alluvial rivers and their deltaic areas face challenges such as, among others, channel deformation, sediment transport, levee stability, and shipping safety. In this study, we analyzed channel changes in the final 500 kilometers of the Mississippi and the final 565 kilometers of the Yangtze in the past approximately 20 years, in order to identify common patterns with respect to where erosion and deposition occurred. For the lower Mississippi River, over 6,000 single-beam cross-sectional measurements surveyed in 1992, 2004, and 2013 were analyzed; For the Yangtze River, navigational charts surveyed in 1972, 2002, and 2013 were digitalized. These data were utilized to create channel bathymetric DEMs, which were used to quantify the changes in the riverbeds from bank to bank. Our study found that the two rivers showed similar fluvial patterns, specifically, 1) the average channel elevation lies below mean sea level; 2) there is a deep channel drawdown with a rapid elevation rise near the river mouth; and 3) widespread riverbed degradation in the recent decade. The lower Yangtze River experienced strong riverbed degradation since the completion of the Three Gorges Dam construction in 2003. Of the entire study river reach, 425 kilometers have undergone substantial erosion (i.e., 2.16 billion m^3 with an annual average channel incision rate between 0.01 and 0.19 m), while the other 140 kilometers have experienced marginal deposition (i.e., 0.31 billion m^3 with an annual average deposition rate ranging from 0 to 0.17 m). Changes in the riverbed of the lower Mississippi were more variable and can be classified into three geomorphic stages: aggradation, degradation, and dynamic equilibrium. While sediment loads in the lower Yangtze River sharply declined since 2003 (from ~270 MT yr^{-1} to ~140 MT yr^{-1}), sediment loads in the lower Mississippi River showed relatively small fluctuation in the past two decades (averaged 120 MT yr^{-1}). Large floods seemed to have a strong effect on riverbed erosion in the lower segment of the backwater zone owing to the drawdown effect. These findings suggest that the lower segments of large rivers are likely experiencing substantial channel erosion, and that the backwater zone of these rivers may shift upstream as global sea level rises. The consequence of these changes on sedimentation and geomorphic processes is unknown. Future studies are needed to determine the underlying mechanisms in these two and other rivers and to examine risk implications for channel stability and sediment transport in estuaries.

Offset in radiocarbon ages between marine bioclast and terrestrial plant pairs in the Holocene sediments along the Pacific coasts around Japan

*Nakanishi Toshimichi[1], Futoshi Nanayama[2], Kazuaki Hori[3], Yuichi Niwa[4], Junko Komatsubara[5], Akihisa Kitamura[6], Wan Hong[7]

1. Japan Atomic Energy Agency, 2. AIST/Kumamoto Univ., 3. Nagoya Univ., 4. Chuo Univ., 5. AIST, 6. Shizuoka Univ., 7. KIGAM

To identify chronological and spatial changes in the radiocarbon (^{14}C) marine reservoir effects, the ^{14}C ages of eight pairs of marine shells and terrestrial plants were measured from the same horizons of one core of Holocene sediments around Japan. The reservoir ages ranged from 60 to 1100 years, scattered over the period 100-10,200 cal BP, which were significantly larger than the values from “prebomb” samples of known age, before AD 1955 in this area. These results indicate that the information on reservoir effects is indispensable for chronological control not only from prebomb samples but also from geological and archaeological samples. Moreover, the effects also reflects the influence of complex river-mouth systems such as deltas and estuaries. To determine the direct chronological changes of the marine reservoir effect between the Kuroshio and Oyashio Currents, radiocarbon ages were measured from the same stratigraphic horizons within Holocene sediment cores alomg the Pasific coast of Japan (eastern Hokkaido; Nanayama et al., 2003, Nanayama, 2020, Sanriku Coast; Niwa et al., 2017, 2019, Arakawa Lowland; Komatsubara et al., 2009, 2010, Shimizu Plain; Kitamura & Kobayashi, 2014; Nobi Plain) and Taiwan. Subsequently, the results were compared with values from the Oita Plain and Hakata Bay on the northern coast of Kyushu, as well as the Korean Peninsula. The study was partially funded by the Japan Society for the Promotion of Science Kakenhi grant number JP18H01310.

Wind Dynamic Process and Ecological Effect in Sand Barrier Environment of Mu Us Sandy land

*Hongyue Li[1,2], Hasi -[1,2], Jie Yin[1,2]

1. School of Natural Resources,Beijing Normal Univ., 2. Faculty of Geographical Science,Beijing Normal Univ.

Abstract: Sand barriers are the main measures to control mobile dunes and promote vegetation restoration in sandy areas. In order to analyze the wind speed, wind direction and the characteristics of the structure of the wind-blown sand flow in the horizontal and vertical directions of the section, explore the degree of surface stability within the barrier, and determine the optimal configuration to promote vegetation restoration, we selected the barchan chain in the hinterland of Mu Us Sandy Land as the research object. Through field observations, we carried out quantitative research on the airflow field, wind-sand flow structure, micro surface morphology and erosion volume of different slopes with different materials (salix, PLA, straw rope), different specifications (1m ×1m, 2m ×2m, 3m ×3m) sand barrier measures. And furthermore,field investigation of vegetation restoration under the same conditions was carried out.The results show that: ①The wind speed at the top of dune is 1.3-1.7 times of the wind speed at the inlet due to the air compression and the effect of windbreak at the foot and middle of slope is better than on the slope.There are differences in the arrangement of sand barriers to achieve the best wind prevention effect at different slope positions: the 1m×1m PLA has the best protection effect at the foot of the slope, and the 2m×2m salix sand barrier in the middle and on the slope have the best performance in reducing wind speed.②The maximum difference of sand transport rate of different types of sand barriers appears in the slope of 2m ×2m: Salix is 24.25 times more than PLA material, and with the greatest sand blocking capacity, its effect is better than straw rope than PLA material.③The amount of surface erosion and accumulation in the sand barrier is significantly related to the years of sand barrier laying. With the increase of time, wind erosion gradually appears. And furthmore, the larger size of sand barrier is, the deeper central erosion depth is, and the more serious the erosion is. Besides, under the same specifications, the surface erosion amount of PLA sand barrier is much higher than that of other two materials. The 3m×3m PLA sand barrier reaches the maximum, and its surface inside the barrier is in a severely unstable state.④Among the three materials, salix sand barrier has the best material to promote the vegetation recovery ability, and straw rope sand barrier is the most beneficial to increase the vegetation diversity. In the lower part of the windward slope, the vegetation coverage under the three specifications of salix sand barriers is 2.67 times, 1.79 times, and 3.88 times than the slope, respectively, and the slope is better than the slope. Shrubs and herbaceous vegetation restoration are complementary. And the small size is more beneficial to herbaceous vegetation restoration. Based on comprehensive cost factors, it is considered that in Mu Us Sandy land, the most suitable sand barrier material is salix.As well as, laying 2m ×2m specifications at the foot and middle of the slope, 1m ×1m specification on the slope can exert the best sand control and ecological effect.

Comparison of Roughness-Cover Models for bedrock bed with Experimental Observations

*Jagriti Mishra[1], Takuya Inoue[1]

1. Civil Engineering Research Institute for Cold Region

Sediment availability and bedrock bed roughness are two important factors controlling the morphodynamics of a bedrock channel. Sediment availability can determine if the bedrock channel incises or adjusts its width and slope. In this study we compare various mathematical models and test their efficacy to reproduce laboratory scale experiments. Some mathematical models have suggested a linear relationship between sediment cover and ratio of sediment supply to sediment transport capacity of the channel.

Keywords: bed roughness, bed cover, bedrock channel

Paleosols distributed in marine terraces in the Goshogawara area, Aomori Prefecture, Northeast Japan

*Aya Omata[1], Kohki Yoshida[2]

1. Division of Science and Technology, Graduate School of Shinshu University, 2. Department of Geology, Faculty of Science, Shinshu University

The paleosol suggests the climatic conditions in the past because major soil groups are formed and affected by the normal soil forming action of climate. Already, Matsui and Kato (1962) reported the existence of red paleosols distributed in the wide area in Japanese Islands, from Kyushu to the northern end of Honshu, and discussed its implications. In particular, the existence of red paleosol in the Tsugaru Peninsula, located at the northern end of Honshu island, is important in discussing the spread of past warm climatic conditions during the last interglacial period.
At the foot of the Tsugaru Mountains, marine terraces formed during the last interglacial period widely developed (Azuma, 1995). In this study, we examined paleosol layers intercalated in the terrace located from Iizume, Goshogawara-city, to Nakasato, Nakadomari-machi, Aomori Prefecture. In the field, the soil color was described using the Munsell soil color chart, and sedimentary facies was described for reconstruction of sedimentary environments.
As a result, the sedimentary environments in the study area was divided into channel, river floodplain, and lake facies. It is conceivable that the lake facies was formed as a part of the river sedimentary facies since the lake facies is located at the top of the floodplain facies and the bottom of the river channel facies. In this study area, 7.5YR brown soil layer have the majority, and only 5YR red soil layer was found at one site. In the laboratory, thin sections of the samples collected from layers with different sedimentary facies and soil colors were observed under microscope to find the soil structure. The paleosol layers that have soil structures such as clay filling and clay coating were found at two sites. In addition, XRD analysis was conducted on the horizons where the development of the clay filling and clay coating were observed. As a result, the clay minerals such as halloysite, vermiculite and kaolinite were found in the sample where the accumulated clay minerals are contained, while the halloysite was almost the only clay mineral contained in the sample where the accumulated clay minerals were not observed. These layers, which were rich in clay minerals of the accumulated clay, correspond to horizon B of the general soil stratigraphy, suggesting the formation of a mature soil.
The paleosol color of B layer of the paleosol layer distributed in this study area is 5YR4 / 8 (red brown), 5YR5 / 8 (light red brown), 7.5YR4 / 6 (brown) and 7.5YR5 / 8 (light brown). The clay mineral composition of horizon B is mainly composed of halloysite and vermiculite and shows the similarity to typical red-yellow soil distributed around eastern Asia present days.
It is revealed that paleosol consisting of red-yellow soil developed on the terrace deposits formed during the last interglacial period in the Tsugaru Peninsula. The climate condition in the Tsugaru Peninsula at the last interglacial period is considered to have been very warm because the current red-yellow soils are formed around subtropical forests.

Effects of soil moisture variation on rainfall infiltration and erosion of the badland soil in Taiwan

*po yuan Chou[1], Yung-Chieh Wang[1]

1. National Chung Hsing University

The mudstone area in southwestern Taiwan has poor geological conditions, severe erosion and poor vegetation. This area, recognized as the badland, is the most difficult area for remediation and revegetation after hillslope disasters. Widely distributed in southwestern Taiwan, the mudstone is known by its poor water permeability. The mudstone is softened with water, but hardens and cracks without water. In this study, we collected the mudstone deposits in the Agongdian Reservoir area, and used them as the soil specimens for investigating the soil erosion processes in the cases of different slope gradients and precipitations. Two major sets of experiments were carried out in this study. The first set of experiments aims to observe the characteristics of soil shrinkage and expansion under different soil moisture conditions. We measured the soil volume at different moisture contents, and estimated the porosity and infiltration rate, in order to obtain the soil characteristic curve values. In the second set of experiments, we applied the artificial rainfall experiments on the soil specimens, which was filled in a glass erosion planform with the dimension of 25 cm, 15 cm, and 75 cm, in width, depth, and length, respectively. Two rainfall intensities (75mm / hr, 100mm / hr) and seven slope gradients (0 ˚, 5 ˚, 10 ˚, 15 ˚, 20 ˚, 25 ˚, 30 ˚) were assigned in the 30-minute simulated rainfall events. During each trial of the simulated rainfall experiments, surface runoff, infiltration, and outflow sediments were collected for every five minutes. Meanwhile, the soil moisture content and erosion topography were monitored by using a soil hygrometer (TDT) and a digital camera. Results from the experiments are analyzed and discussed, in order to propose the inter-relationships among soil moisture content, porosity, infiltration, and runoff erosion. Consequently, the outcome of this study may provide references for the assessments of hillslope erosion and disaster evaluation of the badland in Taiwan.

Forced regression deposits during MIS 5c and 5a observed in the Iioka marine terrace (the Pleistocene Katori Formation, central Japan)

*Hiroko Okazaki[1], Hiroomi Nakazato[2], Toru Tamura[3], Kazumi Ito[3], Masakazu Nara[4]

1. Division of Earth Science, Natural History and Institute, Chiba, 2. Institute for Rural Engineering, NARO, 3. Institute of Geology and Geoinformation Geological Survey of Japan, AIST, 4. Sciences Unit, Natural Sciences Cluster, Research and Education Faculty, Kochi University

The Kanto Plain, eastern Japan, is known to be the largest Quaternary sedimentary basin characterized by the extensive presence of the raised Last Interglacial marine terrace. The Iioka marine terrace, which exposes a marginal terrace section at the eastern end of the Kanto Plain, consists of the Katori Formation. This report presents that the Katori Formation potentially contains the deposits formed during the MIS 5c and 5a with K-feldspar post-infrared infrared stimulated luminescence (pIRIR) dating, tephra correlation, etc. The depositional sequence of the Katori Formation consists of inner shelf, lower shoreface, upper shoreface, beach, and fluvial facies upward above the sequence boundary. The contact between the lower shoreface and the upper shoreface indicates a sharp erosional surface, and the upper shoreface is characterized by tabular-bed sets that may originate from alongshore or oblique shore dunes. The beach and fluvial facies level lower northeastwards (offshore) along with the marine terraces that descend stepwise, which is indicative of a forced regression succession.

Keywords: Forced regression, marine terrace, shallow marine

[H-CG24] Enhancing Integrated Research for Sustainable Future - a human geoscience perspective

convener:Yukio Himiyama(Emeritus Professor, Hokkaido University of Education), Takeshi Sakurai(Graduate School of Agricultural and Life Sciences, The University of Tokyo), Akihiko Kondoh(Center for Environmental Remote Sensing, Chiba University)

Global environmental programmes have been re-structured under the framework of Future Earth, and Future Earth is playing increasingly important role in guiding and coordinating research for the world sustainability, and in contributing to the United Nation's Sustainable Development Goals (SDGs), which has also been impressively successful in mobilizing and leading the society to the more sustainable paths at global, regional, national and local levels. Human geoscience, which has been built on geoscience which studies dynamic nature and phenomena of the Earth including lithosphere, hydrosphere, atmosphere and biosphere, is uniquely committed to human sphere, where human and its various activities, the environment, global environmental problems and disasters all exist and human dimensions of global change is of primary importance, and hence assumes important roles in Future Earth, SDGs, and other programmes for global sustainability or disaster risk reduction. This session relates to all these, and is intended to discuss crucial issues related with them and to seek right ways to implement needed integrated research for sustainable future in human geoscience perspective.

Pattern of Electricity Consumption in Consecutive Hot Days with respect to Microclimate, a case study of Taipei city

*Po Yu Chen[1], Jehn-Yih Juang[1,2]

1. International Degree Program in Climate Change and Sustainable Development, National Taiwan University, Taiwan(R.O.C.), 2. Department of Geography, National Taiwan University, Taiwan(R.O.C.)

Electricity consumption (EC) is highly related to the weather variation owing to utilization of air conditioner (AC) and its embedded design logic. As long as the relationship between electricity and microclimate or meteorological information could be examined and verified, the electricity saving potential could be found and responsive policy could be proposed to improve the situation and make contribution for reducing carbon emission. Cities with huge population and EC will become significant role on mitigating climate change. Taipei, a city with frequent commercial activities and basin-subtropical geographical features was set as the researching target because the ACEC here is considerable with its specific background. Weather data from observing station and electricity variation from electric substations were used in the analysis for examining the temporal and spatial pattern relationship. The variation of EC was compared with variation of temperature and apparent temperature (heat index), which integrated with humidity information, through a time series of consecutive hot days while discussed them by diurnal perspective respectively for precluding interference from the difference of human activities. Geographic information system (GIS) was applied for figuring out the spatial pattern and multilinear regression and geographically weighted regression (GWR) was conducted to quantify the result. Relationship was established through different location within the city area. It was found that both temperature and electricity varied significantly in the daytime and the influence from temperature dominant even though humidity influence apparent temperature which showed different spatial pattern from that of temperature. Outcome could be presented on Web-GIS for the access to the public for reference on the energy saving issue and the (apparent) temperature sensitive area could be improved by better heat insulation refurbishment or other electricity saving application.

Biodiversity and ecosystem functioning under different land management regimes -Case study in grazing lands in northern Ethiopia

*Keiichi Kimura[1], Akito Kono[1], Shigdaf Mekuriaw[2], Yeshambel Mekuriaw[3], Misganaw Wale[3], Asaminew Tassewe[3], Okuro Toshiya[1]

1. Graduate School of Agricultural and Life Sciences, The University of Tokyo, 2. Arid Land Research Center, Tottori University, 3. Bahir Dar University

Biodiversity improves ecosystem functions such as productivity and soil erosion resistance, while loss of biodiversity induces decrease of ecosystem functions through several pathways, depending on the state of functional diversity and process of species loss. However, no prior research conducted on application of positive relationship between biodiversity and ecosystem functioning to grazing land management under framework of sustainable land management (SLM). In northern Ethiopia, severe vegetation degradation and soil erosion have been induced by free grazing in communal lands, where pasture lands have been continuously grazed all year round. Recently seasonal grazing has been proposed as alternative grazing management system to mitigate grazing impact on lands. However, little is known about the effectiveness of seasonal grazing on land conservation through altering biodiversity and ecosystem functions.

Here we addressed the following research question; "how do the differences in grazing management regimes affect ecosystem functions through the changes of biodiversity?" and conducted a field investigation (1) to compare biodiversity (species and functional traits) between free grazing and seasonal grazing systems and explore non-random process of biodiversity loss, (2) to compare ecosystem functions between those systems and explore non-linear process of changes of ecosystem functions, (3) to analyze trade-off/synergy between ecosystem functions and identify key species/functional groups that play key roles in maximizing bundle of ecosystem services, and (4) to compare above results in grazing system with those in tree plantation system, which has been causing land use conflict in grazing land. This paper introduces the outline of the survey and preliminary results of comparison of species and functional diversity between two grazing management regimes.

Simulating the Spatial Flow of Carbon Sequestration Service: A Case Study of Tumen River Watershed

*Jian ZHANG[1], Shizuka HASHIMOTO[1], Weihong ZHU[2], Toshiya OKURO[1]

1. The University of Tokyo, 2. The Yanbian University

The awareness of the carbon sequestration service concept has gained prominence in the decision-making process towards climate change. The inclusion of this issue to date mostly depends on the distribution output of carbon sequestration service value on a static map, whereas its transmission over the spatial units is too often unexploited. On the basis of the cellular automata model and laws of thermodynamics, our research visualized the spatial flow of carbon sequestration service via a grid matching method with a focus on the Tumen river watershed. We simulated flow directions (N = 9) and potential fluxes (0 < F < 87.68 t) of carbon sequestration service flow in the Tumen river watershed, and presented it on a grid map with 1km resolution. Our results illustrated that 15.28% of the trans-boundary watershed was recognized as non-flow regions, which possessed 136.71 Tg of total carbon sequestration. We highlighted how, depending on the spatial flow being simulated, the landscape patterns impact the carbon sequestration service flow, thereby influencing the local value of actual carbon sequestration service supply.

Measuring Urban Sustainability Using Spatial and Socio-Economic Factor and the Impact on Planning Policies in a Rapidly Urbanizing Area

*Anoraga Jatayu[1], Ernan Rustiadi[2,3], Didit Okta Pribadi[4,3]

1. Regional and Rural Development Planning Science Study Program, 2. IPB University, 3. Center for Regional Systems, Analysis, Planning and Development, 4. Research Center for Plant Conservation and Botanic Garden, Indonesian Institute of Science

Regional growth and pattern in urban areas of Monsoon Asia have a relatively similar pattern, which is characterized by the expansion of core-urban areas to the surrounding areas. The growth of urban areas is also affecting its sustainability since spatial growth is followed by a transformation of economic and social activity. Cianjur Regency as one of the region that experiences the expansion process from Jakarta Metropolitan Area (JMA) is currently undergone major growth and transformation from the region with a mostly rural area to become “city-region”, characterized by its growth as a polycentric region with the emergence of newly established urban areas. Those growths are surely going to affect the region’s sustainability locally and regionally. The objective of this research is to measure Cianjur Regency urban areas sustainability (2000 and 2018), also its impact on future and current planning policies. Sustainability in those urban areas is measured using Local Sustainability Index (LSI) with spatial and socio-economic variables. The result shows that the new urban area (Puncak-Cipanas) is less sustainable than the majority of the existing urban area (Cianjur). The decline of urban sustainability on Puncak Cipanas is largely influenced by social and environmental sustainability, because of land-use change occurred in the area and the lack of social services/facilities. Meanwhile, Cianjur urban’s sustainability hardly experiencing any changes, mainly because regional development is currently focused on Puncak-Cipanas urban. Challenges on future and current planning policies are headed towards preserving the environment and providing better infrastructure coverage for all of the urban areas, as urban area tends to have a more complex needs of infrastructure. The integration of all planning policies also needed to achieve sustainable growth.

[H-CG25] Turbidity current: generation, morphodynamics and deposits

convener:Hajime Naruse(Department of Geology and Mineralogy, Graduate School of Science, Kyoto University), Robert Michael Dorrell(University of Hull), Miwa Yokokawa(Osaka Institute of Technology)

We invite research based on all kinds of approaches to understand turbidity currents such as field observation, physical and numerical experiments, mathematical analysis, and studies from rock records. Recent progress in research methodologies has greatly changed our understanding of dynamics of turbidity currents and relevant submarine geomorphology and stratigraphy. The integration of such new knowledge on turbidity currents is important not only for scientific interests but also for practical application such as risk assessment of natural hazards, and exploration of resources. We anticipate interdisciplinary discussions about turbidity currents and related sediment gravity flows.

Inverse Analysis of Experimental Scale Turbidity Currents by Deep Learning Neural Network

*Cai Zhirong[1], Hajime Naruse[1]

1. Kyoto University

Turbidite deposits have been an active area of study due to its close association with petroleum resources and their role in the destruction of sea-floor equipment. Through studies of turbidity currents, the depositional process of turbidite, understanding of specific characteristics of turbidite deposits can be improved. However, knowledge in this area remains limited due to difficulties in the direct observation of turbidity currents. In order to better understand the structure of turbidity current, inverse analysis of turbidity current had been used to reconstruct the initial flow conditions from its turbidite deposits. However, past optimization methods had been computationally over expensive, making it impractical to be applied to actual turbidite deposits in nature. In order to resolve this issue, a new method for the inverse analysis of turbidity current using deep learning neural network (DNN) was proposed, and this research verified the method using artificial data and actual flume experiment data. In this study, DNN was applied to two different types of experiments. One using two different types of plastic particles and the other using a mixture of siliciclastic sand and plastic particles. Our results demonstrate that inverse analysis using DNN can reconstruct the hydraulic conditions and deposit profiles of both types of flume experiments with good accuracy. However, some variation in performance can be observed from the results of application for different types of experiments.

Dynamic stratification enables auto-suspension and thus the ultra-long run-out of sediment-laden buoyancy driven flows

*Robert Michael Dorrell[1]

1. University of Hull

Sediment-laden buoyancy driven flows, turbidity currents, are observed to traverse thousands of kilometers on the seafloor. Such behavior is predicated on auto-suspension, where sediment in suspension provides the motive force to drive the flow and the flow energy is expended keeping sediment in suspension. However, auto-suspension over such distances is enigmatic, as available flow energy is continuously dissipated through raising the centre of suspended mass of the flow. Thus, turbidity currents must ultimately stall and die. However, here a new model for turbidity current flow mechanics is proposed where the potential energy released in the deceleration of dynamically stratified turbidity currents provides sufficient energy to enable ultra-long flow run-out. The new model is validated against the first field-scale observations of a turbidity current traversing the entire length of a submarine canyon-channel system.

Here auto-suspension, and thus the ultra-long run-out of natural turbidity currents, is explained by depth-average dynamic weighting parameters, that appear in system scale shallow water models of turbidity current flow dynamics. In essence dynamic weighting is included to capture the fundamental process, that:

1) Whilst a flow decelerates, turbulent mixing decreases and thus stratification increases.

2) Whilst a flow accelerates, turbulent mixing increases and thus stratification decreases.

As stratification increases, with relative near-bed suspended sediment concentration increasing, the location of the velocity maximum becomes moves closer to the bed. As the velocity maximum is more closely aligned with the most concentrated region of the flow. Moreover, as the relative velocity is concentrated in a smaller region, closer to the bed. The paradoxical results of which is that with increasing stratification, downstream mass and momentum flux becomes more efficient.

As stratification increases the depth average hydrostatic pressure, decreases with the relative center of suspended mass being lowered towards the bed. The critical result is thus that whilst accelerating down steep slopes, where stratification increases, kinetic energy is transferred to, and stored as, potential energy. Yet whilst travelling over more gentle slopes, where the flow decelerates and stratification increases, the center of suspended mass is lowered releasing potential energy to drive the flow over long-distances.

Using dynamic models of flow stratification, turbidity currents traversing canyon-channel systems, over slopes down to 10^{-5} m/m may be predicted for the first time. Here temporally invariant flow, characteristic of the long-duration flows observed in real-world systems, is assumed. The model is applied to the Congo canyon-channel system. In both proximal and distal channel sections, modeled flow velocities match mean flow measurements of a 2004 turbidity current that traversed over 1000 kilometers of the canyon-channel seafloor system (Vangriesheim *et al.*, 2009). Sensitivity analysis shows weak dependence on initial flow conditions, if the flow has sufficient kinetic or potential energy to bypass the proximal

©2020. Japan Geoscience Union. All Right Reserved.

canyon, where it is fully confined. This suggests that flow tuning, through overspill, is a core control on the dynamics of partially confined flows within distal channel reaches.

Dynamics of turbidity currents influenced by tidal flows

*Justine Poppeschi[1], Hajime Naruse[1], Robert Michael Dorrell[2]

1. Kyoto University, 2. University of Hull

Turbidity currents are flows lead by gravity and occur generally in the deep-sea floor in contrast to tidal flows that are known to be present in shallow marine regions. Thus, tidal influence on the dynamics of turbidity currents has been regarded as practically non-existent. However, cyclic oscillations in the grain-size distribution have been occasionally observed in turbidites, and in-situ measurements in turbidity currents have shown oscillations of flows velocity with periodicity of several hours. To understand these periodic oscillations in turbidity currents, we propose a hypothesis that the tidal flows in submarine canyon influence turbidity currents by causing the internal waves at the interface of the two flows. They could interacts each other by the mixing and entrainment processes inside submarine canyons. Firstly, this hypothesis will be tested by numerical experiments. Also, data analysis of in-situ measurements of turbidity currents will be conducted to search the presence of tidal influence. If this hypothesis is verified, that could shed light on the large disparity of the turbidity current presence in submarine canyon. In addition, due to the link between the global sea-level and the tide, the internal tides could be the bridge between global sea-level change and developments of submarine fans.

Evaluation of plant-fragment concentration system in the turbiditic sequence by terrigenous biomarker analysis of sediments from the Kawabata Formation, Yubari area, central Hokkaido, Japan.

*Muhammad Adam Ismail[1], Hiroyasu Asahi[1], Satoshi Furota[3], Ken Sawada[2]

1. Graduate School of Science, Hokkaido University, 2. Department of Earth and Planetary Sciences, Faculty of Science, Hokkaido University, 3. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

Kawabata Formation distributed in Yubari area, central Hokkaido, is formed by basin-filled and slope-apron turbidite systems, and sandstone and mudstone are mainly predominated by turbiditic sequences. Distinctive plant-fragment (PF) concentrated sandstones were found in the Kawabata Formation, and their sedimentological and biomarker analyses suggests that these sediments were deposited by hyperpycnal flow (Furota et al., 2014). In the present study, we conducted biomarker analysis of sandstone and mudstone characterized as several turbidite type sequences from the Kawabata Formation to evaluate sedimentological processes and to compare with the plant-fragment concentrated sandstones in hyperpycnite.

The sandstones and mudstones analyzed were collected from the outcrops of the Takinoue Park, Yubari, central Hokkaido. For the biomarker analysis, lipids were extracted with dichloromethane/methanol, and separated to aliphatic, aromatic and polar fractions. These lipids were identified and quantified by GC-MS.

Three consecutive turbiditic sequences analyzed are two Bouma type sequences (ca. 60 cm and 25 cm thick) and a distinctive ‘PF-concentrated’ type sequence (ca. 34 cm thick), in which the sandstone layer is characterized by abundant plant fragments and particles as reported by Furota et al. (2014). Sedimentary layer in the Bouma type sequences equivalent to Ta units consists of medium - to fine sands with tiny black PFs. Tb unit consists of fine sands with parallel laminations containing the concentrated PFs. Tc unit also consists of fine sands about 1-2cm thick without cross laminations, and the concentrated PFs are observed as many black bands in this unit. Te unit is massive sediment that consists of very fine sands to silty muds without PFs. In the ‘PF-concentrated’ type sequence, a sandstone layer consists of medium to fine sands containing the large plant-derived blackish particles with diameters of ca. 5-10 cm, and many PF thin layers. The mudstone layer, corresponding to the Te unit, is a massive sediment that consists of very fine sands to silty muds without PFs as the Bouma type sequence.

The *n*-alkane concentrations in the turbiditic sequence are of minimal values in the Ta units. The concentrations increase in Tb and Tc, and then decrease in Te units. This trend is also shown in variations in the concentrations of plant-derived terpenoids. The *n*-alkane concentrations are lower than the turbiditic sandstone unit than the mudstone unit. Pristane / phytane ratio (Pr/Ph) of the mudstone unit is 2.12 while the lower and upper layer of the sandstone unit exhibits a strong oxic and terrigenous matter-abundant character at 5.18 and 9.98 respectively. In addition, a peak of higher branched isoprenoid (HBI) alkane, known to be derived from specific diatoms, was found in the mudstone sample. The C27/C29 sterane ratios, which are indicators of marine / terrigenous sources of organic matter, is 0.41 in the mudstone unit, and less than 0.21 in the sandstone units. These results suggest that the organic matter was mainly of terrestrial origin. Triterpenoid compositions are mostly dominated by lupane and oleanane (derived from angiosperms) in both the mudstone and sandstone layers. However, the

©2020. Japan Geoscience Union. All Right Reserved.

sandstone layers had a remarkably higher concentration of the triterpenoids, including A-ring degraded triterpenoid (*des*-A- triterpenoids) such as *des*-A-oleanane, *des*-A-lupane as well as monoaromatic and diaromatic *des*-A-triterpenoids. The *des*-A-triterpenoids are thought to be generated by microbial degradation during early diagenesis. The *des*-A- triterpenoid compositions are also nearly constant as the results of diterpenoids and non-degraded triterpenoids. However, the ratios of *des* -A-triterpenoid/pentacyclic (non-degraded) triterpenoid are higher throughout the turbiditic sequence, especially Tb and Tc units of the Bouma type sequences and sandstone units of the 'PF-concentrated' type sequence. Furota et al. (2014) reported that the *des*-A/pentacyclic triterpenoid ratios in sandstone units were clearly lower than mudstone units in the hyperpycnite, suggesting that more fresh terrigenous organic matter was rapidly transported by the hyperpycnal flow. Our results imply that the organic matter in the current study is mostly of terrestrial origin and rapidly transported by an efficient delivering system.

Grain fabric analysis of massive sandstone beds of the Upper Cretaceous Himenoura Group distributed in Amakusa-Kamishima Island, Kyushu, Southwestern Japan by Deep Learning Convolutional Neural Network

*Sayo Ishii[1], Hajime Naruse[1]

1. Department of Geology and Mineralogy, Graduate School of Science, Kyoto University

The purpose of this study is to clarify the grain fabric of massive sandstones deposited in submarine fans. It has been known that the massive structure is common in submarine sediment-gravity-flow deposits, their formation mechanisms have not been clarified. Rapid deposition from high concentration turbidity currents and en-masse deposition of sandy debris flows are candidates of processes to form massive structure, but it is difficult to distinguish the processes from visible sedimentary structures because they lack characteristic features in macroscopic observation of outcrops. To this end, this study investigated ancient massive deposits by means of the microscopic image analysis. We employed deep learning image analysis for identifying sand particles from rock sections in several tens cm scale. The study area is the Cretaceous Himenoura Group distributed in Amakusa-Kamishima Island, Kyushu, Southwestern Japan. Polished sections of sandstones were scanned by EPSON GT-970 to obtain images. Then the manually traced images were used as teacher images for deep learning. The developed model using Convolutional Neural Network(CNN) automatically distinguishes particles from fine-grained matrix. As a preliminary result, it was revealed that massive sandstones taken from submarine channel-fill deposits and lobe show different features in grain fabric observed at horizontal sections. Preferred orientation of grain long axes tends to vary vertically in channel-filling deposits, whereas those in lobe deposits show relatively stable trends. Future experimental studies may indicate origin of these difference in features of grain fabrics,

Revisiting the meandering channel developed in the Okinawa Trough

*Takeshi Matsumoto[1], Yasuhiro Morii[2], Nobuhiro Yamawaki[2], Itaru Aizawa[2], Sota Hoshina[2], Tsukasa Kinoshita[2]

1. Faculty of Science, University of the Ryukyus, 2. Faculty of Fisheries, Nagasaki University

In 1996, a French survey found that meandering channels existed on both north and south slopes of the trough north of Yonaguni Island, on the western edge of the Okinawa Trough, where active rifting in the north-south direction is taking place on the eastern margin of the Asian continent. Multibeam bathymetric survey during the ACT Cruise in the SPOT area east of Taiwan and the western end of the trough by the research vessel (R/V) 'l'Atalante' first revealed the channels (Sibuet et al., 1998). After that, LEQUIOS Cruise by R/V 'Yokosuka' and Submersible 'Shinkai6500' were conducted in 2000 (Matsumoto et al., 2001). The main purpose of the cruise was to study the formation and development of the central trough, hydrothermal activity in the trough, and wide-area tectonics and dynamics by use of the seafloor observation by the submersible. Marine geophysical observations including the detailed topographic survey in the eastern extension of the SPOT area was also carried out during the LEQUIOS Cruise. As a result, the entire meandering channel on both north and south slopes of the trough was revealed, and it was found that both channel complexes were almost the same size.

Kimura et al. (2001) pointed out that these channels were very similar to a fan formed on a flat land that transitions from a mountain to a plain, or a delta that can be formed at the mouth of a river, through an ROV (remotely operated vehicle) survey along these meandering channels. Then, the authors pointed out that it could have been formed in an environment such as the intertidal zone or the extremely shallow sea when part of the Okinawa Trough became land. However, considering that these meandering channels are developed on the elongated mounds of several kilometers wide in the east-west direction and are bordered by levees, these channels should be formed by turbidity currents from the continent of China. The channels should be in one stage of the process of forming a submarine fan. Larger ones can be found, for example, in the Amazon Fan drilled at ODP Leg155.

The University of the Ryukyus uses the Nagasaki Maru, a training ship of the Faculty of Fisheries of Nagasaki University, to offer undergraduate onboard training courses every year based on a credit exchange agreement with the Faculty of Fisheries. The ship is also used for research in the Ryukyu region. The old Nagasaki Maru was retired in 2017 and a new one entered service in 2018. The new ship is equipped with a multibeam echo sounder. Approximately 20 years have passed since the previous survey of the meandering channels on the Okinawa Trough, and during this time there might have been a supply of new turbidity currents from mainland China, and the shape of the existing meandering channel might have changed. Therefore, a re-survey of the precise bathymetry of these meandering channels was carried out during the one-week cruise of the training vessel 'Nagasakimaru' in May 2019. Due to rough sea conditions and time constraints, the authors focused on the channel on the northern slope of the trough during the cruise .

As a result, the position change of the flow path of the meandering channel developed on the mound for last 20 years were not detected. And also, no new mounds appeared. However, the water depth of the bottom of the meandering channel on the mound extending from 25° N, 122° 55’ E towards east-northeast is generally 5-15 m deeper than that of 20 years ago, while the levees on both sides of the channel is 15-20m shallower (higher). These suggest that the turbidity current supply from mainland

©2020. Japan Geoscience Union. All Right Reserved.

China has continued for last 20 years, and that the erosion of the bottom of the channel and the growth of the levees has been taking place. On the other hand, meandering channels located in the area near 25° 08’ N, 123° 25’ E, which is not on a mound, had no change in water depth.

Future monitoring of the channel topography regularly and conducting a topographic survey again on the southern slope of the Okinawa Trough will help clarify the turbidity current supply mechanism at the western end of the Okinawa Trough.

Cyclic steps inside submarine canyon and in canyon-fan transition zone: Numerical experiments by 2D shallow-water model of turbidity currents

*Hajime Naruse[1]

1. Department of Geology and Mineralogy, Graduate School of Science, Kyoto University

Cyclic steps are upstream-migrating bedforms accompanied with hydraulic jumps. Recent high-resolution geophysical surveys indicated that they are common topographic features especially in submarine canyons and fans where turbidity currents are dominant process of landform developments. Cyclic steps are common in submarine canyons or upstream regions of submarine fans (canyon-fan transition zone), but their morphological features are significantly different. Upstream bedforms inside submarine canyons are relatively small in wavelength and height, and generally show the crescent shaped or mound-like morphology. On the other hand, cyclic steps in less confined canyon-fan transition zone tend to be large in wavelength and height. The origin of these morphological features has not been clarified yet. Thus, we conducted numerical experiments to investigate the conditions for producing cyclic steps at the canyon-fan transition zone. The model is based on two dimensional shallow water equation of turbidity currents, and it was solved by CIP-CUP method that is the the third-order-accurate scheme. We set a submarine canyon and a flat basin plain in calculation domain, and the experimental turbidity currents is injected from the upstream end of the canyon. The canyon was 5% in slope, 2 m long and was 20 cm wide at the transition to the basin. The basin was 3 m in length and 2 m in width. The turbidity currents were 10 cm thick in maximum, 1vol.% in concentration. Grain size was set to be 30 micron meters. As a result of numerical experiments, upstream-migrating bedforms were formed both inside submarine canyon and on the canyon-fan transition zone. All bedforms are associate with hydraulic jumps, so that it can be classified to cyclic steps. However, bedforms inside the canyon show mound-like shape and have relatively short wavelength, whereas those developed on the canyon-fan transition zone were longer in wavelength and their crests were more continuous. The mound-like bedforms in canyons produced in this study resemble crescent bedforms observed in modern submarine canyons, and the laterally continuous cyclic steps are common features of lobate submarine fans at the upstream end. Judging from the observation of the velocity fields, it is inferred that difference of two bedforms was caused by diagonal cross waves that are steady three-dimensional surface waves of supercritical flows. It has been known that the steady surface waves interact with step and pool structures in mountain rivers. This study implies that the same mechanism may govern the supercritical bedforms in the natural submarine canyons systems.

Sedimentary facies related to supercritical-flow bedforms in foreset slopes of middle Pleistocene Gilbert-type delta, central Japan

*Hiroko Okazaki[1]

1. Division of Earth Science, Natural History and Institute, Chiba

This study examined sedimentary facies related to supercritical-flow bedforms in foreset slopes of a Gilbert-type delta in the middle Pleistocene Kamiizumi Formation, central Japan, paying particular attention to bed architectures and internal structures, grain-size distributions, and molluscan assemblages. Coarser grained chute-and-pool deposits laterally alternate with finer grained antidune to subcritical deposits on progradational steep delta slopes. The cyclicity of foresets is an intrinsic characteristic of supercritical flows on progradational steep delta slopes. Cyclic steps in the lower part of the delta foresets may reflect enhanced flood currents on the gentler parts of the delta slope. The vertical changes from cyclic steps to chutes-and-pools to antidunes represent decreasing flow velocity and are the result of autogenic flow transitions during rapid aggradation. Remarkable variations in the facies of delta foreset beds reflect the conditions of inflowing sediments as well as the intrinsic instability of supercritical flows on the foreset slope.

[S-GD01] Geodetic Infrastructure for Monitoring the Dynamic Earth: The Global Geodetic Observing System

convener:Basara Miyahara(GSI of Japan), Richard S Gross(NASA Jet Propulsion Laboratory)

The Global Geodetic Observing System (GGOS) measures the time-varying shape, rotation, and gravity field of the Earth, which provide accurate geodetic reference frames and enable us to understand various dynamic processes occurring on the Earth. The measurements are achieved with various geodetic techniques such as VLBI, SLR, GNSS, DORIS and gravity measurements. Many institutions in the world have developed their geodetic infrastructure to contribute to GGOS realization and devoted to research activities for Earth science. These activities are well coordinated and supported by the international scientific services of the International Association of Geodesy such as the International VLBI Service for Geodesy and Astrometry (IVS), the International Laser Ranging Service (ILRS), the International GNSS Service (IGS), the International DORIS Service (IDS), the International Gravity Field Service (IGFS), and so on. Through the coordination and support of these efforts, GGOS has fostered global collaboration and advocated stable production of geodetic products such as geodetic reference frames, earth rotation parameters and earth's gravity field models. This session will focus on reporting and discussing recent GGOS activities including geodetic data DOI working group, status of geodetic infrastructure and the results of data analysis for GGOS, and highlight the importance of geodetic observations to monitoring and understanding the dynamic Earth system for the benefit of science and society.

The International VLBI Service and Its Role in GGOS

*Hiroshi Munekane[1], Dirk Behrend[2], Nancy Wolfe Kotary[3]

1. Geospatial Information Aurhotiry of Japan, 2. NVI, Inc., 3. MIT Haystack Observatory

The International VLBI Service for Geodesy and Astrometry (IVS), inaugurated in 1999, is an international collaboration of organizations that operate or support very long baseline interferometry (VLBI) components. The IVS is a service of the International Association of Geodesy (IAG) and the International Astronomical Union (IAU) and comprises more than 80 permanent components in over 20 countries. IVS organizations are currently in the process of implementing the next-generation broadband VLBI component of GGOS. This broadband VLBI system, the VLBI Global Observing System (VGOS), will ultimately replace the legacy S/X-band systems worldwide. VGOS broadband observations are made by fast-slewing 12-meter antennas in four bands between 2.5 GHz and 14 GHz. Once fully realized, VGOS will provide positional accuracies of 1 mm on global scales and involve continuous observations. The IVS also provides highly accurate and unique products through VLBI for the realization and maintenance of the celestial and terrestrial reference frames, ICRF and ITRF, and the Earth Orientation Parameters (EOP). VLBI plays a unique and fundamental role in the realization and maintenance of the global reference frames and in the determination of the EOP, including observation of quasars (necessary to realize the ICRF), the complete set of EOP including UT1−UTC, and the most precise measurements of intercontinental baselines for the realization and maintenance of the ITRF.

Keywords: VLBI, VGOS, ITRF, ICRF, EOP

DORIS: 30 years of success in precise orbit determination and ground station positioning

*Frank G Lemoine[1], Guilhem Moreaux[2], Jérôme Saunier[3], Pascale Ferrage[4], Laurent Soudarin[2], Koichiro Doi[5]

1. NASA Goddard Space Flight Center, Greenbelt, Maryland, U.S.A., 2. Collecte Localisation Satellites, Ramonville Saint-Agne, France, 3. Institut National de l’ Information Géographique et Forestière, St-Mandé, France, 4. Centre National d’ Etudes Spatiales, Toulouse, France, 5. National Institute of Polar Research, Tachikawa-City, Tokyo, Japan

Doppler Orbitography and Radiopositioning Integrated by Satellite (DORIS) system is one of the four techniques that contributes to the International Terrestrial Reference Frame (ITRF). The technique was developed to support orbit determination on LEO satellites, most notably the suite of ocean radar altimeter satellites. The DORIS system consists of a global well-distributed set of ground beacons emitting on two frequencies (2 GHz and 401 MHz) and a satellite constellation consisting of an evolving suite of satellites that carry different generations of satellite receivers. Presently DORIS has colocations with other geodetic techniques at 47 out of 58 sites, many with GNSS. These include Badary, Greenbelt, Wettzell, and Yarragadee who host all four space geodesy techniques (DORIS, GNSS, SLR & VLBI), and Arequipa, Grasse, Kauai, Mt. Stromlo, Ny Alesund, Papeete, Jiufeng, and Syowa (Antarctica) who host three of the space geodetic techniques, including DORIS. The DORIS system became operational 30 years ago in February 1990, with its inauguration on the SPOT-2 satellite. Presently six satellites on-orbit carry a DORIS DGXX receiver (Cryosat-2, HY-2A, Jason-3, Saral, and Sentinel-3A and Sentinel-3B). A DGXX receiver can track up to seven ground beacons when they are in view of the orbiting satellite. This capability greatly increases the amount of data available for orbit determination and strengthens the DORIS contribution to the ITRF.

In this paper we provide a summary of the current status of the DORIS system, its science contributions, and its contributions to GGOS. We describe the evolution of the DORIS system including the improvements in the ground network, and summarize the products that are made possible by DORIS, including its contributions to the ITRF, and to the measurement of the change in Global Mean Sea Level.

In addition, we highlight the performance of select stations, such as the DORIS station in Syowa, Antarctica, including its contributions to science missions, and comparisons with other geophysical measurements.

The International Gravity Field Service (IGFS) and its contributions to the GGOS infrastructure

Riccardo Barzaghi[1], George S Vergos[2], *Basara Miyahara[3]

1. Politecnico di Milano, 2. Aristotle University of Thessaloniki, 3. GSI of Japan

The International Gravity Field Service (IGFS) promotes the interaction, cooperation and synergy between the Gravity Services, namely the Bureau Gravimétrique International (BGI), the International Service for the Geoid (ISG), the International Geodynamics and Earth Tides Service (IGETS), the International Center for Global Earth Models (ICGEM) and the International Digital Elevation Model Service (IDEMS). Furthermore, through its Product Center, namely the International Combination Service for Time-variable Gravity Fields (COST-G), IGFS provides consolidated monthly global gravity models in terms of spherical harmonic coefficients and thereof derived grids by combining solutions from individual Analysis Centers.

The IGFS Central Bureau is hosted at the Aristotle University of Thessaloniki (Greece) and, besides other activities, provides a link to the Global Geodetic Observing System (GGOS) Bureaus in order to communicate their requirements and recommendations to the IGFS-Centers. Moreover, IGFS provides a coordination host for the utilization of gravity-field related products and services towards their inclusion within a GGOS consistent frame.
In this work, an outline is given on the recent activities of IGFS, namely those related to the contributions to the implementation of the International Height Reference System/Frame; the Global Geodetic Reference System/Frame; the new Global Absolute Gravity Reference System/Frame and the combination of temporal monthly global gravity field models. Particularly, the impact that these activities have and will have in improving the estimation of the Earth’ s gravity field, either at global and local scale, is highlighted also in the framework of GGOS.

Activities of the Ishioka VLBI Station as a VGOS station

*Haruka Ueshiba[1], Tomokazu Nakakuki[1], Saho Matsumoto[1], Nobuhiro Ishikura[1], Michiko Umei[1], Kyonosuke Hayashi[1], Toru Yutsudo[1], Tadao Kikkawa[1], Hiroshi Munekane[1]

1. GSI of Japan

The International VLBI Service for Geodesy and Astrometry (IVS) promotes the transition from the legacy VLBI system with S/X frequency bands to the next-generation VLBI system called VGOS (VLBI Global Observing System), which is part of Global Geodetic Observing System (GGOS). The goals of VGOS are to achieve: 1-mm position accuracy on global scales, continuous measurements for time series of station positions as well as Earth Orientation Parameters, and turnaround time to initial geodetic results of less than 24 hours. To achieve these goals, the VGOS stations should be equipped with antennas with high slewing rate, receivers for broadband observations (2-14 GHz) and high speed recording systems up to 32 Gbps. Currently, because the number of VGOS stations is not sufficient, legacy S/X observations are mainly conducted at IVS while VGOS observations are also regularly conducted.

The Geospatial Information Authority of Japan (GSI) constructed a new VLBI facility in Ishioka in 2014 which meets the VGOS requirements and began its operation in May 2016. The Ishioka Station uses two different types of receiver depending on a type of an observation: tri-band feed for S/X observations and QRFH for broadband observations, and it is necessary to replace receivers when switching types of observations, which takes about one week. Hence, the Ishioka Station mainly participates in legacy S/X international observation, and participates in broadband observation for several months every year. In the latest broadband observation term from December 2019 to February 2020, the Ishioka Station participated in VGOS Test observations organized by IVS (once every two weeks, 24 hours observation. Since January 2020, these have been operated as official observations.), and also participated in test observations organized by the European VLBI Group and VGOS-intensive test observations (once a week, 1 hour) for the first time. The Ishioka Station also participated in experiments for the inter-continental frequency comparison project conducted by National Institute of Information and Communications Technology (NICT).

To avoid the replacement of receivers when switching types of observations, we are promoting investigations and improvement for “Mixed Mode” observations in which S/X and broadband signals are received simultaneously without replacing receivers. In the Mixed Mode observations, S/X and broadband signals are received at the same time by QRFH. With the Mixed Mode Observations, the Ishioka Station may participate in broadband observations as one of VGOS stations while regularly participating in S/X observations for stable position products until IVS moves to full VGOS.

For achieving the Mixed Mode observations, it is necessary to mitigate the effect of strong RFI around S-band (2-3 GHz). Currently, a high pass filter which cuts off signals lower than 3GHz is inserted in the circuit of QRFH. To receive S-band signals by QRFH, it is necessary to design the band pass filter to allow the reception of S-band signal while avoiding signal saturation caused by RFI. The GSI is currently developing a superconductor band pass filter whose design reflects the investigation of RFI around the Ishioka Station (Hayashi et al., 2019), which will replace the current high pass filter.

This talk will summarize activities of the Ishioka station as one of VGOS stations and progress of improvement of QRFH for Mixed Mode observations.

Satellite Laser Ranging and GNSS observations in the Shimosato Hydrographic Observatory, Japan

*Shun-ichi Watanabe[1], Noritsune Seo[2], Yuto Nakamura[1], Yusuke Yokota[3], Hiroko Fukura[4]

1. Hydrographic and Oceanographic Department, Japan Coast Guard, 2. Shimosato Hydrographic Observatory, 5th Regional Coast Guard Headquarters, Japan Coast Guard, 3. Institute of Industrial Science, University of Tokyo, 4. 8th Regional Coast Guard Headquarters, Japan Coast Guard

The Shimosato Hydrographic Observatory (SHO) of Japan Coast Guard, located in the southernmost part of Wakayama Prefecture, operates Satellite Laser Ranging (SLR) observations since 1982 as well as continuous GNSS observation. Collected SLR and GNSS data are transferred to the International Laser Ranging Service (ILRS) and the International GNSS Service (IGS), respectively. The transferred data contribute to the construction and development of the International Terrestrial Reference Frame (ITRF). The SHO which operates two kinds of global geodetic techniques is now one of the Global Geodetic Observing System (GGOS) sites.

In order to enhance the usability of the SLR observation system, the SHO has updated its laser ranging equipment in 2018. We installed a laser oscillator with changeable pulse repetition rate up to 1 kHz (i.e., kilohertz laser), by which we can collect the ranging data at a higher rate than by the former one with a pulse repetition rate of 5 Hz. The relevant updates on the control devices contribute to the simplification of SLR operation.

In this presentation, we first describe the summary of our laser ranging system update in the SHO, and then show the geodetic results of SLR and GNSS positioning at the SHO. The SLR monthly positions were calculated using LAGEOS-1 and LAGEOS-2 ranging data with the analysis software C5++ (Otsubo et al., 2016, Earth Planets Space). The results clearly reproduced the coseismic displacements due to the 2004 southeastern off Kii Peninsula earthquakes (M7.4 and M6.9) and the 2011 Tohoku-oki earthquake (M9.0). In addition, significant postseismic displacements following the Tohoku-oki earthquake were also obtained.
Acknowledgments: Dr. Otsubo of the Hitotsubashi University provided us the analysis software “C5++” and the adjusted data/parameters for SHO’s data analysis.

Current Status and Prospect of GEONET, Japanese dense GNSS network

*Takayuki Miyazaki[1], Koki Kumagai[1]

1. GSI of Japan

GSI of Japan has operated domestic dense GNSS network (GNSS Earth Observation NETwork system: GEONET), which consisted of over 1,300 observation stations covering most region of Japan and control center at GSI of Japan, Ibaraki prefecture. Observation data and daily coordinates of each GEONET station are provided for surveyors or earth scientists and so on. GEONET data and products are used as infrastructure regarding precise positioning.

For keeping GEONET being infrastructure of precise positioning, it is indispensable to devote considerable efforts to maintenance work. In 2019, two huge typhoons (typhoon 15 category 4 and typhoon 19 category 5) impacted Kanto and Tohoku region and these typhoons damaged many GEONET stations. In this presentation, we will introduce maintenance work of GEONET through response to these typhoons.

Introducing new techniques regarding GNSS observation to GEONET is also important. GSI conducts investigation for implementation of multi-GNSS and 5th generation mobile communication system. We will mention these topics.

Crustal Deformation Measurements in Himachal Himalaya: A New Evidence of Extensional Tectonics

*Yogendra Sharma[1], Sumanta Pasari[1], Kuo En Ching[2], Onkar Dikshit[3], Javed N Malik[3]

1. Birla Institute of Technology and Science, Pilani, 2. National Cheng Kung University, Taiwan, 3. IIT Kanpur

In this work, we have used five years of GPS data to understand the contemporary crustal deformation pattern in the Himachal region of the Northwest Himalaya. Surface velocities estimated in International Terrestrial Reference Frame 2008 (ITRF08) are observed to lie in the range of *42-48* mm/yr with an uncertainty level of *~1* mm/yr. To analyze the kinematics of major faults in the study region, horizontal and vertical GPS velocities are inverted for the fault slip rate and fault geometries using a 2-D dislocation model. The horizontal velocities are also decomposed into the fault-parallel and fault-normal components. We have then selected a velocity profile across two major faults, namely MFT (Main Frontal Thrust) and MBT (Main Boundary Thrust). To perform the 2-D fault modeling along the profile, we assume that the fault geometry comprises a décollement known as MHT (Main Himalayan Thrust). The considered fault parameters are dip angle, fault depth, locking depth, location of faults on the surface, slip rates and rake angle. We search for the optimized fault parameters using the Monte Carlo-Metropolis inversion method. In the velocity profile, no remarkable velocity gradient is observed across the fault lines. However, a small patch of extension with a rate of about 3.7 mm/yr between MFT and MBT can be seen in this profile. The slip rates of MFT and MBT are estimated as ~0.8 mm/yr and ~2.8 mm/yr, respectively. The low slip rate of MFT indicates a locking behavior of the thrust-fault. Nevertheless, the maximum vertical velocity between HFT and MBT reaches up to 17.5 mm/yr. Following the uplift and minor extension, this region appears to be rising upside or emerging as a new pop-up structure. However, spatial resolution of sparse GPS stations inhibits stringent conclusions on this localized deformation.

Crustal deformation by the 2019 Typhoon Hagibis: High time-resolution study

*Wei Zhan[1], Kosuke Heki[2]

1. The First Monitoring and Application Center, China Earthquake Administration, 2. Department of Natural History Sciences, Hokkaido University

Powerful typhoon Hagibis (2019 #19) which made landfall in Japan on 12 October 2019 was the one of the strongest typhoons to hit the country. In the Gulf Coast of southern USA, Milliner et al. (2018) analyzed crustal deformation using a dense network of continuous GNSS (Global Navigation Satellite System) receivers due to the stormwater load of the 2017 Hurricane Hurvey. They found ~1/3 of the total precipitation stayed on land for days and caused significant crustal subsidence. Here we study crustal deformation caused by the water load left by the 2019 Typhoon #19 Hagibis, based on the coordinate time series of the dense continuous GNSS network of Japan GEONET (GNSS Earth Observation Network) downloaded from the Univ. Nevada Reno (UNR) data base (Blewitt et al., 2018). Discussions using daily GSI F3 solution are given in another paper, Heki et al. (this session).

In this paper, we concentrate on high time resolution crustal deformation, and use the 5 min solution from the UNR data base to study sub-daily vertical coordinate changes in four regions, Izu (R1), Boso (R2), Fukushima (R3), and Jo’ etsu (R4) (Fig.1a). To reduce the noise, we calculated 1h-average and 6h-average coordinates and show their time series in Fig.lb. The station J620 (0620) in region R1 showed that the station started to subside by up to ~2 cm on 11 October, corresponding to the day of the year (DOY) 284, one day before the Typhoon Hagibis made landfall. It recovered to the original position on 12 October (DOY 285) (days and times are all in UT). Conversely, station I025 (3025) in region R2 did not show significant subsidence on 12 October. Station G176 (1176) in region R3 showed a large subsidence of 2-3 cm during 12 October. Station J820 (0820) showed a subsidence of ~2 cm over a longer duration, starting on 12 October and lasting until 13 October (DOY 286).

From these results, we can study distribution of stormwater load and its decay by draining to ocean as was done by Milliner et al. (2018) in USA. These results demonstrate that the dense GPS network is a useful sensor to understand water dynamics associated with extreme weather events with high spatial and temporal resolution.

Analyzing the Tropospheric Delay Estimates on Global Navigation Satellite Systems (GNSS) with Precise Point Positioning (PPP) Services using the goGPS software.

*Syachrul Arief[1], Kosuke Heki[1], Andrea Gatti[2], Eugenio Realini[2]

1. Hokkaido University - Sapporo, Japan, 2. Geomatics Research and Development s.r.l. - Lomazzo, Italy

The tropospheric delay is an essential source of error for positioning using the Global Navigation Satellite System (GNSS). Scientific applications of GNSS positioning such as the study of earth crust deformation and earthquake prediction require high accuracy in positioning, an analysis of tropospheric delay calculations is needed to improve the accuracy of GNSS positioning. One part of the tropospheric delay is Zenith tropospheric delays (ZTD), which are estimated using the Precise Point Positioning (PPP) method. ZTD estimates can be beneficial for meteorological applications, for example, is the estimation of water vapor levels in the atmosphere from the estimated ZTD. We use GNSS data from the BAKO station in Cibinong and JOG2 station located in Yogyakarta. The GNSS data format is an Independent Exchange Receiver (RINEX) which we extracted using the sophisticated open-source GNSS software, called goGPS version 1.0 Beta from Geomatics Research and Development s.r.l. - Lomazzo, Italy. We validate the results of the extraction process with two international tropospheric products from International GNSS Services (IGS) with commercial software Bernese version 5 and the University of Nevada Reno (UNR) with software from NASA Jet Propulsion Laboratory (JPL) namely GIPSY / OASIS II. Epoch in this study, we use days of the year (DOY) 022-025 / 22-25 January representing the rainy season and DOY 230-233 to coincide on August 17-20 representing the dry season 2018. Then we use DOY for a full month in January 2018 and August 2018 to determine the value of Zenith Wet Delay (ZWD). Our results obtained RMS values throughout DOY, both at BAKO and JOG2 stations showing small values < 2 mm. The RMS value is relatively minimal, meaning that the troposphere estimation process with goGPS shows good agreement because it is almost the same as the international troposphere product from UNR and IGS. Then the RMS values, both in January and August and the two BAKO and JOG2 stations, are relatively consistent and work well at different times and stations. ZWD values tend to be higher in the rainy season than in the dry season, which shows that ZWD can be useful for meteorological purposes.

Development of novel ground-based microwave radiometer for earth science -results of the first measurements-

*Ryuichi Ichikawa[1], Hideki Ujihara[1], Shinsuke Satoh[1], Yusaku Ohta[2], Basara Miyahara[3], Hiroshi Munekane[3], Taketo Nagasaki[4], Osamu Tajima[5], Kentaro Araki[6], Takuya Tajiri[6], Hiroshi Takiguchi[7], Takeshi Matsushima[8], Nobuo Matsushima[9], Tatsuya Momotani[10], Kenji Utsunomiya[10]

1. National Institute of Information and Communications Technology, 2. Tohoku University, 3. Geospatial Information Authority of Japan, 4. RIKEN, 5. Kyoto University, 6. Meteorological Research Institute, JMA, 7. Japan Aerospace eXploration Agency, 8. Kyushu University, 9. National Institute of Advanced Industrial Science and Technology, 10. Japan Weather Association

We have started to develop a next-generation microwave radiometer to be used in millimeter-wave spectroscopy for the high-resolution and high-precision monitoring of water vapor behavior. The new radiometer will be suitable for not only space geodetic techniques such as VLBI and GNSS, but also field measurements to monitor, for example, volcanic activities and cumulonimbus cloud generation. The planned front-end system for our new microwave radiometer has a wide bandwidth feed of 20–60 GHz. A signal from the feed is separated into two linear orthogonal polarized signals using an orthomode transducer (OMT); one is in the 20–30 GHz feed and the other is in the 50–60 GHz feed. We are now planning to cool the wideband feed, OMT, and LNA for each signal at 77 K using a Stirling cryocooler to improve the signal-to-noise ratio. We assembled a room-temperature 20–30 GHz receiver without the cooling system until the middle of 2019 as a first step of our development. We implemented the new receiver into the 3.7 m dish at Okinawa Electromagnetic Technology Center, National Institute of Information and Communications Technology (NICT), and carried out the first measurements using this receiver for validation tests in October 2019. Quick-look data obtained by the new receiver shows good power signals for the expected receiving band of 18–28 GHz. We are now developing another receiver for a higher band of 50–60 GHz, and we are going to implement the second one into the new prototype radiometer by the end of this fiscal year.

Use Delay-Doppler Map Made by Oceanic Reflected GPS Signal to Evaluate Ocean Surface Wind

*Wen-Hao Yeh[1], Yung-Fu Tsai[1], Chen-Tsung Lin[1], Hwa Chien[2], Lin Zhang [2]

1. National Space Organization, National Applied Research Laboratories, Taiwan, 2. Institute of Hydrological & Oceanic Sciences, National Central University, Taiwan

The research of GNSS-Reflectometry (GNSS-R) begins at the end of 20 century. As the first GNSS-R satellite mission, UK-DMC satellite carries an experimental payload to receive the reflected GNSS signal from ocean surface. The output of UK-DMC GNSS-R payload is Delay-Doppler Map (DDM), which is the cross-correlation results of received ocean surface reflected GNSS signal in different delay and Doppler. After UK-DMC, the follow on GNSS-R mission are TDS-1 and CYGNSS, which are the mission from UK and USA. In the second half of the year in 2021, the Taiwan built satellite of GNSS-R mission, TRITON, will be launched. TRITON also carries the Taiwan built GNSS-R payload to receive ocean refelcted GNSS signal and produce DDM. In order to retrieve the ocean surface wind from DDM, the system for DDM retrieving will be developed. In this study, the retrieval method will be introduced.

Keywords: GNSS-Reflectometry, Delay-Doppler Map, TRITON

[E] Poster | S (Solid Earth Sciences)：S-SS Seismology

[S-SS03] Seismological advances in the ocean

convener:Takashi Tonegawa(Research and Development center for Earthquake and Tsunami, Japan Agency for Marine-Earth Science and Technology), Takeshi Akuhara(Earthquake Research Institute, University of Tokyo), Pascal Audet(University of Ottawa), Taka'aki Taira(Berkeley Seismological Laboratory, University of California, Berkeley)

Seismic observations in the oceans have been steadily increasing in the last two decades due to continued deployments and recent advances in temporary arrays and permanent (cabled) networks including seismometers, hydrophones, and pressure gauges. The use of ocean data on the seafloor and in the seawater has compelled the community to create/modify data processing techniques, with exciting new findings on, e.g., seismicity, wave phenomena, seismic structures from active and passive surveys, and underwater phenomena. Some of these studies may be related to environmental seismology in the ocean. The purpose of this session is to share recent advances in seismology from data obtained in the oceans, including new seismicity and seismic velocity, progress in instrumentation, data processing on active and passive seismic approaches, characterization of ambient noise, e.g., microseisms and infragravity waves, as well as challenges in suppressing contamination from ocean-related noise.

Incoming directions of broadband infragravity waves observed at the central part of the Pacific Ocean

*Takashi Tonegawa[1], Kiwamu Nishida[2], Yoshio Fukao[1]

1. Research Institute for Marine Geodynamics, Japan Agency for Marine-Earth Science and Technology, 2. Earthquake Research Institute, The University of Tokyo

Infragravity waves (IGWs) are commonly observed at deep water, and their propagation characteristics have been investigated mainly by array analyses based on seafloor observations using seismometers and pressure gauges. Tonegawa et al (2018) revealed that IGWs at a frequency of 0.005-0.02 Hz observed at an absolute pressure gauge (APG) array with an aperture of 30 km off Aogashima Island, south of the Japanese Islands, are coming from South America in boreal summer and North and South America in boreal winter: the IGWs pass through the Pacific Ocean. To investigate the excitation and its seasonal variation of the IGWs in broadband frequency, arrays of seismometers or/and pressure gauges at the central part in the Pacific Ocean with wider apertures are useful. In this study, we used continuous records of differential pressure gauges (DPG) deployed around Hawaii islands by The Hawaiian PLUME Project to investigate IGW characteristics passing through the Pacific Ocean.

We used 22 DPGs with an array aperture of 600 km and station spacing of ~50 km. The observation periods were (1) from January 2005 to January 2006 and (2) from April 2006 to June 2007. In this study, we used the data from the first observation because the array aperture and station spacing in the first one was suitable for detecting IGWs. For continuous records, we applied a cross-correlation technique with one-bit normalization, and estimated incoming directions of IGWs using the calculated cross-correlation functions (CCFs) at frequency bands of 0.5 –1 mHz, 1–2 mHz, 2–10 mHz, and 10–20 mHz by assuming that IGWs wavefront is planar.

For the CCF, we changed the stacking time length of CCFs to detect IGW propagations. As a result, IGWs could not be retrieved in the 1-day averaged CCFs, but they emerged in the 30-day CCFs in the four frequency bands. Our results on the incoming IGW direction show that long-period IGWs (0.5–1 mHz) are coming from all directions in boreal winter and between east and south in boreal summer, while short-period IGWs (10–20 mHz) are coming between north and east in boreal winter and between east and south in boreal summer. This means that the IGW characteristics between long and short periods in boreal summer are consistent, but in boreal winter are significantly different. To investigate the excitation and seasonal variations of IGWs more details, the calculation of ray paths would be required.

Structure of the northern Hikurangi margin from receiver functions using broadband OBS data from the HOBITSS experiment

*Pascal Audet[1], Martha K Savage[2], Anne Sheehan[3], Kimihiro Mochizuki[4]

1. University of Ottawa, 2. Victoria University of Wellington, 3. University of Colorado at Boulder, 4. University of Tokyo

The HOBITSS (Hikurangi Ocean Bottom Investigation of Tremor and Slow Slip) experiment was designed to instrument the seafloor offshore northern New Zealand with absolute pressure gauges and ocean-bottom seismometers (OBS) to record an expected slow slip event on the Hikurangi subduction interface near Gisborne. The experiment was successful in recording the slow slip event, and the data yielded outstanding results showing slip to the trench (Wallace et al., 2016) as well as temporal changes in the seismic velocity structure of the overlying plate accompanying the SSE (Warren-Smith et al., 2019; Zal et al., 2020). In this work, we investigate the seismic velocity structure of the subduction zone using teleseismic receiver function data using the broadband OBS (BBOBS) stations deployed as part of HOBITSS. In total there are 10 BBOBS stations available; however, several instruments were found to have problems or did not record sufficient data for further processing (Zal et al., 2020). Here we re-examine this data set for its suitability to determine shallow crustal structure using receiver functions by first pre-processing the BBOBS data in two ways: 1) we re-orient the stations using a recently proposed method that minimizes the constant term in a harmonic expansion of tangential P-wave receiver functions near zero lag time (Lim et al., 2017). We find azimuths similar to those of Zal et al. (2020) and; 2) we remove compliance and tilt noise on the vertical component following the approach of Bell et al. (2015). Following pre-processing, we apply a standard receiver function method based on the multitaper deconvolution technique of Park and Levin (2000). We perform preliminary modeling of the receiver functions using stacks of horizontal layers (Audet, 2016; Audet et al., 2019), and find that the incoming Pacific plate can be modeled by a shallow, thin low-velocity sedimentary layer overlying a ~16 km thick crust.

Seismic interferometry analyses of teleseismic coda waves on a dense network of permanent ocean bottom seismometers (S-net) offshore Honshu, Japan

*Tomoya Takano[1,2], Florent Brenguier[1], Pierre Boue[1], Ryota Takagi[3], Kaoru Sawazaki[4], Tetsuya Takeda[4], Yosuke Aoki[2], Kiwamu Nishida[2]

1. Institut des Sciences de la Terre, Univ. Grenoble Alpes, 2. Earthquake Research Institute, The University of Tokyo, 3. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University, 4. NIED

Seismic imaging around the subducting slab where earthquakes nucleate is crucial. The S-net seismic network composed of 150 permanent ocean bottom seismometers offshore Honshu, Japan provides a unique opportunity to study the oceanic trench in one of the most active subductions. Ambient noise correlation analyses have been used to image the Earth’ s structure. However, since surface waves propagating in the thick sedimentary layer is dominant in ambient noise recorded at S-net, it is difficult to extract the waves propagating in a crustal scale structure. Here, we study the properties of cross-correlations of coda part of teleseismic earthquakes in the quest for reconstructing surface- and body-waves traveling across the network. We analyze 361 teleseismic earthquakes recorded at S-net from August 2016 to May 2019. The epicentral distances for the events range from 30 to 85 degrees. We compute cross correlations from 50 s to 300 s after the direct P arrival time. Peak arrival times of cross correlations for different station pairs depend on the source location. We therefore stack the correlations for station-pairs along a great circle path from the events to avoid the spurious phases. Stacked cross correlations show the wave packets traveling with about 8 km/s and 13 km/s, which seems to be corresponding to Pn velocity and apparent velocity of teleseismic phase, respectively. These observations might show the body waves propagating through ocean bottom stations are recovered from cross-correlation of the coda part of teleseismic events.

“N”-shaped Y/X coda spectral ratio observed for in-line type OBS of S-net and ETMC

*Kaoru Sawazaki[1], Takeshi Nakamura[1]

1. National Research Institute for Earth Science and Disaster Resilience

We detected anomalous peak and notch in spectral ratio of Y (perpendicular to cable axis) and X (along cable axis) components of coda wave in frequencies about 5 - 10 Hz and 10 - 20 Hz, respectively, for considerable number of S-net and ETMC (Earthquake and Tsunami Monitoring Cable deployed along the Sagami-Trough) OBS stations. The Y/X spectral ratio shows “N”-shape due to the peak and notch. This “N”-shape is not observed for S-net stations installed at water depths shallower than 1500 m, at which pressure vessels and cables are installed within groove in the seafloor. Seismograms of DONET are buried in the seafloor and do not show the “N”-shape, either. Considering these observations, we think the “N”-shaped Y/X spectral ratio is not caused by horizontal anisotropy below the subsurface medium, but is due to specificity of response functions of X and Y components.

We make a hypothesis that natural vibrations are excited in the pressure vessel due to insufficient coupling of cylindrical shaped pressure vessel placed on the seafloor. The natural vibrations are excited if longitudinal (X component) and transverse (Y component) guided waves incident from both ends of the pressure vessel via connected cables. Depending on the length L of the pressure vessel, these two types of natural vibrations have natural frequencies given by $f_X=V_P/2L$ and $f_Y=V_S/2L$, and relationship given by $f_X/f_Y=V_P/V_S$ is established. Considering that observed notch and peak frequencies correspond to f_X and f_Y, respectively, observed ratio of notch/peak frequencies are around 1.5 to 3 and the ratio seems to be reasonable for V_P/V_S of pressure vessel. Also, since the length L is 2.3 m and 1.6 m for S-net and ETMC, respectively, f_X and f_Y of ETMC are expected to be 1.4 times higher than that of S-net: it is actually found in the observed spectral ratio. Not only guided waves but also S-coda wave incidents from coupling zone and vibrates the pressure vessel. If coupling is sufficient, energy of S-coda wave will be much stronger than guided waves and natural vibrations of pressure vessel will become invisible. We think this is the reason why DONET and shallow S-net stations do not show “N”-shaped Y/X spectral ratio.

The “N”-shaped Y/X spectral ratio is likely to be specific to in-line type OBSs having cylindrical pressure vessel placed sideways. Enhancing coupling with seafloor by underwater technologies such as installation within groove and burial would be effective to suppress the emergence of natural vibrations in the pressure vessel. Users of in-line type OBS record without sufficient coupling are recommended to correct response functions of X and Y components if necessary, especially when using frequencies above about 3 Hz.

Spatiotemporal Variations of PM Excitation in the Northern Okinawa Trough Revealed by OBS Array

*Chih-Chieh Chien[6], Ying-Nien Chen[3], Yuancheng Gung[6], Ban-Yuan Kuo[1], Shu-Huei Hung[6], Eh Tan[1], Kate Huihsuan Chen[5], Shuichi Kodaira[2], Yasushi Ishihara[2], Mamoru Nakamura[8], Chau-Chang Wang[4,7], Ching-Ren Lin[1]

The amplitude asymmetry between the causal and acausal signals of noise cross-correlation functions (NCFs) is closely related to the characteristics of the source excitations of ambient noises. In this study, we explore the spatiotemporal variations of the primary microseism (PM) excitations in the Northern Okinawa Trough using the data recorded by a newly deployed array in this area. The seismic array, composed by 32 ocean bottom seismometers (OBSs), was deployed from September, 2018 to June, 2019. With the recorded continuous data, we first compute NCFs of the Z-Z component for each station pair. During the calculation, the signal is whiten in frequency. The spectra of the resulting NCFs indicate that the major energy is dominated by PM (10 –20 s) energy, and the amplitude asymmetry in NCFs also suggests that there are strong spatial variations in its source excitations. We then apply the migration technique to image both the spatial and temporal distributions of the contributed PM sources. Such an approach is also applied to examine its temporal variations by taking a shorter term (monthly) stacking of NCFs. The results suggest that the strong PM sources are located around the offshore in Kyushu, and it is more energetic during the spring.

Rayleigh wave ellipticity estimated from earthquake and noise cross-correlations of OBS data: Effect of ocean and sedimentary layers.

*Shun Fukushima[1], Kiyoshi Yomogida[2]

1. Hokkaido University,Graduate school of Science,Department of Natural History Sciences,Seismology Laboratory , 2. Department of Earth and Planetary Dynamics, Graduate School of Science, Hokkaido University

The ellipticity of Rayleigh waves can be used to infer shallow seismic structures.
Recent development of OBS stations such as S-net and DONET now enables us to measure the ellipticity of Rayleigh waves in detail. Boundary conditions of OBS are different from land observations, in addition to soft ocean bottom sedimentary layers, but their influence on the ellipticity has not been well studied yet. In this study, we numerically calculated the ellipticity on the seafloor with several models. We also measured V/H values of earthquake data recorded by DONET as well as ambient noise data recorded by S-net .
Phase velocity decreases with a period of about 20 seconds when there is a sedimentary layer, in the observation on land while their ellipticity is small, because the horizontal motions get large due to a low-velocity layer on the surface. In contrast, the ellipticity on sea bottom becomes large in a period range from 10 to 40 seconds, whose character gets stronger as the period shorter. Unlike the case of the sedimentary layer on land, only the vertical component selectively increases because there is a layer with only P wave above the observation point (i.e., sea water) . In the case of including a sedimentary layer on the ocean floor, the ellipticity is reduced as in the case of land, and the effect of the vertical enhancement is suppressed. As a result, there is some possibility of a large V/H observed on a seafloor, even with the existence of a soft sedimentary layer.
Next, we measured V/H values on the sea floor with two different approaches: ambient noise and signals from earthquakes. We processed the ambient noise recorded by S-net stations. We took cross-correlations of records at two selected stations: 1-day in each record length with 2-40 sec bandpass filtering and one-bit processing (e.g., Bensen et al., 2007). Cross-correlations among stations perpendicular to the trench axis clearly show surface wave signals with relatively good symmetry of causal and anti-causal waveforms in the period range from 4 to 8 sec. Their group velocity is very small, about 0.2-0.3 km/s. This signal probably correspond to Scholte waves. Scholte waves propagate parallel to the water-sediment interface, when the shear velocity of the solid is lower than the compressional velocity in the water (1.5 km/s). V/H spectral ratios observed by ambient noise data of S-net stations are dominant in the horizontal component, in the case that the P-waves velocity of the sedimentary layer is slower than that of the ocean, then P-wave in the ocean can't propagate in the vertical direction. In other words, V/H ratio of a too slow sedimentary layer is not affected by the existence of the ocean. In addition, we picked up Rayleigh-wave signals recorded at DONET stations for several earthquakes in the ocean with epicentral distance of 500 ~ 1300km. Their V/H ratios are relatively large, unlike the results of ambient noise, that is, the vertical component is dominant in period of 5 ~ 25 sec, as our calculations predict.
Since we have the precise information on the ocean depth (and P-wave velocity) at every point of the studied area, the recorded V/H ratios will help us to estimate S-wave velocity structure near the ocean bottom including a very soft sedimentary layer with the correction of the effect of the sea mater.

A Temporal Variation of Auto-correlation Function Calculated from Ocean Bottom Seismometers off Miyagi Prefecture

*Miyuu Uemura[1], Yoshihiro Ito[2], Kazuaki Ohta[3], Ryota Hino[4], Masanao Shinohara[5]

1. Graduate School of Science, Kyoto University, 2. Disaster Prevention Research Institute, Kyoto University, 3. National Research Institute for Earth Science and Disaster Resilience, 4. Graduate School of Science, Tohoku University, 5. Earthquake Research Institute, University of Tokyo

Seismic interferometry is one of the most effective techniques for detecting temporal variations in seismic velocity caused by a megathrust earthquake or a slow slip event (SSE). A lot of previous studies reported the temporal variations caused by megathrust earthquakes or SSEs (e.g. Wegler et al., 2009; Zhen and Song, 2009; Rivet et al., 2011; Sawazaki et al., 2016; Nimiya et al., 2017; Ikeda and Tsuji, 2018). We had evaluated temporal variations in seismic velocity with auto-correlation functions (ACFs) calculated from ambient noise recorded by ocean bottom seismometers (OBSs) installed near the Japan trench off Miyagi Prefecture (Uemura et al., 2018). As a result, we had pointed the velocity decrease caused by the 2011 Tohoku-oki earthquake (Mw. 9.0) and possible velocity fluctuation during SSE preceding the 2011 Tohoku-oki earthquake. However, because some of similar velocity fluctuations had been also detected without any megathrust earthquakes and SSEs, it was difficult to conclude that the fluctuation caused by the SSE.
To reveal causes of such temporal variations in ACF calculated during some of periods without any megathrust earthquakes and SSEs, we try to evaluate temporal variations in ACF calculated from 5-year data (from 2008 to 2012) in the same region. The result shows two interesting characteristics of some temporal variations in ACF. One is that ACFs have obviously annual variation which was detected only near the Japan trench. Another is that temporal variations in some specific phases on ACF are commonly detected in the whole study area. We will discuss what causes the annual variation on ACFs and their temporal variations in the specific phases.

Similar earthquake activity in the northern part of the Ryukyu subduction zone observed by onshore and offshore seismic data

*Yukihiro Nakatani[1], Hiroshi Yakiwara[1], Shuichiro Hirano[2], Reiji Kobayashi[2], Hiroki Miyamachi[2], Shigeru Nakao[2], Yusuke Yamashita[3], Kazunari Uchida[4], Takeshi Matsushima[4], Hiroshi Shimizu[4], Kazuo Nakahigashi[5], Tomoaki Yamada[6], Hideji Abe[7], Masanao Shinohara[7]

Disaster Prevention Research Institute, Kyoto University, 4. Institute of Seismology and Volcanology, Faculty of Science, Kyushu University, 5. Tokyo University of Marine Science and Technology, 6. Japan Meteorological Agency, 7. Earthquake Research Institute, the University of Tokyo

In the northern part of the Nansei Islands, regular and slow earthquake activities associated with subduction of the Philippine Sea plate have been observed by onshore seismic and geodetic network. By contrast, no earthquakes with magnitude 7 or more have occurred since the 1911 Kikaijima earthquake of magnitude 8.0. In comparison with other subduction zones around Japan, spatial patterns of regular and slow earthquakes and relationship between seismic gaps and past large earthquakes are less well understood in this region. The biggest reason is due to observational constraints; seismic stations are located only at the islands that are linearly arranged along the arc and far away from the Ryukyu Trench. We have conducted annual repeating long-term ocean bottom seismographic observation off the northern part of the Nansei Islands over the past five years. By integrating six ocean bottom seismometers data with station interval of 40-60 km, the accuracy of hypocenters, especially in focal depths, has been improved and geometry of the subducting plate interface is becoming clear. In addition, shallow low-frequency tremors have been also detected which may show a complementary spatial distribution to active seismic regions.
In this study, we investigate similar earthquakes which occur along the plate interface using both onshore and offshore seismic data. In order to obtain small-magnitude offshore earthquakes, we apply a matched-filter technique to continuous waveform data. As a result of the year 2017, we identify three types of similar earthquake families; repeating-type, burst-type, and mixed-type. These similar earthquake families occur at around 20 km depth of the plate interface. This result suggests the similar earthquake activity locates on the down-dip side of the observed tremor activity. In this presentation, we extend the analytical period and discuss the characteristics of the similar earthquake families.

Spatiotemporal distribution of fin whale signals in northeast Japan

*Takeshi Nakamura[1], Ryoichi Iwase[2]

1. National Research Institute for Earth Science and Disaster Resilience, 2. Japan Agency for Marine-Earth Science and Technology

We investigated spatiotemporal distributions of whale signals observed by ocean-bottom seismometers of S-net (Seafloor observation network for earthquakes and tsunamis along the Japan Trench) deployed in and around the source area of the 2011 Tohoku earthquake.

We used velocity waveform data from 2017 to 2019. We found characteristic signals with the spectral peak in narrow frequency bands of 14-25 Hz that are different with typical bands of seismic waves and T-phases. The signals have a short duration of about 1 second and are repeatedly found at regular intervals of several tens of seconds. These features are consistent with those of acoustic signals from fin whales as shown in hydroacoustic and seismic observation data by previous studies (e.g., Watkins et al., 1987; Sciacca et al., 2015). We thus assume that the characteristic signals observed at S-net stations are ones associated with fin whale activities.

We developed a detection system that automatically picks the signals of the activities from continuous seismic data. Most of the signals detected by this system are found at stations off Kushiro and Aomori areas from early fall to spring months. The signals are also detected at stations deployed in the outer rise area. In summer months, however, these are not clearly found at all stations. Our results also show that the migration of the signals among the stations from the northeast to southwest direction is found during winter. From analyzing the three-year data, these features are repeatedly seen every year. Considering whale sighting survey results that fin whales are abundant in high latitude areas during warm months and low latitude areas during cold months (e.g., Edwards et al., 2015), such spatial and seasonal variations of the detected signals shown in this study probably associate with the migratory behavior of fin whales. At some stations, we also find the rotation motion in horizontal components during several minutes or hours, which would be also caused by the migration around a station.

We suppose that integrated scientific studies across marine ecology to geophysics using S-net data could contribute to developing our understandings of various signal sources observed in ocean-bottom areas and of ecological behavior of marine mammals.

After the 1995 Hyogoken-Nanbu (Kobe) earthquake, many records from nationwide strong-motion observation networks such as K-NET have been accumulated and released to the public, and have been widely used in the seismology and earthquake engineering. Under such circumstances, many research groups have proposed improved strong-motion prediction methods, such as ground-motion equations, based on the observed records. However, strong-motion databases have been constructed independently by individual research groups. As a result, the moment magnitude and the source fault model used are differ among research groups even if the same earthquake. For this reason, there is no strong-motion database in Japan at present to systematically develop a strong-motion prediction method and objectively verify the validity of the method.

To overcome this situation, we constructed a prototype strong-motion database consisting of K-NET and KiK-net records (about 1 million). As the source data (about 17,000 events), not only the hypocenter location and magnitude by Japan Meteorological Agency, but also the moment tensor parameters determined by F-net, NIED were registered. In addition, some source fault models by SRCMOD (Mai and Thingbaijam, 2014) were also registered. As the station data, site codes, location, and underground structure information were registered. We registered not only the average S-wave velocity up to 30m depth (Vs30) obtained from the PS logging data, the Vs30 from the engineering geomorphological classification and information on the deep sedimentary layers model by J-SHIS of NIED. Peak acceleration, peak velocity, instrumental seismic intensity, and 5% damped acceleration response spectrum (59 points with a period from 0.02 to 20 seconds) were registered as strong-motion data. For horizontal component, not only the amplitude of each of the two orthogonal components (NS, EW), but also RotD0, RotD25, RotD50, RotD75, and RotD100 were registered. We also registered vertical component.

In the future, we will add and expand data from other organizations such as Japan Meteorological Agency and overseas, and ground motion simulation data. Technical issues such as distinction of earthquake types (crustal, subduction inter-plate, and subduction intra-plate), selection of source fault models, and procedures to remove noise data remain. At the same time, efforts should be made to establish a framework for updating and maintaining the database.

Tilt and rotational motions during the strong shaking

*Toshimi Satoh[1]

1. Shimizu Corporation

Satoh (2019) showed that some velocity time histories by integrating acceleration records of vertical components have linear trends to the downward direction then become almost flat using mainly KiK-net records. Satoh (2019) defined the absolute flat value as Vnon. In this study we estimate Vnon from vertical components of K-NET, KiK-net, JMA and local government strong motion records with PGAs of larger than 300 cm/s^2. The velocity time histories of horizontal records with large Vnon have linear trends during the strong shaking except for records with the largest Vnon at Chokubetsu (HKD086) of the 2003 Tokachi-oki earthquake. In other words, acceleration records of horizontal components have step functions. Therefore, we also estimate the tilt angles and the rotational angles in the horizontal plane using the step values of horizontal components of records with Vnon greater than 1 cm/s.

NIED showed by the site investigation at HKD086 after the 2003 Tokachi-oki earthquake that the foundation of the seismometer had floated up accompanied with the tilt and rotation due to the liquefaction. Since the existence of Vnon suggests the settlement of the ground, the floating up occurred after the strong shaking, that it, post-liquefaction. The velocity time histories of horizontal components at HKD086 have curved trend. This result indicates that the tilt and rotation of the ground is changing during the strong shaking. For comparison, array records observed at Port Island during the 1995 Hyogo-ken Nanbu earthquake are analyzed. The velocity time history of the vertical component at the ground surface has no Vnon. Since the liquefaction intaneously occurred and excess pore water pressure ratio kept 100 % during the strong shaking (Kawase et al.,1998), it is thought that the consolidation settlement did not occur during the strong shaking. On the other hand, duration of records at HKD086 are long and so the dissipation of the excess pore water pressure is considered to occur during the strong shaking. The velocity time history of vertical component observed at the depth of 16 m at Port Island has the linear trend to the upward direction then becomes almost flat. This phenomenon may occur by the floating up due to upward seepage flow by liquefaction.

Many records with large Vnon are observed at special soil, such as volcanic clayey soil or high organic soil and the particle orbits on the horizontal-vertical plane show tilt or rotational motions. Some records with large Vnon have been pointed out the increase of the excess pore water pressure by previous studies. The record at Kushiro observed by JMA during the 1993 Kushiro-oki earthquake has large Vnon and the predominant frequency of vertical motion is twice of horizontal components. On the other hand, the record at Kushiro observed by BRI 50m away from the JMA Kushiro with smaller ground motions than JMA Kushiro has no Vnon and the vertical motion dose not dominant at twice of the peak frequency of horizontal components. The feature that vertical motions with very large Vnon are twice of predominant frequencies of horizontal motions has been pointed out as the negative dilatancy of dry soil by experimental and analytical studies. Therefore, the difference of strong motions at two statins can be interpreted by the difference of nonlinear site responses with and without the negative dilatancy.

The directions of tilt estimated from the linear trends of horizontal velocity time histories in the near-fault regions are almost radial and the tilt starts at S-wave potions. The tilt angles are much larger than tilt angles of the crustal deformation due to source processes. We interpret from these results that the tilt and rotational motions are caused by the increase and dissipation of excess pore water pressure or the

Analysis of pulse-like waves observed in the eastern part of Fukushima Prefecture during the 2011 Tohoku earthquake

*Tomiichi Uetake[1], Kazuhito Hikima[1], Akihito Shimmura[1], Masatoshi Fujioka[1], Ryosuke Sugimoto[1]

1. Tokyo Electric Power Company Holdings

1. Introduction

Strong motion records from the 2011 off the Pacific coast of Tohoku Earthquake (M9) were obtained over a wide area, and the waveform characteristics differed from region to region. In the records obtained in Fukushima Prefecture, several large pulse-like waves were observed. These pulses are considered to generated at the strong motion generation area (SMGA) existing on the fault plane, and source models considering multiple SMGAs has been proposed [e.g. Asano and Iwata (2012) , Kurahashi and Irikura (2013)]. There is also a study confirming the correspondence between pulse waves and high-frequency excitation sources on the fault plane by array analysis [Aoki et al. (2012)]. In this study, we focus on many strong motion records obtained in the eastern part of Fukushima prefecture, and examine the propagation and shape change of the pulse-like waves.

2. Records and target waves

In the eastern part of Fukushima Prefecture, many strong motion records have been obtained by K-NET, KiK-net and the seismic intensity meters. In this study, the velocity waveforms integrated from the acceleration records were used for the examination. A high-pass filter with a lower frequency limit of 0.05 Hz was applied during integration, but for records with poor signal to noise ratios in the lower frequency range, the lower limit frequency was raised to 0.1 Hz or 0.2 Hz. The figure shows the velocity waveform (EW component) of the stations along the coastline. In the velocity waveform, a plurality of pulse-like wave groups with different apparent periods are confirmed. In this study, the pulse-like wave that gave the maximum velocity at the FKSH20 was targeted.

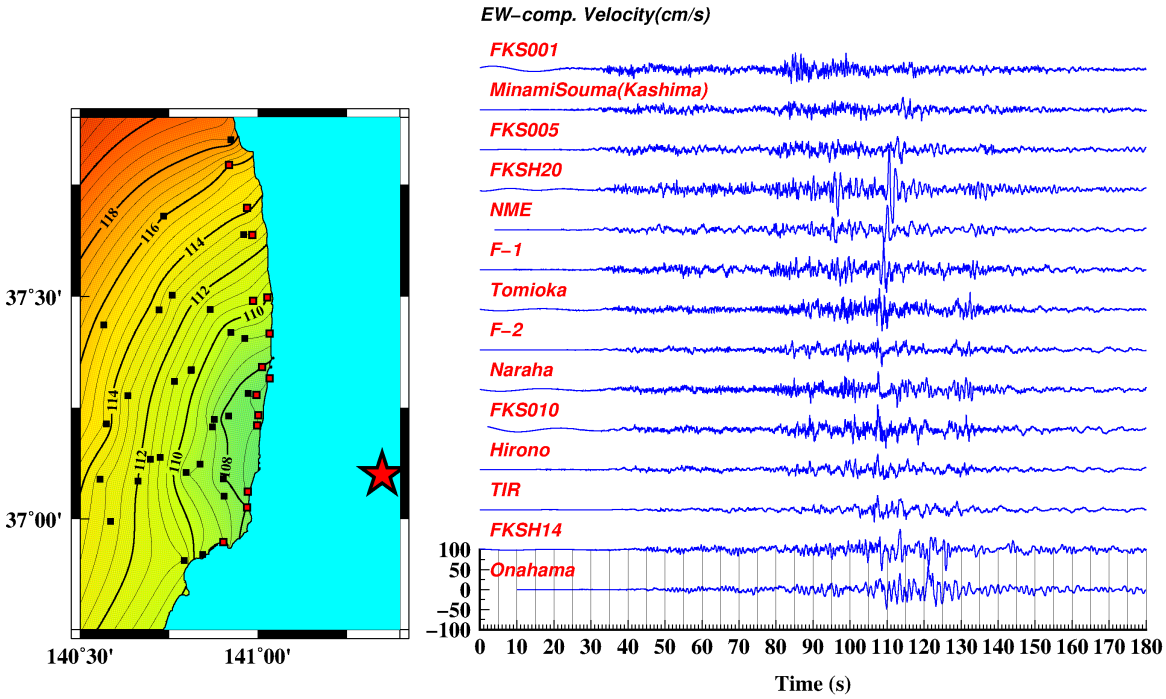
3. Propagation characteristics of target waves

From the temporal continuity of the wave groups at adjacent observation stations, the target waves were detected along the coastline from north to south of Fukushima Prefecture. On the inland side, pulse waves can be recognized in a wide area of Abukuma Highland. The source of pulse-like waves estimated from the isochron using the JMA2001 travel-time table[Ueno et al. (2002)] was shown as the star mark (141.35 E, 37.10 N) in the figure. This position is close to the SMGA estimated by Kawabe and Kamae (2013).

4. Characteristics of target waves

Focusing on the shape of the pulse-like waves, it was a triangular shape at FKS010 and several stations close to SMGA, but a sine shape was clear at the stations a little away to the north along the coastline. The dominant frequency of the pulse wave part was about 0.5 Hz. On the south side of FKSH14 along the coast line, another wave group overlapped on the target waves. On inland side, the dominant frequency of the pulse shifted to higher frequencies and the amplitude of the pulse decreased. The largest amplitude of the target pulse wave was recorded at the station a little away from SMGA and the amplitude is different at the observation stations on the isochron. The amplitude variation of the pulse cannot be explained by a simple attenuation relation. It is considered that the site factors greatly influence the variation of wave characteristics including the amplitude.

©2020. Japan Geoscience Union. All Right Reserved.



5. Conclusions

The propagation characteristics and shape variation of pulse-like waves observed in the eastern Fukushima Prefecture during the 2011 Tohoku Earthquake were investigated. Judging from the isochron of pulse-like waves, it was propagated from the SMGA off the east coast of Fukushima Prefecture. Also, considering the spatial change of the shape and amplitude, it is considered that site characteristics have a strong influence.

Ground Motion Estimation from the Initial P Wave of the Great Earthquake

*Zijun WANG[1], Boming ZHAO[1], Takao KAGAWA[2], Masanori HORIKE[3]

1. Beijing Jiaotong University, 2. Tottori University , 3. Hanshin Consultants Co., Ltd.

We proposed a quick method to estimate the site ground motion using the initial P wave from a single station. First, the ground motion estimation technique from the first 3-second P wave spectral intensity ($SI_{(3s)}$) was presented; meanwhile the peak amplitude of displacement (P_d) and the integral of the squared velocity (IV2) were selected as comparisons. With the aftershocks of the 2008 Ms 8.0 Wenchuan earthquake, we investigated the regression relationships between these 3 parameters and ground motion parameters (the peak ground acceleration, peak ground velocity and spectral intensity), based on which the ground motion estimation formulas were derived accordingly. The results showed that the proposed $SI_{(3s)}$ was of the highest accuracy with regard to the PGA estimation. Aiming at large magnitude earthquakes i.e. the Wenchuan main-shock, we put forward to introduce an amplification coefficient to revise the characteristic parameters in advance to predict the ground motions, thus the underestimation of great earthquakes could be mitigated to a certain extent.

Damage Hazard Caused by the Great Earthquake Ground Motion

*Boming ZHAO[1], Zijun WANG[1], Takao KAGAWA[2], Masanori HORIKE[3]

1. Beijing Jiaotong University, 2. Tottori University, 3. Hanshin Consultants Co., Ltd.

Given the fact that the degree of structural damage caused by earthquakes depends both on the characteristics of strong ground motions and the anti-seismic performance of structures, we collected and processed the sufficient observation-based data of the Wenchuan earthquake, from which the corresponding ground motion parameters to the 10 targeted districts were derived by the methods of interpolation and attenuation curves. We then established the vulnerability curves between the damage ratios (DRs) and the peak accelerations, peak velocity, peak spectrum acceleration as well as spectrum intensity. In addtion, an effective method for estimating the structural damage levels by using the fragility curve between DR and PGA $/a_F$ was proposed to eliminate the deviation in the design forces for these structures, which can provide important benefits for the structural damage studies. We showed that the reasonable seismic fortification plays a decisive role in improving buildings' anti-seismic performance, that based on the improved "Code for Seismic Design of Buildings", the predicted DRs for the 10 targeted districts can be reduced significantly compared with the actual damage they were suffered.

Disaster mainly of stone torii by the Yamagata Offshore Earthquake in 2019

*Takayuki Kawabe[1]

1. Ex. Faculty of Education, Arts and Sciences, Yamagata University

A large earthquake 6.7 Mj(according to JMA), called the Yamagata-ken Oki jishin (Yamagata Offshore Earthquake), occurred on 18th June 2019 at 22:22 JST, offshore of Yamagata Prefecture, northwest Japan. There is few human damage luckily, but damage of less than 800 houses occurred near the epicenter around the border of Yamagata and Niigata Prefectures.
Maximum seismic intensity is 6 upper in northern margin of Murakami City, Niigata Prefecture and the second largest seismic intensity if 6 lower in southern margin of Tsuruoka City, Yamagata Prefecture. According to JMA Estimated seismic intensity map. Seismic intensity decreases as moving farther away from the epicenter.
The Author made a survey of damage of stone toriis by the earthquake distributed in Tsuruoka City and northern part of Murakami City. According to prior research of Kawabe (2007) which surveyed damage of 250 stone toriis in Noto Peninsula, direction of strong seismic movement can be provided from the positions of damage of the stone torii as shown in Fig. 1, and converted seismic intensity can be converted from total damage points of individual point of individual place shown as Table 1 and 2.
According to the result of the survey of 135 stone toriis shown in Fig.2, distribution of converted seismic intensity is resembles generally JMA estimated seismic intensity map. but values of converted seismic intensity of several points in Murakami City are larger than JMA estimated seismic intensity. This may be caused by the difference of the calculation method of two seismic intensity. That is, converted seismic intensity depends on pulsed strong motion and JMA estimated seismic intensity depends on the amplitude and fr3equency of seismic wave.
Calculated directions of strong motion of stone toriis in northern Tsuruoka City show the direction to the epicenter, though the directions of strong motion in most of surveyed area direct diagonally to the epicenter. This difference may be caused by the geology of the Neogine non-concrete sediments in northern Tsuruoka City and of rigid granitic rocks in other area.

Source inversion using empirical Green's functions for the 2019 Off Yamagata earthquake (Mj 6.7)

*Yoshiaki Shiba[1]

1. Central Research Institute of Electric Power Industry

During the 2019 Off Yamagata earthquake on June 18, JMA seismic intensity scale of 6 upper was recorded at maximum on Niigata Yamagata border region. Further even at the strong-motion station on the bedrock, seismic intensity of 5 lower was observed, which is located on the epicentral distance of 16 km. Aftershocks distribute on the area north of the 1964 Niigata earthquake (Mj 7.5) fault region, so that the relation of the slip area of both events should be focused. In this study the inversion method using empirical Green's functions is adopted for the source modeling of the 2019 Off Yamagata earthquake and estimated model is compared with the slips during the 1964 Niigata earthquake.
From the aftershock distribution and CMT solution of the main shock estimated by F-net, we assumed the reverse fault plane model with the strike in the N40E direction and the south-east dipping with 30 degrees. This fault plane model has the conjugate relation with that of the 1964 Niigata event adopted by Shiba and Uetake (2011). Observed records from the aftershock of Mj 4.0 occurring near the hypocenter of the main shock were used for the empirical Green's functions. Velocity motions of two horizontal components for KiK-net subsurface stations, K-NET stations and one bedrock station operated by CRIEPI (RK-net) are used for the source inversion in the frequency range up to 2 Hz. The spatial distribution of the seismic moment density, effective stress, rise time and rupture time on the fault plane are estimated simultaneously by using the simulated annealing, which is one of the heuristic search techniques.
The obtained source model indicates large slips mainly in the north east area apart from the hypocenter, which corresponds to the region just outside the fault plane of the 1964 Niigata earthquake. The distribution of the effective stress roughly coincides with the slip distribution. Peak slip and effective stress reach 1.0 m and 14.2 MPa respectively. On the other hand, the rise time distribution does now show obvious correlation to other source parameters, which might be due to the low resolution at the low frequency range. The rupture front propagates almost concentrically, but slightly accelerates on the high effective stress area. It suggests the increase of surface energy with high stress drop contributes the acceleration of rupture velocity on asperity or SMGA.

Source rupture process and strong motion generation areas for the 2018 Hokkaido Eastern Iburi earthquake

*Kazuhiro Somei[1], Ken Miyakoshi[1], Yujia Guo[1]

1. Geo-Research Institute

The 2018 Hokkaido Eastern Iburi, Japan, earthquake (M_w 6.6) occurred at a depth of 37 km, which is provided by Japan Metrological Agency (JMA), in western part of the Hidaka arc-arc collision zone. This earthquake caused strong ground motions with a maximum seismic intensity of 7 in the JMA scale and a maximum peak ground acceleration of over 1000 cm/s^2. In order to understand the mechanisms of generating the broadband strong ground motions during this earthquake, we estimate the spatio-temporal source rupture process based on the waveform inversion using strong motion data, and also construct the characterized source model consisting of Strong Motion Generation Areas (SMGAs) through the broadband ground motion simulations around the source area. To reveal the rupture process, we employ the multi-time window linear waveform inversion by using the strong motion waveforms (0.05-0.5 Hz) recorded around the source area. A curved source fault with a variation in strike angle is assumed by referring the relocated aftershock distribution. The theoretical Green’s function is computed assuming a 1D velocity structure model for each station. The SMGAs are estimated on the basis of forward ground motion simulation in broadband frequency range from 0.2 to 10 Hz using the empirical Green’s function method.

From the results of these source models and ground motion simulation, our principal findings are following. 1) The main large ground motions observed at near-source stations were generated by the up-dip rupture in the large slip area (i.e., the asperity area) identified at the depth shallower than the hypocenter, which coincides with the position of the SMGA1. 2) The SMGA2 and 3 played a key role to generate the observed later phases, which are not explained enough only by the SMGA1 or asperity area. 3) The estimated stress drop or short-period level, which control the high-frequency ground motion radiations, were larger than the average value of past large crustal earthquakes usually occurring in Japan. These findings are important to understand the source characteristics of the earthquakes occurring at deep depth in arc-arc collision tectonic zone.

Acknowledgements: The strong motion data from K-NET, KiK-net, and F-net were provided by the National Research Institute for Earth Science and Disaster Resilience (NIED). We also used the strong motion data from the seismic intensity observation networks of the JMA, Moment tensor solutions were routinely determined by F-net. The JMA unified earthquake catalog was produced by the JMA in cooperation with the Ministry of Education, Culture, Sports, Science and Technology (MEXT). This study was based on the 2019 research project “Examination for uncertainty of strong ground motion prediction for inland crustal earthquakes” by The Secretariat of the Nuclear Regulation Authority (NRA), Japan.

Conjugate fault model of the 2018 Anchorage, Alaska, intraplate earthquake (M_W 7.1) based on strong-motion waveform inversion

*Yujia Guo[1], Ken Miyakoshi[1], Masato Tsurugi[1]

1. Geo-Research Institute

The Anchorage, Alaska, earthquake (M_W 7.1) on 30 November 2018 occurred in the upper part of the Pacific plate or Yakutat microplate subducting beneath the North American plate. A relocated aftershock distribution (Ruppert *et al.*, 2020) and moment tensor solutions (Richards, 2019; West *et al.*, 2020) suggested the possibility that this earthquake was a rare intraplate event with conjugate source faults. Based on this possibility, we performed a source inversion using strong-motion waveforms at periods of 2.5–20 s and investigated the source characteristics of this earthquake.

The source inversion was performed using the multi-time-window linear waveform inversion method (Hartzell and Heaton, 1983). The assumed conjugate faults consist of a gently east-dipping (strike = 5˚, dip = 30˚) fault and a steeply west-dipping (strike = 185˚, dip = 60˚) fault. The hypocenter was located on the former. The Green's functions were calculated by the discrete wavenumber method (Bouchon, 1981) and the reflection/transmission coefficient matrix method (Kennett and Kerry, 1979). For the calculations, 1D seismic velocity structure models (Dutta *et al.*, 2007; Eberhart-Phillips *et al.*, 2019) were adjusted using waveforms of an M_W 5.0 aftershock.

Our inversion estimated the seismic moment, average slip, and maximum slip to be 5.91×10^{19} Nm (M_W 7.11), 0.97 m, and 2.7 m, respectively. Two large slips were estimated on the steeply west-dipping fault and the deeper part of the gently east-dipping fault, respectively. Because the rupture initiated on the gently east-dipping fault, we also tested an inversion without assuming the steeply west-dipping fault. The test result showed that, compared with the inversion with assuming the steeply west-dipping fault (i.e., the large slip on the steeply west-dipping fault), the inversion without assuming could not sufficiently reproduce the waveforms observed at the stations on the northern and western sides of the source region. The necessity of the steeply west-dipping fault was also reported by the analyses of teleseismic body waves (Liu *et al.*, 2019) and GPS static displacements (West *et al.*, 2020).

Although this earthquake was a rare event with conjugate faults, the source scaling relationships of its source parameters (e.g., average slip, entire rupture area, and large slip area) to the seismic moment were consistent with the empirical relationships derived by Iwata and Asano (2011) and Allen and Hayes (2017). This consistency was found for the 2016 Iniskin, Alaska, intraplate earthquake (M_W 7.1), but not for the 2017 Puebla intraplate earthquake (M_W 7.1), which occurred in the Cocos plate beneath the central Mexico and severely damaged the Mexico City (Guo *et al.*, 2019). In spite of the same M_W of these recent earthquakes, the difference between Alaska and central Mexico implies that the source parameters of intraplate earthquakes have regional characteristics.

Acknowledgements: Strong-motion waveform data were downloaded from the data management center of the Incorporated Research Institutions for Seismology. This study was based on the 2019 research project "the methodology of ground motion prediction for megathrust earthquakes" by the Nuclear Regulation Authority, Japan.

An idea to extract effective fault size from a slip distribution estimated by inversion analysis

*Kazuhito Hikima[1], Akihiro Shimmura[1]

1. Tokyo Electric Power Company Holdings, Inc.

- Objective -

Fault length and width (also fault area of those multiplication) are the basic and important parameters for source information. In recent decades, these parameters are estimated by inversion analyses using observed data in most cases. When the source process inversions are performed using, for example, waveform or geodetic data, larger fault area than true area is set first. Therefore, we have to perform additional operations to extract real fault area from the derived slip distribution.

As such a method, Somerville *et al.* (1999) proposed a method in that marginal rows or columns having relatively small slips are trimmed from inverted slip distributions and rectangular main area is extracted. Mai and Beroza (2000) and Thingbaijam and Mai (2016) also proposed other methods which estimate effective source dimensions based on autocorrelation width of the spatially variable slip. Many authors have discussed source scaling relations using the parameters estimated in such a way. However, the roughness of estimated slip distributions (the amplitude of spatially variation) tends to differ depending on the analysis methods and analysts. Furthermore, it is some problem that the distinct and physically clear criteria are not determined to extract main slip area from those results.

Therefore, we considered a procedure to extract a rectangular effective fault area based on wavenumber spectra of slip distribution, considering more physical validity.

- Method -

Analyses considering wavenumber spectra of slip distributions have been already discussed by, for example, Somerville *et al.* (1999). We also calculate two-dimensional wavenumber spectrum of subject fault model as same as their procedure. The steps now adopted are follows.

First, a slip distribution at 1 km intervals for length (X-direction) and for width (Y-direction) is made from an original spatially variable slip. Then, zero values are added outside of the fault area to make 256 x 256 size data set. Amplitude wavenumber spectra of these data are calculated using two-dimensional FFT. For these spectra, we consider that the wavenumber spectrum at k_y=0 (k_y: wavenumber for Y-direction) is in length direction and the spectrum at k_x=0 (k_x: wavenumber for X-direction) is in width direction, respectively.

On the side, Fourier transform of a rectangular function having width as L is $f(\nu)=L\sin(\pi L \nu)/(\pi L \nu)$ [$\nu=1/\lambda$; λ: wavelength]. As well known, this sinc function crosses with zero line at n=n/L [n=1, 2, ⋯], and these correspond to trough of the spectrum in the case of amplitude spectrum.

To determine fault length, we basically fit this sinc function with the spectrum at k_y=0 in length direction previously obtained. However, the calculated spectrum becomes irregular curve actually due to its slip distribution. Therefore, only lower part than first trough (it corresponds to n=1) of sinc function is used for fitting operation. And we placed emphasis on lower wavenumber part especially. Additionally, we apply the same means to the spectrum at k_x=0 in width direction to determine fault width.

- Result -

We performed preliminary analyses using the fault models in the SRCMOD (Mai and Thingbaijam, 2014). Although goodness of fitting is evaluated visually, in the current procedures, the optimal dimensions can be determined with the error lower than a few km. Thingbaijam *et al.* (2017) estimated the fault length

©2020. Japan Geoscience Union. All Right Reserved.

and width by using their ways and have listed in the paper. The lengths determined by our methods were almost comparable with their values. However, we also recognized that some models show somewhat smaller length than published one. To pursue causes of these results, we performed a model calculation using synthetic fault model having asperity. As a result, the tendency that estimated area become smaller than whole fault area was found, depending on the conditions. It is thought because proposed method estimates an equivalent rectangular fault area with considering the slip distribution.
We would like to report on the features of the method after further considerations, also including comparison with other methods.

Estimation of subsurface structure based on microtremor and gravity observation in Shigaku area, Mt. Sanbe, Shimane Prefecture, Japan

*Tatsuya Noguchi[1], Yutaro Itohara[1], Mayuko Kuya[1], Isamu Nishimura[2], Takao Kagawa[1]

1. Faculty of Engineering, Tottori University, 2. Graduate School of Engineering, Tottori University

An earthquake (Mj6.1) occurred in the vicinity Ohda city western Shimane Prefecture in Japan on April 9, 2018. Characteristics of site amplification effect of the temporary sites were understood from analysis of seismic data. We need to investigate the causes of the local site effects for the prevention or mitigation of earthquake disasters in the area. The purpose of our study was to estimate the subsuface structures of the target area by using microtremor and gravity survey. Therefore, densely microtremor and gravity observations were carried out to estimate the characteristic of ground motion in the damage area, Shigaku area, Mt. Sanbe, Shimane Prefecture. 3-compoent single-site observations at 80 points and array observations at 1 site were made to observe microtremor, and 51 points were made to observe gravity in the area.

There are two clear peaks in H/V spectrum in the short-period band (0.2 - 0.5 s) and the long-period band (1 - 3 s). The feature of the distribution of the predominant period is thought to be influenced by the ground structure of the sedimentary layer due to the volcanic deposits of Mt. Sanbe. From the estimation results of the S-wave velocity structure, the thickness of soft soil with S-wave velocity of 170m/s to 250m/s was about 40m. The S-wave velocities of 700m/s and 1300m/s corresponding to hard sedimentary rocks were about 200m and 500m, respectively.

Gravity anomalies were corresponded characteristic of the caldera topography of Mt. Sanbe, and there were low and high anomalies reflecting the complex structure near the summit. The basement altitude was obtained by performing a three-dimensional analysis using the gravity anomaly with a surface layer of 2.2g/m^3 and a base layer of 2.5g/m^3. As a result, the feature of the shape of the basin by the caldera topography were able to be grasped. It was found that the altitude of the basement surface was about -200m on a flat part (surface thickness of about 700 m) and about -1500m at the deepest part (surface thickness of about 1500m).

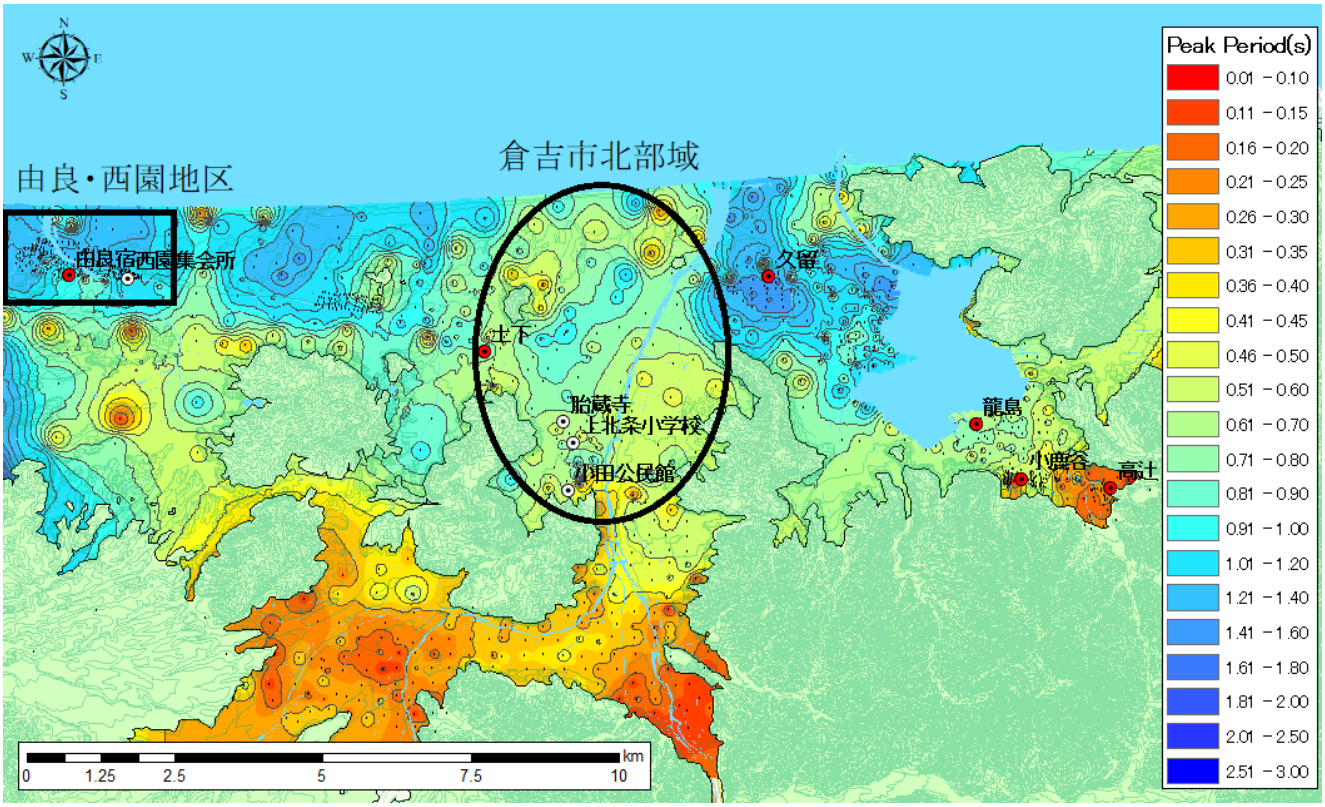
Estimation of Subsurface Structure and Ground Motion Characteristics in the Damaged Areas of the 2016 Central Tottori Prefecture Earthquake



*Isamu Nishimura[1], Tatsuya Noguchi[2], Takao Kagawa[2]

1. Tottori Univercity Graduate School of Engineering, Department of Management of Social Systems and Civil Engineering, Civil Engineering Course, 2. Tottori Univercity Graduate School of Engineering

On October 21, 2016, an earthquake with MJMA 6.6 occurred in the central part of Tottori Prefecture in Japan. Observed JMA seismic intensity were 6 lower at Kurayoshi city, Yurihama town and Hokuei town. Housing damage due to the earthquake was concentrated in limited areas. In this study, we carried out microtremor observations around damaged area to estimate subsurface structure and ground motion characteristics with the data by previous studies. We consider that the damages are affected by ground motion characteristics.
Low-velocity layer with S-wave velocity 80-180 m/s were estimated at all observation sites and the layers tend to be thicker to coastal plain and thinner to inland areas. The thickness of deeper subsurface structure with S-wave velocity more than 700 m/s was found to be different between Yurihama town and Hokuei Town from diffuse wavefield approach to H/V spectrum estimated from earthquake ground motion data. Many microtremor H/V with multiple peaks were observed at limited regions Yura and Nishizono, and most H/V with a single peak were observed at northern Kurayoshi Plain. It is suspected to reflect the difference in velocity structures of surface layers. The predominant period at Yura and Nishizono regions were 1.0-1.6 seconds, and at northern Kurayoshi Plain was 0.4-1.0 seconds. Comparing with housing damage, the layer thickness estimated from the quarter wavelength low, it was found that the damage occurred at the part where the layer thickness changed steeply. Comparing the ground amplification index such as ARV with housing damage, the relevance was found to be weak. Therefore, it is suspected with 2-D or 3-D effects that the damage caused by irregular subsurface structures.

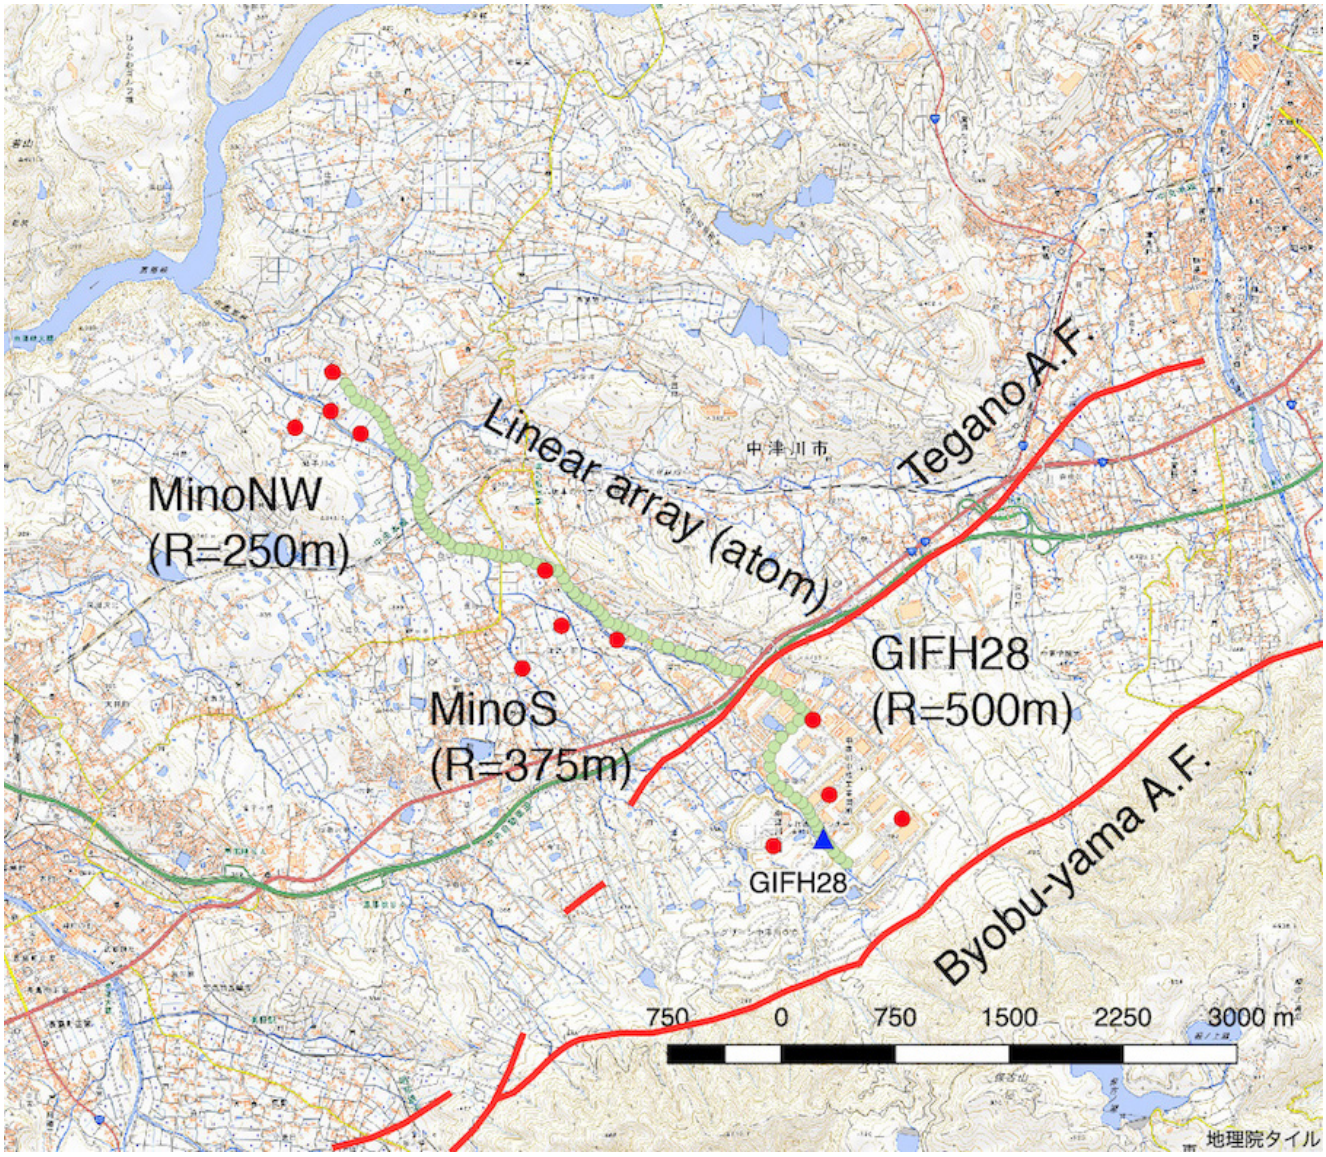
CMP-SPAC and SPAC microtremor array surveys around Tegano active fault, Gifu, Japan

*Masayuki Yoshimi[1], Haruhiko Suzuki[2]



1. Geological Survey of Japan, AIST, 2. Oyo Corporation

We conducted microtremor array measurements for subsurface velocity structure around a reverse active fault, Tegano Active fault, Gifu prefecture, central Japan. We set about 5 km long NW-SE trending measurement line from the GIFH28 KiK-net station, where the bedrock depth is GL -360m, to the area where granite outcrop is seen.
Two types of microtremor observations were made on Dec. 2019. One is regular triangle array and the other is linear array. For the regular triangle array, we deployed eight 3-component velocimeters (Tokyo Sokushin Corp. SE-321, natural period 10 seconds), and for the linear array observation, we used 40 geological McSeis-AT systems (hereinafter Atom).
Regular triangle arrray observations were conducted at three locations: near GIFH28 (for one night), near the granite outcrop (MinoNW: for one hour), and at an intermediate point (MinoS: for one hour). The maximum array radius is 500 m for GIFH28, 375 m for MinoS, and 250 m for MinoNW. The SPAC method is used for analysis.
As for the linear array observation, we used a vertical motion velocimeter Sunful PS-2B with a natural frequency of 2 Hz (Suzuki et al., 2019). The seismometers were installed at intervals of about 50 m, and three sets of observations were made with a deployment of about 2 km and an overlap of 0.5 km, so the total line length was about 5 km . The measurement was performed at a sampling frequency of 250 Hz and about 40 minutes each time. Data are analyzed with a microtremor tomography CMP-SPAC method (Hayashi et al., 2018). The analysis section length is 65.536 seconds, and the bin size of CMP is 250m.
The observed phase velocities around GIFH28 showed good agreement with the theoretical phase velocities based on PS logging results. Furthermore, it was found that the phase velocity tended to increase from GIFH28 to the northwest, and especially at the Chuo rail way line, about 3 km NW from GIFH28) the phase velocity gets quite large.

Acknowledgement
We used PS logging data by the National Research Institute for Earth Science and Disaster Resilience.

Improvement of Accuracy to Estimate Phase Velocity using Arbitrary Shape Arrays with Extra Observation Sites

*Huan Zhang[1], Kahori Iiyama[1], Hitoshi Morikawa[1]

1. Tokyo Institute of Technology

Based on the analytical solution of Lamb's problem for vertical components of Rayleigh wave, the relationship between two observation points, p and q for example, is given in a discrete representation with the Bessel function of the first kind and higher-order Bessel functions, which is called Complex Coherence Function (CCF) [4]. Zhang and Morikawa [5] extended the CCF to apply it to linear array situation. By adding an extra observation points, the relationship between p and s can be expressed [6]. At last, the CCF equations have only 5 unknowns left, including the phase velocity. Therefore, we proposed an algorithm [7] to estimate the phase velocity using Artificial Bee Colony (ABC) algorithm [8] under a constraint of $kr \in [0, 5]$. The numerical simulation results confirmed the availability of the proposed algorithm for array shapes that are not near linear-array situations [7]. And for near linear-array situations, relative accurate results might be get by increasing the observation time.

In theory, we can extend the CCFs to the array with 4 and more observation points [7]. Although the total number of CCFs increases with increasing observation points, the 5 unknowns remain the same. That is to say, with increased observation points, the number of CCFs will be greater than the unknowns' number 5. Then we think better results can be obtained due to the increased constraint conditions. Numerical simulations of a 4-site array, as shown in Figure 1, were conducted. It consists of one 3-site obtuse triangle and one 3-site near linear-array triangle. With same wave field consisting of 8 randomly generated wave sources, the results of shape 1 (obtuse triangle), shape 2 (near linear-array triangle), and 4-site array are shown in Figure 2. It can be seen that for shape 2, the near linear-array triangle, the results are not satisfactory and the constraint line $kr = 5$ can be obviously seen. And compared with shape 1's effective range [0.25Hz, 0.9Hz], the 4-site array's effective range can be seen as [0.25Hz, 1.25Hz], although still with fluctuations around 1.0Hz and the shape of the constraint line clearly seen after 1.0Hz. In conclusion, the 4-site array results are better than the more regular shape, as predicted before. But the computation time is longer than 3-site arrays since the total number of the equations increased from 3 to 6.

To confirm the availability of the proposed algorithm, a field test will be conducted.

Site Classification Method in Microtremor Array Exploration Using a Supervised Machine Learning

*Takumi Hayashida[1]

1. International Institute of Seismology and Earthquake Engineering, Building Research Institute

Seismic wave is amplified in the subsurface soil layers and understanding of the amplification effect is important for the estimation of ground motion characteristics. The average S-wave velocity in the upper 30m (AVS30) has been widely used as a simplified indicator of site classification since the 1980s (e.g. NEHRP site classification). The microtremor array exploration, a method to estimate subsurface S-wave velocity structure using seismic noise recordings, has been used globally as a low-cost and practical tool for site classification. However, recent blind tests show the possibilities of different interpretation for the dataset among analysts (e.g. Yong et al., 2018; Ohori et al., 2018), which could be caused by different ways of preprocessing, parameter selection for data processing, initial model setting for phase-velocity inversion, or by differences of user’ s knowledge and experiences, as well as software for analysis. In this study we propose a way of dealing with the problem, using a machine learning method. Here we test the possibility of site classification with randomly constructed 720 subsurface soil structure models. Each model consists of three layers; the minimum S-wave velocity of the top layer is 100 m/s and the maximum value of the bottom layer is 1,700 m/s. Assuming array radii of 5, 10, 15, and 20 m we derive Bessel functions of the first kind of order zero (i.e. theoretical SPAC coefficients) and characterize each function by extracting frequencies at which the values become 0.5, 0.0, and the minimum value. We employ supervised machine learning methods to the extracted dataset and investigated the possibility of soil type classification. The results show that soil type could be classified well for soil classes B and E, but sometimes show the difficulties for soil classes C and D. On the other hand, when we assume that microtremor array surveys are conducted with two or more different size arrays, the performance has been substantially improved. Our results indicate that the machine learning methods effectively work for interpretation of microtremor exploration and variabilities attributable to analyzers and tools could be reduced.

Verification for the Deep Sedimentary Velocity Structure in the Kathmandu Valley using Receiver Function Analysis

*Michiko Shigefuji[1], Nobuo Takai[2], Subeg Bijukchhen[3]

1. Kyushu University, 2. Hokkaido University, 3. Khwopa Engineering College, Nepal

The Himalayan continental collision zone of the Indian plate and the Eurasian plate has experienced devastating earthquakes in the past. In addition, the future great earthquakes in Nepal Himalaya have the potential to occur in the Central Seismic Gap of the Main Frontal Thrust. The Kathmandu Valley in Nepal is filled with soft lake sediment of Plio-Pleistocene origin, more than 650 m thick in the central part of the valley. This soft lake sediment might be one of the causes of seismic heavy damage. Therefore, we must examine the amplification characteristics of the valley and grasp the susceptible to the risks of strong ground motion at the next great earthquake.

In order to understand the basement topography of the valley and depth of the sediment, Shigefuji *et al.* (WCEE2020) applied the receiver function analysis to strong-motion waveforms recorded at 17 stations in the Kathmandu Valley (Takai *et al.* EPS2016, Ichiyanagi *et al.* EPS2016; Takai *et al.* JpGU2018). We examined the relationships between the spatial variation of peak phase from the receiver functions and the basement topography of the valley. The peak times of the receiver functions almost correspond with the theoretical time differences between the direct P-wave and Ps-wave converted at the basement-sediment boundary calculated from the 1-D velocity structure (Bijukchhen 2018) under each station. The Ps-P times are large differences in the range of 0.28 to 1.06 second in the sedimentary sites, this feature shows the complex basement topography of the valley.

In this report, we verify the previous deep sedimentary velocity structure model in the Kathmandu Valley (Bijukchhen, 2018) by comparing the observed receiver function with the theoretical one. The theoretical receiver function was calculated in the previous model based on the P-SV propagator matrix method. The P-wave velocity and density were derived from S-wave velocity based on some empirical relationships. The observed receiver functions agreed with the theoretical ones in most stations except stations on the center and marginal part of the valley, which is not used by the construction of this velocity model. Additionary, We will examine the effect of the middle layer of the velocity structure, the direction of the epicenter and the Vp/Vs ratio, to the receiver functions.

This research was supported by Science and Technology Research Partnership for Sustainable Development (SATREPS), Japan Science and Technology Agency (JST) / Japan International Cooperation Agency (JICA) Grant Number JPMJSA1511.

Detect of Underground Velocity Discontinuity by Autocorrelation of Strong Motion Data in the Osaka and Kyoto Basins

*Shuta Fukutome[1], Kimiyuki Asano[1], Tomotaka Iwata[1]

1. Disaster Prevention Research Institute, Kyoto University

The Osaka and Kyoto basins in southwest Japan are mainly composed of sedimentary layers called ”the Osaka Group”. Three-dimensional basin velocity models down to the basin basement have been constructed by using geophysical exploration results, such as reflection surveys, microtremor measurements, deep boring, etc. (e.g. Horikawa *et al.*, 2003; Kyoto prefecture, 2006; Iwata *et al.*, 2008; Sekiguchi *et al.*, 2016). It is important to validate those basin velocity models by using other methods or data set. The seismic interferometry technique is used to obtain a seismic response and it can be used to explore the underground structure. For example, Pham and Tkalcic (2017) demonstrated that the autocorrelation function of the seismic waveform observed at a station shows the response of the reflected waves from the velocity discontinuities (Moho discontinuity and ice-rock interface) and they wrote that this method can be applied to more shallow construction (e.g. sedimentary layer). We use autocorrelation functions of strong motion waveform data at some KiK-net strong motion stations in the Osaka plain and Kyoto basin. Since the strongest velocity discontinuity above the crust is the basin basement, dominant signals emerging in the autocorrelation functions would be the reflected S-waves propagating between the ground surface and the basin basement (e.g. Yoshimoto *et al.*, 2007; Watanabe *et al.*, 2011; Chimoto and Yamanaka, 2019). We use the spectral whitening that enlarge high frequency components to detect the response waves more clearly, then we stack the autocorrelation functions of records from local events using the phase weighted stack (PWS) to emphasize the response as with Pham and Tkalcic (2017), pick up the delay time of the reflected waves and estimate the depth of the underground velocity discontinuity surface of the Osaka and Kyoto basins. Acknowledgement: The observed waveform data from KiK-net were used in this study.

CONSTRUCTION OF SHALLOW AND DEEP LAYERS COMBINED MODEL IN THE KANTO REGION, JAPAN

*Hiroaki Yamanaka[1], Yoko Tono[2], Shigeki Senna[3], Masahiro Ohbuchi[4], Hiroyuki Fujiwara[3]

1. Interdisciplinary Graduate School of Science and Engineering,Tokyo institute of Technology, 2. Earthquake Research Institute, University of Tokyo, 3. National Research Institute for Earth Science and Disaster Resilience, 4. Ministry of Education, Culture, Sports, Science and Technology

The Earthquake Research Committee, the Headquarters for Earthquake Research Promotion (ERC/HERP) keeps updated "National Seismic Hazard Maps for Japan" consisting of two types of maps: probabilistic seismic hazard maps, and scenario-based ground motion maps. The latter requires a three-dimensional velocity structure model involving density, P- and S-wave velocities, Q-values, and the boundary shapes for each layer. Conventional nation-wide velocity models ERC used (e.g., Koketsu et al., 2008) have been only deep sedimentary layers by which accuracy of broadband ground motion is limited. For improving reliability of the seismic ground motion prediction, ERC newly applied the procedures to develop 3D models of shallow soil layers with S-wave velocity less than 350 m/s over engineering bedrock with S-wave velocities of 350-700 m/s and deep sedimentary layers having S-wave velocities from 350 to 3,000m/s over the seismic basement with an S-wave velocity of about 3 km/s for the shallow and deep layers combined model (SDLCM in the following). So far, ERC published “Procedures to establish a subsurface structure model” and established a new SDLCM for the Kanto region, Japan. This paper shows characteristics of the shallow and deep layers combined model constructed in the Kanto region.

One of advantages of application of SDLCM to seismic hazard maps is that amplification factors of ground motion on the surface to that in the seismic basement can directly be obtained at every grid point of the SDLCM. The new distribution of amplification factors by SDLCM shows a more complex spatial variation of the Vs30s than ones by geomorpholgical classification which was applied in the previous method. In particular much low Vs30s are identified in the new map along the major rivers. We furthermore calculate amplification factors of PGV between the surface and the top of the engineering bedrock using the two maps of the Vs30s. As comparing the amplification factors by SDLCM and by the previous method, it is noted that the amplification factors are calculated using the same empirical equation of a Vs30 from different Vs30s and the S-wave velocities of the engineering bedrock of the two models. The variation of the amplification factors for the new model is much wider than that of the previous one. In particular the amplification factors for the two types of the terraces are so large in the new model of SDLCM. Thus, it’s concluded that the new SDLCM for Kanto region, Japan can be used for a reliable seismic ground motion prediction for future large events.

Estimation of earthquake ground motions at MeSO-net stations

*Atsushi Wakai[1], Shigeki Senna[1], Atsushi Shimizu[1]

1. National Research Institute for Earth Science and Disaster Resilience

In the past national project of Japan, “Metropolitan Seismic Observation network” (hereinafter, referred to as “MeSO-net”) was constructed for the investigation of the tectonic plate structures and earthquake ground motions in the Tokyo metropolitan area around ten years ago. The MeSO-net has about 300 stations with sensors installed around 20 meters underground in the area. Also, they are spatially distributed at intervals of 2 to 5 kilometers in the area.

In recent years, we have worked a subproject of “acquisition of spatially very-high-resolution earthquake observation data and development of the database by private-public partnerships” as a member in a national project or “Tokyo Metropolitan Resilience Project.” As one of the topics, we have tackled a challenge for estimation of seismic ground motions based on bore-hole seismic records observed at each MeSO-net station.

The point is as follows. First, a seismometer is installed on the ground surface at each station during two to three months and some earthquake observation records are obtained in addition to the bore-hole records at each station. And then, an observed frequency response function is obtained by calculating spectral ratios of the ground surface records to the bore-hole ones. Also, increment of seismic intensity is obtained by calculating that from the ground surface records and from the bore-hole records. At the same time, a miniature and centerless array microtremor measurement is performed at each station. This method of measurement can be adopted principally for estimation of an S-wave velocity structure in the surface ground. It consists of 4-point miniature array with a radius of 60 centi-meters and 3-point centerless array with around 10 meters on a side. An S-wave velocity structure is estimated based on a disperse curve of a phase velocity and an H/V spectrum calculated from microtremor data. And then it can be enhanced based on an observed frequency response function described above. Therefore, a transfer function can be obtained using 1-dimensional multiple reflection theory based on the S-wave velocity structure at a station.

In this project, we will develop the system for estimation of earthquake ground motions based on bore-hole seismic records by means of the a variety of amplification factors mentioned above. In this presentation, we will report on the results in the analyses of earthquake observation data and microtremor measurement ones at this moment.

Modeling of subsurface velocity structure from seismic bedrock to ground surface based on array microtremor observation in Aso area

*Shigeki Senna[1], Atsushi Wakai[1], Atsushi Yatagai[2], Yoshiaki Inagaki[2], Hisanori Matsuyama[2], Hiroyuki Fujiwara[1]

1. National Research Institute for Earth Science and Disaster Resilience, 2. OYO Corp

One of the important issues for improving the prediction of strong ground motion is to construct a ground model that can evaluate broadband ground motion characteristics. For that purpose, it is essential to integrate the shallow ground model and the deep ground model, which have been separately modeled, and to create a model that can reproduce the observation records. In this study, the K-NET, KiK We collected seismic records at seismic stations such as -net, the Japan Meteorological Agency, and local governments, as well as array surveys and records of single points (H / V spectral ratios) using many microtremors. In addition, the S-wave velocity structure model was examined from the analysis results as a basic study for constructing the ground model of the Aso area. In this report, we report the results of microtremor array observations and the results of the study on the construction of an integrated shallow and deep ground model.
In this study, an initial geological model was created, and the distribution of AVS30 (m/s) and an integrated shallow / deep ground model were constructed using microtremor array survey and microtremor measurement results. The distribution of the AVS30 and the engineering-based equivalent layer based on the ground model created in the Aso region this time is harmonious with the existing drilling data, similar to the results of research conducted in the Kanto and Tokai regions. ing. The theoretical H/V (periodic characteristics) and amplification characteristics calculated from the S-wave velocity structure model calculated in this study were also confirmed to be in harmony with the seismic records. The results show that the evaluation of phase velocities and periodic characteristics (H / V spectral ratios) per se by microtremor observations is very effective in improving the accuracy of the model, and is very effective for engineering platforms (for example, S-wave velocities such as Vs350). When it is difficult to set the depth of the upper surface of the structure, it is considered to be very useful as a method of correcting the engineering base depth based on geological and geological information using micro array microtremor observation. In the future, we plan to examine various amplification factor indices in comparison with the method using micro-topography and earthquake records, which are used as the ground amplification factor.

The examination of liquafaction damage rate by recent earthquakes

*Shigeki Senna[1], Kyoko Ozawa[1]

1. National Research Institute for Earth Science and Disaster Resilience

The 2011 off the Pacific coast of Tohoku Earthquake caused liquefaction that caused large-scale and severe damage. The quake was severely shaken by a seismic intensity of less than 5 and liquefaction occurred in many areas. In this study, it was possible to determine liquefaction using detailed aerial photographs, and seismic intensity 6 or lower was observed. Based on information on liquefaction occurrence points of five earthquakes such as the 2018 Hokkaido Eastern Iburi Earthquake, estimate liquefaction occurrence rate based on 250m mesh unit and liquefaction area rate considering liquefaction area in each mesh, A formula for estimating liquefaction risk based on liquefaction occurrence rate and area ratio was proposed. We also examined the building damage rate from information on building damage caused by liquefaction.

Ground Motion Estimation by using Microtremor H/V Spectral Ratio

*Guan-Yu Chen[1], Che-Min Lin[2], Kuo-Liang Wen[1]

1. Department of Earth Science, National Central University, Taoyuan, Taiwan, 2. National Center for Research on Earthquake Engineering, Taipei, Taiwan

It has been proved that the H/V spectral ratio method, proposed by Nakamura (1989), is effective in estimating the site response of ground motion. Because the density of strong-motion stations is still insufficient to provide accurate ground motion distribution in a highly developed region. This study proposes a method by using microtremor H/V spectral ratio (HVSR) to correct the site effect and predict the ground motion of nearby sites. Considered two sites at a very close distance and assume that under the influence of the same earthquake, the source and path effect in observed seismic waves are almost the same, the difference ground motion between this two sites just control by their site characteristics, that is the different of their HVSR. So, the ratio of HVSR can be seen as a correction factor to estimate the ground motion of the sites around a strong-motion station. Here, we selected the Ilan plain of Taiwan as a test site, and the seismic records with PGA > 8 gal from 1993 to 2013 were collected to evaluate the error and stability of this method including the relative site distance, hypocenter distance, Vs30, and the spectral different. Finally, the scenarios of several historical events in the Ilan plain were simulated by using the site correction of microtremor HVSR. Consolidate the variations in ground motion for these events to evaluate the effect of site characteristics for ground motion distribution.

ISNL-- an new parameter of soil nonlinearity used for Taiwan and New Zealand earthquake

*Kao Ching[1], Huang Jyun-Yan[2], Wen Kuo-Liang [2]

1. National Central University, 2. National Center for Research on Earthquake Engineering

Previous studies indicated that nonlinear site response occurred when strong ground motion wave propagating through surface soft soil layers. This phenomenon can be identified from comparing site transfer functions (i.e. Horizontal to vertical spectral ratio method, HVSR, Wen et al., 2006) of strong ground motion against the reference weak motion.

Meanwhile, Noguchi and Sasatani (2008) constructed a quantitatively method to identify soil nonlinearity (Degree of nonlinearity, DNL) that was calculated from the summation of differences between HVSR of strong and weak motions. However, basic idea of DNL calculation might miss some hint from identification of de-amplification or amplification in high frequency band.

Therefore, this study attempts to build a new and improved nonlinearity method ISNL (Index of soil nonlinearity) to avoid the traditional DNL only considering the difference between HVSR of the strong and weak motions that it couldn’ t recognize dominant frequency drop and de-amplification of high frequency band correctly. Finally, in this study, comparison from traditional DNL and improved ISNL were checked with PGV/Vs30 (Strain proxy, Idriss, 2011) from 2016 Meinong, Taiwan; 2010 Jiaxian, Taiwan and 2018 Hwalien, Taiwan earthquakes.

Finally, higher correlation between both DNL, ISNL against PGV/Vs30 proxy was resulting in 2018 Hwalien earthquake comparing to 2016 Meinong as well as 2010 Jiaxian earthquakes. Moreover, ISNL behaved better linear correlations with PGV/Vs30 than DNL. Then, earthquake sequences in New Zealand will be also checked in this study to test the ability of newly constructed ISNL for application to worldwide regions.

Assessment of the liquefaction risk at Re-liquefied site

*CHIH-SHENG KU[1], Yun-Ling Hsieh[1], Po-Wei Cheng[1]

1. I-SHOU University

The Beishih village, Hsinhua Dist., Tainan City, Taiwan is the only confirmed location in Taiwan having soil liquefaction and sand boil for the Hsinhua earthquake on 1946, Taoyuan earthquake on 2010, and Meinong earthquake on 2016. The soil liquefaction and sand boil in Beishih Village were observed from Taoyuan earthquake on March 4, 2010 and Meinong earthquake on Feb. 6, 2016. The authors surveyed the two liquefaction sites and used GPS to obtain the coordinates of each crater of sand boil cone, the authors found that the locations of the liquefaction were highly overlapped for those two liquefaction cases.

The seismic stations at Koupi elementary school (CHY063) and Yongkang meteorological station (CHY078) are close to Beishih Village. The seismic peak ground accelerations in the vertical, N-S, and W-E motion measured at station CHY063 for the earthquakes of Taoyuan and Meinong were 71.24, 174.66, and 385.18gal, and 163.26, 238.64, and 416.92 gal, respectively. Moreover, the seismic peak ground accelerations in the vertical, N-S, and W-E motion measured at station CHY078 for the earthquakes of Taoyuan and Meinong were 25.3, 61.54, and 101.66gal, and 43.6, 101.86, and 143.86 gal, respectively. The monitor information of the groundwater level obtained from liquefaction site shows that the variations of the groundwater level were quite a lot in this area. The ground water levels were about 0.24 to 3.67m below the ground surface.

The re-liquefied site is an alluvium at the west edge of the Hsinhua Hill. The Hsinhua fault passes through the east of the site. Based on the site investigated results, four different sub-soil layers were categorized for the soil layer within the depth of 30m in the site studied. The first sub-soil layer was from ground surface to the depth about 3m below surface and was characterized as low resistances soft soil. The second layer was at 3-6m below the surface and was characterized as sandy soil; the third layer was at 6-11m below the surface and was characterized as clayey soil (clay or silt); the fourth layer was characterized as dense sandy soil. The average shear wave velocities (V_{s30}) obtained from 3 different sampling locations for soil layers 30m below ground surface were 215, 201, and 213m/sec, respectively.

In this study, the CPT-based, SPT-based and Vs-based methods were applied to the LPI for the evaluation of the liquefaction potential. The LPIs obtained from different evaluation method were varied. The smaller and the largest of the LPI were obtained from SPT-based method and CPT-based method, respectively. Based on the Iwasaki criteria the liquefaction risk potentials were classified as high to extremely high under attack of these two earthquakes. However, the real investigation report shows that the liquefaction hazards were classified as moderate in which was conservative comparing to the analyzed results.

Experimental Study on Dynamic Shear Modulus of Cohesive Soil in Beijing Plain

*Yi Fang, Guoxing Chen, Yanju Peng, Yuejun Lyu

As an important parameter of soil dynamic characteristics, the dynamic shear modulus can better reflect the nonlinearity of the soil, but it is affected by the combination of factors such as the genesis, age, burial depth. A class needs specific analysis to determine its dynamic shear modulus characteristics. The seismic environment of the Beijing Plain area is complex, and the site soil is mainly cohesive soil. There is no systematic study on the dynamic shear modulus of cohesive soil. In this paper, 17 undisturbed soil samples from Beijing area were collected for laboratory test used resonance column and field shear wave velocity tests, the results show that: (1) The results of Gmax by filed test are greater than Gmax of laboratory tests, both of which have a linear relationship with depth, and also show good linear correlation between them; (2) There are many reasons which lead to the difference between the field test with the laboratory test, such as the mechanism of the tests, the conditions of tests ; (3)G/Gmax of regional clay soil is significantly affected by the groundwater level. Non-linearity of the soil above the groundwater level decreases with depth, and non-linearity of the soil below the groundwater level increases with depth. (4) The non-linearity of cohesive soils in Beijing Plain is significantly stronger than Fuzhou and other places within 0-20m, but slightly weaker than Suzhou, which is closely related to the genesis and sedimentary environment of each place.

[S-SS05] Innovative data analysis methods for characterization of seismicity

convener:Francesco Grigoli(ETH Zurich Swiss Federal Institute of Technology Zurich), Bogdan Enescu(Department of Geophysics, Kyoto University), Aitaro Kato(Earthquake Research Institute, the University of Tokyo), Yosuke Aoki(Earthquake Research Institute, University of Tokyo)

In the last two decades the number of high quality seismic instruments being installed around the world has grown exponentially and likely will continue to grow in the coming decades. This led to a dramatic increase in the volume of available seismic data and pointed out the limits of the current standard routine seismic analysis, often performed manually by seismologists. Exploiting this massive amount of data is a challenge that can be overcome by using new generation, fully automated and noise-robust seismic processing techniques. In the last years, waveform-based detection and location methods have grown in popularity and their application has dramatically improved seismic monitoring capability. Moreover, machine learning techniques, which are dedicated methods for data-intensive applications, are showing promising results in seismicity characterization applications, opening new horizons for the development of innovative, fully automated and noise-robust seismic analysis methods. Such techniques are particularly useful when working with data sets characterized by large numbers of weak events, with low signal-to-noise ratio, such as those collected in induced seismicity, seismic swarms and volcanic monitoring operations. This session aims to bring to light new methods that can be applied to large data sets, either retro-actively or in (near) real-time, to characterize seismicity (i.e., perform detection, location, magnitude and source mechanisms estimation) at different scales and in different environments. We thus encourage contributions that demonstrate how the proposed methods help improve our understanding of earthquake and/or volcanic processes.

Erecting and Observation Data of Broadband Seismic Array in Haiyuan- Liupanshan Fault Zone, Ningxia, China

*Guofu luo[1], Heqin - Ma[1]

1. Earthquake Administration of Ningxia Hui Autonomous Region

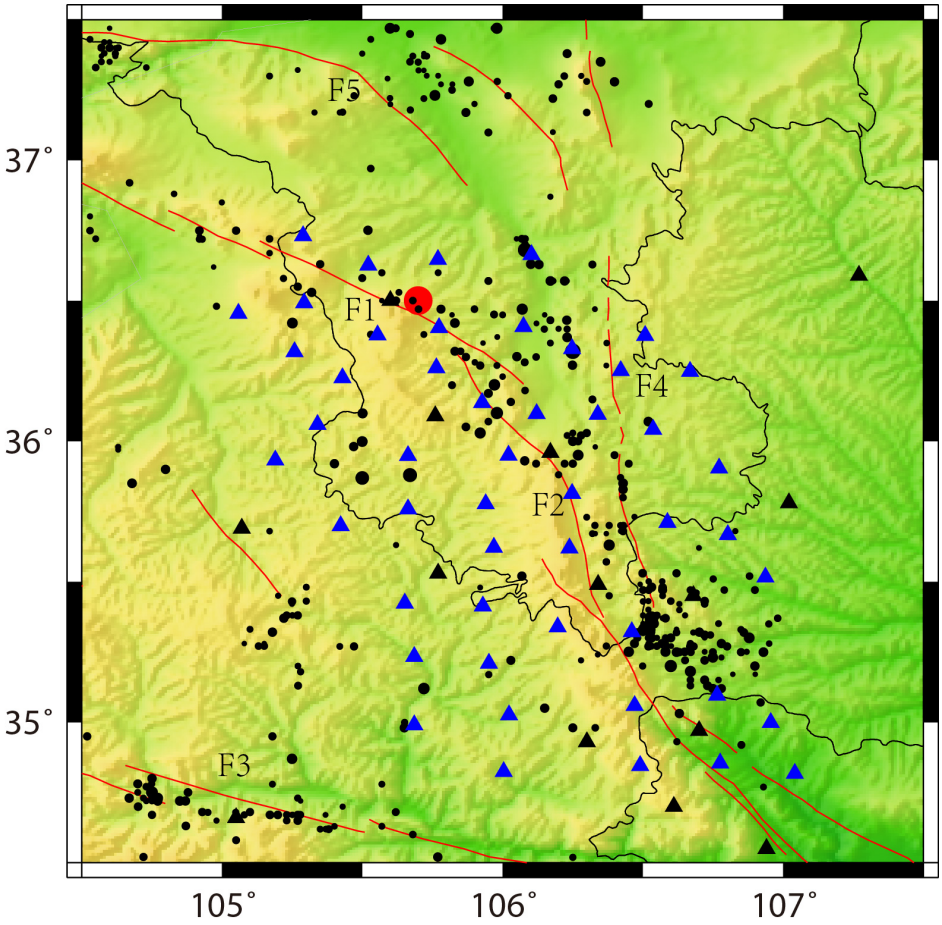
Ningxia Haiyuan –Liupanshan fault zone is located at the junction of southern Ningxia Hui Autonomous Region and eastern Gansu province. The seismogenesis and active structure of this fault zone are highly similar to the seismogenic structure Longmenshan fault of Wenchuan 8.0 earthquake in 2008. There is also a large thrust fault tectonic system, and there is no record of large earthquakes in history. Therefore set up broadband seismometers around Haiyuan-Liupanshan fault zone, seismic array, using seismic waves of the interior of the earth "projector", the fault zone around the earth's crust, mantle and core structures, deepen the flame breeds of deep structure in the region, environment, promote the development of earthquake prediction and earthquake prediction research, for Ningxia to make positive contribution to earthquake prevention and disaster relief cause.

Since Campillo and Paul established the relationship between the two points' wake wave cross-correlation function and green's function, and extracted the surface wave green's function, they pioneered the application of background noise in seismology. Then Shapiro and Campillo obtained California high-resolution surface wave tomography using the US array, and the background noise method has been widely used in high-resolution tomography at global scale, regional scale and small scale. The imaging of background noise combined with highly dense seismic array with uniform distribution greatly improves the horizontal and vertical resolution of imaging, and provides a possibility for the research of 3d high-resolution fine structure.

In this project, on the basis of observation data from regional fixed stations, a two-dimensional mobile seismic array consisting of 50 seismographs was scientifically and rationally arranged around the Haiyuan - Liupanshan fault zone in October 2018. Continuous seismic observations were carried out for a period of 2 years to obtain continuous waveform data (figure 1).Using the two-year data, three methods, such as the method of receiving function, the method of noise surface wave dispersion and the method of seismic surface wave dispersion joint inversion of three-dimensional s-wave velocity structure, were used to analyze the relationship between the velocity structure and the seismic mechanism and the dynamic mechanism of fault zone.

In this project, 50 sets of mobile and dense seismic array are arranged around the Haiyuan-Liupanshan fault zone in Ningxia, and the observation data are carried out for 2 years, so as to draw the following conclusions.

(1) More than 50 sets of wide-band seismographs were installed across the Haiyuan-Liupanshan fault zone for continuous observation of earthquakes over a period of 2 years, providing basic observation data for subsequent studies on fine structure of the crust.



(2) Extracted from distant earthquake seismic waveform P wave and S wave function, the study area is obtained by receiver function inversion depth of Moho surface, and on this basis, the joint background noise and obtain Haiyuan seismic surface wave dispersion inversion - Liupanshan fine 3 d crustal velocity structure in the fault zone and its adjacent area, the study of seismic activity and the relationship between

velocity structure, explore the mechanism of earthquake gestation, the seismogenic mechanism, crustal dynamics and seismic risk.

(3) Collect seismic phase travel time data of near earthquake and artificial blasting, carry out tomography research of near earthquake travel time, and obtain 3d fine velocity model of the study area.

Energy release patterns and shaking effects of earthquakes in the Japan Trench: A Hilbert-Huang Transform approach

*Swapnil Mache[1], Kusala Rajendran[1]

1. Indian Institute of Science, Bangalore

Subduction zones showcase the multiplicity of earthquakes—interplate, intraplate and intraslab—with shallow, intermediate, or deep focus, associated with different energy release patterns and frequency contents. An understanding of the duration and frequencies associated with various pulses of energy is useful for damage assessment. Empirical Mode Decomposition (EMD) of strong-motion records and the application of Hilbert transform have been suggested to overcome the limitations of the Fourier spectral analysis in dealing with highly non-linear strong-motion records (Huang et al., 1998, Zhang et al., 2003). Following the same approach, we have been trying various methods of analysis using the KiK-net strong-motion records to explore the efficacy of these techniques in representing the source of the rupture, in terms of energy release and frequency distribution. Our previous studies used EMD and time-frequency analysis tools such as spectrogram, scalogram, and Hilbert spectrum, using Intrinsic Mode Functions (IMFs) of the original signals as inputs. Nishant (2019) made random picks of IMFs to represent sources by correlating the sum of the selected IMFs with the original signal but found that the results were station dependent. We selected IMFs based on their frequency content (0.1 to 3 Hz) and used their linear combinations to develop the Energy Release Functions (ERF) for individual earthquakes (Mache et al., 2019). They reported that the ability to capture the signature of the original signal using the IMFs varied between earthquakes and stations. Next, we selected stations based on the direction of rupture inferred from teleseismic waveform models. The use of appropriate combinations of individual IMFs, chosen based on the direction of slip, resulted in ERFs whose shapes compared better with the Moment Rate Functions (MRFs) obtained from the teleseismic models. To further explore the station dependence on the resolution of ERFs viz-a-viz the MRFs, we used the instrumental seismic intensity distribution maps (JMA 1996, Shabestari and Yamazaki 2001) to select the stations. We analyzed five earthquakes; two interplate (Mw 7.2 2005 Miyagi, and Mw 6.9 2008/07/19), two intraplate (Mw 7.0 2003 Sendai, and Mw 7.2 2012 Kamaishi) and one intraslab (Mw 7.1 2011 Miyagi), following the above methodologies. This abstract presents the initial results of our study, which to our knowledge, is the first of its kind and holds significant potential in understanding the spatial and temporal patterns of energy release and their associated frequencies.

On the use of IMFs based on their frequencies, we find that a linear combination of appropriate signals can lead to ERFs that compare well with their respective MRFs. The selection of stations in the direction of rupture generates better-resolved spectra. While using the seismic intensities, we find that for values three and higher, stations located along the direction of rupture propagation produce ERFs that correlate better with their respective MRFs, as observed for the 2011 Miyagi earthquake. The use of stations located along the direction of the trench also shows a good correlation. For seismic intensities lower than 3, there is a decay in the energy release and hence a poor reproduction of the ERFs. For complex ruptures (2003 Sendai, 2005 Miyagi, and 2012 Kamaishi), the ERFs are not smooth, with their energy distributed in bands of varying frequencies. It could be due to changes in slip direction or generation of sub-events, but the fact that the shapes of both the MRF and ERF are comparable adds credence to our analysis. We find that the local geology also plays an essential role in limiting the energy distribution within a frequency range, an issue that needs further exploration using more examples.

The 2019 September 15th Stigliano natural seismic sequence revealed by a local network designed for induced seismicity monitoring

*Chiara Cocorullo[1], Giancarlo Graci[2], Stefano Limonta[1], Alexander Garcia[3], Thomas Braun[3], Francesco Grigoli[4]

1. SolGeo srl, 2. TOTAL E&P ITALIA, 3. INGV, 4. ETH-Zurich, Swiss Seismological Service

In 2014, after the public debate about the possibility that the industrial activities in the Emilia region (North Italy) could have triggered the Magnitude Mw 6.1 earthquake occurred on 20 May 2012, the Italian Oil & Gas Safety Authority (DGS-UNMIG, Ministry of Economic Development) published a set of guidelines that establish the need to monitor seismicity in areas subject to industrial activities such as hydrocarbon production, waste water injection and natural gas storage operations. In this framework, TOTAL E&P ITALIA, company owner of the Gorgoglione Concession for hydrocarbon production in the Basilicata region (Southern Italy), is monitoring the seismicity with a local microseismic network. The network, installed and managed by SOLGEO srl on behalf of TOTAL E&P ITALIA, consists of 12 seismic stations, each equipped with two sensors (surface seismometer (11 short period and 1 broadband) + accelerometer). In this work, we focus on the seismic sequence occurred on 2019 September 15th, near the Stigliano town, in the eastern edge of the local microseismic network. In order to demonstrate how the data integration of local and national networks can produce better results, both in terms of number of detected events and location quality, we show the comparison of the catalogues produced by analysing the data from the national seismic network, the local microseismic network and the combination of the two. While the INGV catalogue based on the national seismic network shows only 4 events associated with this sequence, by using the data of the local seismic network, we detected and located more than 25 events with local magnitude between 0.2 and 2.0. Since the smallest events are visible only at the closest station, we used a new single station location technique that allow to better constrain the location of clustered seismic sequences.

The systematic spatial bias pattern of earthquakes related to tectonic heterogeneity

*Yijun Zhang[1]

1. Southwest JiaoTong University

Back-projection (BP) is a source imaging approach that combines both time-reversal and grid-search techniques. BP utilize coherent waveforms to image a finite source process without any prior parameterization of the source itself, and the recent development of large dense seismic array has triggered its severe growth. BP can also be used for earthquake detection and location. As aftershocks of one earthquake always occur in the neighboring area, their rays towards a specific teleseismic array will travel along similar paths as that of the mainshock. The travel time errors from the mainshock hypocenter can be derived by cross-correlating its P-arrival waveforms, and if applied right on the waveforms of aftershocks, one can obtain the aftershocks' BP-inferred locations. However, small-scale heterogeneity caused by the real Earth 3-D structure will result in the so called 'spatial bias', which is the spatial offset between the BP-inferred location and the true epicenter locations. Meng et al (2016) has proposed an aftershock-based method to calibrate the travel time errors due to the near source structural heterogeneity. In this study, we take the 2017 July Mw 7.8 Near-Islands Aleutian earthquake as an example to investigate the spatial bias artifact of the source region. We found that in the ~500 km long rupture area, three systematic patterns of spatial biases exist, which correlate to three different structure characteristics. The three segments are the northwestern termination of the Aleutian island (169°-170°E), southeast of Mednyi Island with the Shirshov Ridge in the arc (170°-171°E), and the western segment of the Aleutian arc around Attu Island and northwest of it (171°-172 °E). The spatial bias directions in the three areas can be observed to have a good consistence with the nodal planes of focal mechanisms in the three areas, separately. This phenomena can be attributed to the sudden change in this elongate area brought by the Shirshov Ridge in the arc (170°-171°E). Besides, the coincidence between fault-planes solutions for the earthquakes in this area and the systematic spatial bias patterns also demonstrate that the state of stress experiences a sudden change, which reflects the tectonic heterogeneity in the near-source area, validating the necessity of subarea slowness calibration for this earthquake and providing us insight into the tectonic structure characteristics of this area.

Location of seismic events with a single station using Distance Geometry Solvers

*Francesco Grigoli[1], William L Ellsworth[2], Miao Zhang[3], Simone Cesca[4], Claudio Satriano[5], Mostafa Mousavi[2], Gregory C Beroza[2], Stefan Wiemer[1]

1. ETH-Zurich, Switzerland, 2. Stanford University, United States, 3. Dalhousie University, Halifax, Canada, 4. GFZ-Potsdam, Germany, 5. IPGP-Paris, France

Earthquake location is one of the oldest problem in seismology. With the advent of modern seismic monitoring networks it is possible nowadays to obtain reliable locations also for tiny events. However, there are still many cases where the lack of a dense enough microseismic monitoring network affects the performance of the routine data analysis procedures, limiting the ability to obtain reliable results increasing the risk of wrong interpretations. In this work we propose a novel approach based on Distance Geometry Solvers (DGS) that allow to locate seismic events by using a single seismic station.
DGS are used to solve a Distance Geometry Problem (DGP), consisting in the characterization and study of sets of points based only on given values of the distances between member pairs. The DGP is the one of finding the coordinates of a set of points by using the distances between some pairs of such points. In this work we introduce a new method that allow locate earthquakes using only the inter-event distance between pair of seismic events using one or two seismic stations. This location method requires only four non-coplanar reference locations for which the absolute hypocentral coordinates are known (at least). In order to show the potential of this approach we firstly validated the method with synthetic datasets resembling different cluster geometries. We finally tested the methods with two seismic sequences occurred in California, 1) the Mw 6.0 Napa Earthquake occurred in August 2014 and 2) the Mw 7.1 Ridgecrest seismic sequence occurred in July 2019. We show that our approach provides better results than any other single station location method and when using the inter-event station estimated with two optimally oriented stations the results are comparable to high resolution Double Difference locations based on the use of multiple stations. This method is particularly useful in poorly monitored areas where only a limited number of stations is available.

Evaluation of deep-neural-network-based seismic arrival-time picking method for S-net data

*Rintaroh Suzuki[1], Naoki Uchida[1], Weiqiang Zhu[2], Gregory C Beroza[2]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions Graduate School of Science, Tohoku University, 2. Department of Geophysics, Stanford University

The number of detectable earthquakes is increasing rapidly as seismograph networks expand. Off the Pacific coast of Tohoku Japan, seismograms recorded by a 150 cabled ocean bottom seismic stations (S-net) available from 2016 enable much clearer characterization of offshore seismicity. Many approaches to automatic phase picking methods have been proposed to improve seismic monitoring. In this study, we evaluate an arrival-time picking method based on a deep neural network, PhaseNet (Zhu and Beroza, 2019), to detect and locate more earthquakes offshore Tohoku. PhaseNet estimates P and S arrivals as probability distributions using three-component seismic waveforms. PhaseNet has already achieved good performance for the Northern California Earthquake Data Center Catalog using the model trained by the seismograms of the region as input.

To evaluate the performance of the deep-neural-network-based seismic arrival-time picking model, we compared the output of PhaseNet with manual picks for S-net data. We used 512 offshore earthquakes listed in the Japan Metrological Agency (JMA)’s catalogue which are detected by land stations and the manual picks for S-net performed by the analysts in Graduate School of Science, Tohoku University. Please note that in this comparison we have not re-trained PhaseNet model with S-net arrival data for the evaluation of the model. According to the application for 22 stations belonging to the S-net S1 cable during 22 months, PhaseNet detected P-picks within 0.1 second from the manual picks (hereafter we call this good P or S-picks) for about the half of input, and good S-picks for 24.7% of input. We note that the data of S-net located at the ocean bottom tends to have weaker first arrivals for P and S waves than do on land stations on which the model was trained.

To evaluate the performance with existing method, we compared the result of PhaseNet with the ‘auto pick’ function of the WIN system (Urabe and Tsukada, 1991). We found that the ratio of good P-picks is larger for PhaseNet (53.2%) than that for the WIN system (21.4%). For S-wave, PhaseNet also achieves a higher ratio (24.7%) than that for the WIN system (10.0%). We also compared the results with the automatic earthquake location system in operation at Tohoku University (Horiuchi et al., 2014; Nakayama et al., 2014). Please note the system is working for land stations and the comparison does not contains S-net data as input. For 695 waveform data recorded in January 2017, PhaseNet was able to detect 99.9% of the P-picks with high precision (81.4%) and recall rate (81.3%) that are two standard performance measures for deep learning models (Zhu and Beroza, 2019). In addition, the performance for S-wave is much better than existing methods (the Tohoku University’s automatic earthquake location system and the WIN system could detect good S-picks for about 10 % of input, but the PhaseNet detected 54.8% of input).

These results suggest that even for S-net data, PhaseNet is an effective method to find accurate arrival times for both P and S waves, though the performance could be improved with a re-trained model. We expect that arrival-time picking methods based on deep neural networks will help reveal the distribution of small earthquakes in offshore Japan from continuous S-net waveform data.

[S-SS06] Active faults and Paleoseismology

convener:Hisao Kondo(Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology), Mamoru Koarai(Earth Science course, College of Science, Ibaraki University), Takashi OGAMI(National Institute of Advanced Industrial Science and Technology), Yoshiki Sato(Advanced Industrial Science and Technology, Geological Survey of Japan)

Recurrence of past earthquakes through historic, geomorphic and geologic time provide us essential information on location, size and timing of future large earthquakes. The study of past faulting, source fault and seismicity has played important role for seismic hazard assessment and mitigation of the related hazards. Furthermore, active fault studies contribute to understanding active tectonics under the on-going tectonic stress field. In this session, we encourage submissions from scientists in relation with all aspects of active fault studies and paleoseismology, including interdisciplinary fields of geology, geomorphology, archaeology, historical earthquake, seismology, geodesy and numerical simulations.

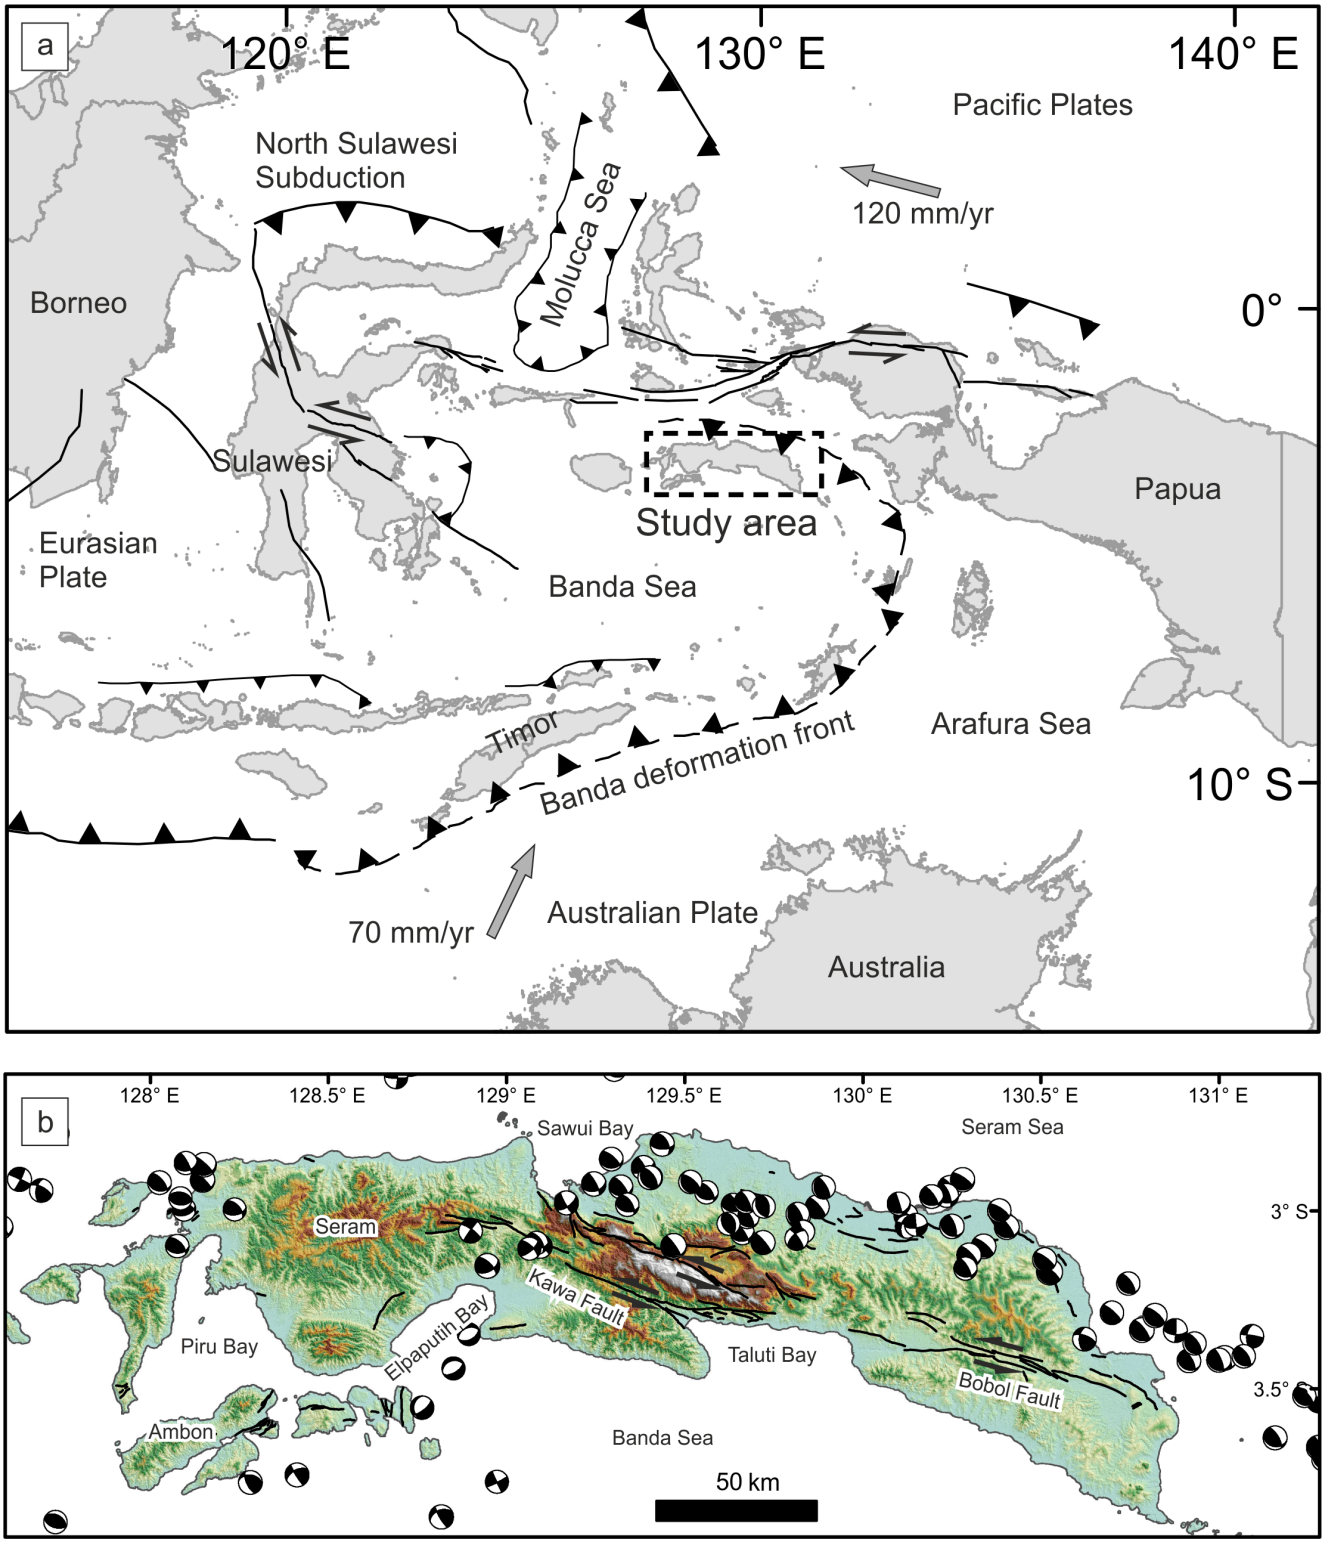
Active tectonics of the northern Banda Arc, eastern Indonesia: a preliminary geomorphic mapping



*Adi Patria[1,3], Hiroyuki Tsutsumi[2], Danny Hilman Natawidjaja[3]

1. Graduate School of Science and Engineering, Doshisha University, 2. Department of Environmental Systems Science, Doshisha University, 3. RC for Geotechnology, Indonesian Institute of Sciences (LIPI)

The 180°-curved Banda Arc is located in the tectonically complex region where the Eurasian, Indo-Australian, and Pacific plates converge. The northern Banda Arc, which includes Seram, Buru, Ambon, and surrounding islands, is a seismically active region. Seismicity is mainly observed around the northeast Seram with the domination of thrust faulting mechanisms, while strike-slip faulting activity is mainly located in the central Seram. Although the area is vulnerable to earthquakes, there has been limited effort to study the active tectonics of the area. This study investigates the tectonic geomorphology of the northern Banda Arc based on the Indonesian DEM (DEMNAS) to understand the active tectonics of the region and relates the interpreted structures to seismicity in the region. The Kawa and Bobol faults elongate across Seram and show a left-lateral movement. The faulting activity is recorded in geomorphic features such as triangular facet, beheaded river, pressure ridge, and river offset. The northeast Seram lacks geomorphic expression, but evidence such as uplifted marine terrace, deformed fluvial terrace, and water gap illustrate thrust faulting activity. Other faults with less than 20-km length are observed in Ambon, Haruku, and Saparua, majorly deforming uplifted marine terraces. The faulting activities in the region might be related to the oblique convergence between the northern Banda Arc and the West Papua.

Paleoseismological studies along the un-ruptured southern segment of Yokote Basin Fault Zone, northeast Japan

*SHREYA Arora[1], Hisao Kondo[1]

1. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

The mapping of active faults and how the associated earthquakes have repeated in space and time are the key to unraveling future seismic activity. With the advent of extensive paleoseismic and geodetic data, the more complex behavior of earthquake ruptures such as events incompletely rupturing or bleeding into adjacent segments is indicated (e.g. Zielke, et al., 2010; Bilham, et al., 2019; Katsube et al., 2017). The 1896 Rikuu earthquake, Mw 7.2, is one such example which ruptured 35 km of the northern section of the eastern margin of the Yokote Basin (EFZYB), which is one of the largest east-dipping fault system in northeast Japan (e.g. Matsuda, et al., 1980; Kagohara, et al., 2009) while leaving the southern section un-ruptured since at least 100 years. Since then tremendous efforts have been made along the ruptured section of EFZYB to determine slip rates and recurrence interval of the earthquakes (Kagohara, et al., 2006; 2009; Imaizumi et al.,1997; Research Group for the Senya Fault, 1986). However, the trace of the active faults, slip rates, past earthquake chronology and recurrence intervals along the un-ruptured southern section of EFZYB remained poorly understood. Therefore, through detailed aerial photo interpretation, airborne LiDAR DEM survey, and field investigation an attempt has been made to map the active faults in the un-ruptured southern section of EFZYB, which is integrated with seismic survey and borehole data to determine slip rates. Here we will present the preliminary results of the work which will help in the seismic hazard assessment of the Yokote Basin.

Parametric study on ground surface deformation forming pull-apart basin

*Hidetaka Saomoto[1]

1. National Institute of Advanced Industrial Science and Technology

Understanding the forming process of pull-apart basin due to faulting is an important topic in the field of geomorphology and several types of studies on pull-apart structure have been widely conducted: field works (e.g., Aydin and Nur, 1982), theoretical studies (e.g., Du and Aydin, 1995), and numerical studies (e.g., Liu and Konietzky, 2018). As an example in Japan, the Suwa Basin along the Itoigawa-Shizuoka Tectonic Line is considered to be a pull-apart basin produced by two left-lateral strike-slip faults (e.g., Fujimori, 1991).

Since most of the previous studies were limited to individual case studies or a few simulation cases, a systematic parametric study is needed to methodically understand ground deformation patterns resulting in pull-apart basins. Here, I performed a series of three-dimensional finite element analyses to understand the deformation patterns of the ground surface by changing the parameters that control both the fault configuration and the stress field around the faults. In this study, all procedures for the finite element simulations were implemented in a multi-purpose finite element package (COMSOL Multiphysics).

On the basis of 715 simulations, the followings are obtained:

(1) When the step-over width equals to 3.0 km and the overlap equals to 2.0 km, strong basin subsidence is observed irrespective of the directions for principal stresses.

(2) An extremely large overlap cannot produce strong basin subsidence irrespective of the magnitudes of step-over widths.

(3) The direction of principal stress affects the magnitude of the basin subsidence, but it does not affect the displacement pattern of the ground surface.

(4) The sensitivity of overlap to the basin subsidence is larger than that of the step-over width to the basin subsidence.

S wave seismic reflection survey on the Shikano fault appeared in the 1943 Tottori earthquake

*Takao Kagawa[1], Tatsuya Noguchi[1], Koji Yamada[2], Tetsuya Takemoto[2]

1. Tottori University Graduate School of Engineering, 2. Hanshin Consultants Co., Ltd.

A shear wave seismic reflection survey was conducted across the Shikano fault that appeared in the 1943 Tottori earthquake (M_J7.2) at Horakuji area in Shikano, Tottori city, Japan. The length of the survey line was 200 meters, shot and seismograph intervals were both set as 1 meter. The resulting interval of Common Mid Point (CMP) was 0.5 meters. Mechanical plate hitting machine by hydraulic pressure was used as seismic source. The figure shows the depth section along the survey line with evaluated shear velocities. The Shikano fault locates at CMP number 200. Disturbance is seen in shallow surface layers in around the point. Furthermore, rather strongreflection boundary is seen at depth about 45 meters. We will interpret the results together with the data of microtremor surveys conducted in the surrounding area.
Accnowledgement: This work was supported by JSPS KAKENHI Grant Number 19H02406.

Offset streams across active faults in Chugoku region in the southwestern Japan

*Takashi Azuma[1]

1. National Institute of Advanced Industrial Science and Technology

Evaluation of slip rate of strike slip fault is difficult caused by absence of age information for references, such as streams and mountain ridges. Relationships between amount of stream offset (D) and length of stream upper than fault (L) were used as one of the methods to estimate it. In this study, data of D and L were gather from four active faults (Itsukaichi, Tsutsuga, Jifuku, and Ooharako) in Chugoku region in the southwestern part of Japan. These faults are right-lateral strike-slip faults with direction of northeast-southwest. Length of faults are 27 km, 58 km, 27 km, 42 km, respectively. Digital elevation model was used to measure amount of stream offset and length of stream. Results will be used for studies of slip rate of strike-slip faults, together with data of erosion rate around this region.

Keywords: Active fault, Slip rate, Offset stream

Change in stress with seismic cycles in coherent and mélange units in the Cretaceous Shimanto Belt, SW Japan

*Makoto Hashiguchi[1], Yoshitaka Hashimoto[1]

1. Kochi University

Stress state in a subduction unit can be exchanged between reverse and normal fault regimes with earthquake cycles. A similar change in paleostresses has been also obtained in some exhumed accretionary complexes. However, the previous studies in exhumed accretionary complexes cover only mé lange units along the coastline.In this study, we spatially examined a regional paleostress change in a coherent unit as well as an adjacent mélange unit in a mountain area.

The study area is located in the Cretaceous northern Shimanto Belt. A coherent unit distributs in the north and a mélange unit is located at the south adjacently. Strike and dip of the bedding and foliations of mé lange are NE-SW and steeply to the north, respectively. Many micro-faults are observed in both areas with nicely visible slicken side and slicken steps. We have measured slip data from the micro-fault for the inversion analysis of paleostress. Among six stresses estimated, our stresses could be reasonable for each unit because many unique faults are found. In the coherent unit, the stress states include two reverse fault regimes, one strike-slip fault regime and one normal fault regime. In mélange unit, one reverse fault regime, one strike-slip fault regime and two normal fault regime were identified. The orientations of the principal stresses are mostly consistent in NW-SE, NE-SW and almost vertical directions. The results suggest that the stress exchange is commonly observed in both coherent and mélange units.

In order to constrain stress magnitude, stress polygon was employed. Effective vertical stress (Sv’) was assumed as 140 MPa corresponding to the depth about 5.5 km which came from the maximum paleo-temperature (165 ˚C) of vitrinite reflectance. The stress magnitude for the reverse fault regimes is larger than that for the normal fault regime normally in both areas. In addition, the difference of the maximum shear stress (stress drop) was examined. The maximum shear stresses for each stress regime were estimated by the half of the differential stress (SHmax-Shmin). The stress drops between reverse and normal stresses ranges 1.8-63 MPa in the coherent unit. The stress drops are consistent with the range of 0.01-100 MPa in trench type earthquakes. Therefore, it is possible for our results to be related to earthquake cycles at least for the coherent unit.

In the mélange unit, because reverse fault regime did not fit the stress polygon with 140 MPa of Sv’, the stress drop could not be estimated.

Fluid inclusion analysis was conducted in mélange unit to obtain pressure-temperature (P-T) conditions of mélange unit. Homogenization temperatures of methane inclusions give methane density and these of water-rich inclusions show the trap temperature because water was saturated with methane at the time. The trap pressure can be obtained from the combination between methane density and the trap temperature. Two samples were measured so far. One is a normal fault and the other is a reverse fault. The P-T conditions for the normal fault range 190–237˚C and 174.2–196.9 MPa, respectively. These for the reverse fault are 167–211˚C and 79.5–91.5 MPa, respectively. The pressure for the normal fault shows twice higher than that for the reverse fault. The P-T conditions are not consistent each other, suggesting that the timing of the micro-fault development in the units are different.

©2020. Japan Geoscience Union. All Right Reserved.

In conclusion, the exchange of stress accompanying earthquake cycles could occur both in the coherent and mélange units. The interpretation that the exchange of stress observed both in mélange and coherent units implies that the exchange in stress state could be recorded after mélange unit was located adjacent to coherent unit. It suggests that the micro-faults were activated within an accretionary wedge. However, the P-T condition of fluid in the both faults show inconsistent. To understand the effects of fluid, further fluid inclusion analyses in the mineral veins will be required.

Long-term level and temperature changes in groundwater at the frontier land zone for impending great earthquakes at the Nankai trough, southwest Japan
- Recent anomalous changes, possible great earthquake precursors -

*Tameshige Tsukuda[1]

1. none

For the purpose of monitoring the preparing process of the impending Nankai and Tonankai earthquakes, groundwater measurements are being conducted in the Nanki region,Wakayama Prefecture, southwest Japan. Semiconductor pressure sensors for water level and platinum resistance thermometers for water temperature are exploited.
We have 16 groundwater observation stations for temperature, and 3 stations for water level in the Tokai and Nanki regions, central and southwest Japan, respectively, where are close to the source regions of the great Nakai-trough earthquakes. This paper reports the seismological meaning of the data from Nanki region.
At stations HA and WA in Shionomisaki, Nanki region, Wakayama Prefecture, the long-term trend of the water level is rising with a rate of about 70mm/year, corresponding to the ground subsidence found by levelling and GNSS data (Kobayashi, 2013) till around 2015. The recent water level changes are nearly constant in time. Here, we deal with one-year moving average of levelling data. At the two stations, the trend of temperature is similarly rising with a rate of about 50 m degree/year, suggesting contraction of the rock medium under Shionomisaki, the southernmost end of Honshu.
At KZ(Kozagawa)about 15km northeast of HA or WA in the Nanki region, the temperature is monotonously falling since the observation started in 2002 with some precursory change for the 2004 Kii-Hanto-Oki earthquake(M7.4). However, the decreasing temperature changed to severely increase in the middle of 2015, and changed to decrease again in 2017.
The groundwater temperature changes are related to preparatory earthquake generations. In the preparing process of a large earthquake, the medium would be deformed generating regions of contraction and dilatation around the nucleus of the shearing stresses. According to a hydraulic model, pore fluid flow is driven upward to the ground surface through crack systems serving as flowing pipes by high pressure pumps at a deep spot. The change in the quantity of the upwelling hot water from deep underground causes a change of groundwater temperature(Tsukuda et al., 2005).
As mentioned above, the deformations of the rock medium are accelerated under the regions close to the source regions of the great erthquakes at the Nankai trough. For prediction studies for the impending great erthquakes, we should start to conduct detailed and multidisciplinary observations.
The observations are supported by the NPO, CADASU(Collaborators Association for Detecting Anomalous Signs from Underground).

Application of different statistical tools to investigate radon time-series data for earthquake precursory studies in Taiwan

*Vivek Walia[1], Arvind Kumar[1], Ching-Chou Fu[2], Shih-Jung Lin[1], Cheng-Horng Lin[1,2]

1. National Center for Research on Earthquake Engineering, NARL, Taipei, Taiwan , 2. Institute of Earth Sciences, Academia Sinica, Taiwan

For past few decades, anomalous temporal changes in radon concentrations have been reported in relation to earthquake occurrences. However, radon anomalies in all cases are not only controlled by seismic activity but also by meteorological parameters which make isolation of earthquake precursory signals complicated. The present study is an attempt to assess and quantify the influence of the meteorological and hydrological parameters on the soil gas radon emission at monitoring stations established along different active faults of Taiwan. Characteristics of temporal variability of soil-gas radon concentrations for the monitoring stations have been examined by using statistical tools e.g.Singular Spectrum Analysis. In order to make continuity and regularity of the data before applying the analysis, the radon data were carefully edited for rare duplicate sampling, gaps and discontinuous jump following intervals of malfunctioning of equipments. Digital filter has been applied in eliminating the long term trend in the data and retains variations of less than 30 days. The radon variations exhibit dominant daily variations, which are controlled by atmospheric temperature inducted evaporation in surface water saturated soil (Capping Effect). The decay of radon after the recession of rainfall is approximated by double exponential decay terms, one corresponding to the natural decay of radon with half life of 3.84 days and second representing slow weakening of capping effect. The effect related to internal loading due to rise and fall of groundwater modulates the propagation of radon in overlying strata, accounting for the long term variations in radon. The rainfall inflicted changes in radon look strikingly similar to earthquake related precursory or co-seismic perturbations, inferred by long term synotopic observations. It is surmised that unless radon variations are corrected for meteorological/hydrological contamination, some precursory signals are masked on one hand while on the other hand some anomalies are falsely viewed as earthquake precursors.

Correlations of earthquake properties with geomagnetic ULF precursor characteristics over multiple events

*Muhammad Khairul Adib Muhammad Yusof[1], Mardina Abdullah[1,2], Nurul Shazana Abdul Hamid[1,3], Suaidi Ahadi[4], Akimasa Yoshikawa[5]

1. Space Science Center, Institute of Climate Change, Universiti Kebangsaan Malaysia, Malaysia, 2. International Center for Space Weather Science and Education, Kyushu University, Fukuoka 812-8581

We investigated the correlations of earthquake properties with precursor characteristics over multiple events by analyzing geomagnetic field data from 10 observatory stations around the world. Earthquake precursory anomalies were detected by employing the polarization ratio analysis method to process the signal in ultra-low frequency (ULF) ranges (i.e., 0.01 –0.1 Hz), while the polarization ellipse method was utilized for direction estimation. Earthquakes (n = 34) were studied to characterize their precursors in terms of the frequency band, amplitude, error percentage of direction estimation and lead time. The correlations of these characteristics with earthquake properties (i.e., magnitude, epicentral distance, hypocentral depth and local seismicity index) were then determined. We found that 20 earthquakes were preceded by precursors. Weak correlations were identified when all found precursors were included, but stronger correlations were identified when the study was focused on precursors from a station in Japan. We concluded that some earthquake properties are correlated with several precursor characteristics when the study area is restricted to a specific location.

Recent Advances in Earthquakes Relocation and Probabilistic Seismic Hazard Assessment for Risk Mitigation and Planning in West Africa

*Umar Afegbua Kadiri[1], Tahir Abubakar Yakubu[1], Friday Ezomo, Brassnavy Manzunzu

1. Centre for Geodesy and Geodynamics Toro

This work is aimed at utilizing modern techniques to improve earthquakes location and establish seismic hazard parameters for planning in West Africa. Over the years, dearth of data and well-defined velocity models have hindered robust seismological researches in the region. For the first time therefore, Regional Seismic Travel Times and iloc in Geotool software were used to relocate significant earthquakes; and Probabilistic Seismic Hazard Assessment was carried out using earthquake catalogue (1618-2018), with different levels of magnitude completeness determined for the sub-catalogues. The results showed enhanced events characterization and epicenters with attendant improved seismicity scenario. Maps of b-values, earthquakes density and that for updated seismicity have been produced for West Africa from this study. The regional maximum possible magnitude is estimated to fall in the range of [6.62; 7.17]. The b-value and activity rate were computed as 0.71±0.2 and 3.44±0.17 respectively. A forecast of future earthquakes occurrence shows that a magnitude 6.80 is likely to occur in West Africa approximately every 370 years. The Probabilities of the same event occurring annually and once in 50, 100 and 1000 years are 0.27%, 12.59%, 23.50% and 91.8% respectively. The annual probability of occurrence of small magnitude earthquakes (less than 5.0) is high. The 10% probability of exceedance of PGAs in 50 years ranged from 0.05 m/s² to 0.34 m/s². The significant hazard levels were observed in South Western Cameroon, South-Western Nigeria, Southern parts of Ghana, Eastern parts of Benin Republic, Guinea, Togo, Guinea Bissau, The Gambia, and Sierra Leone respectively.

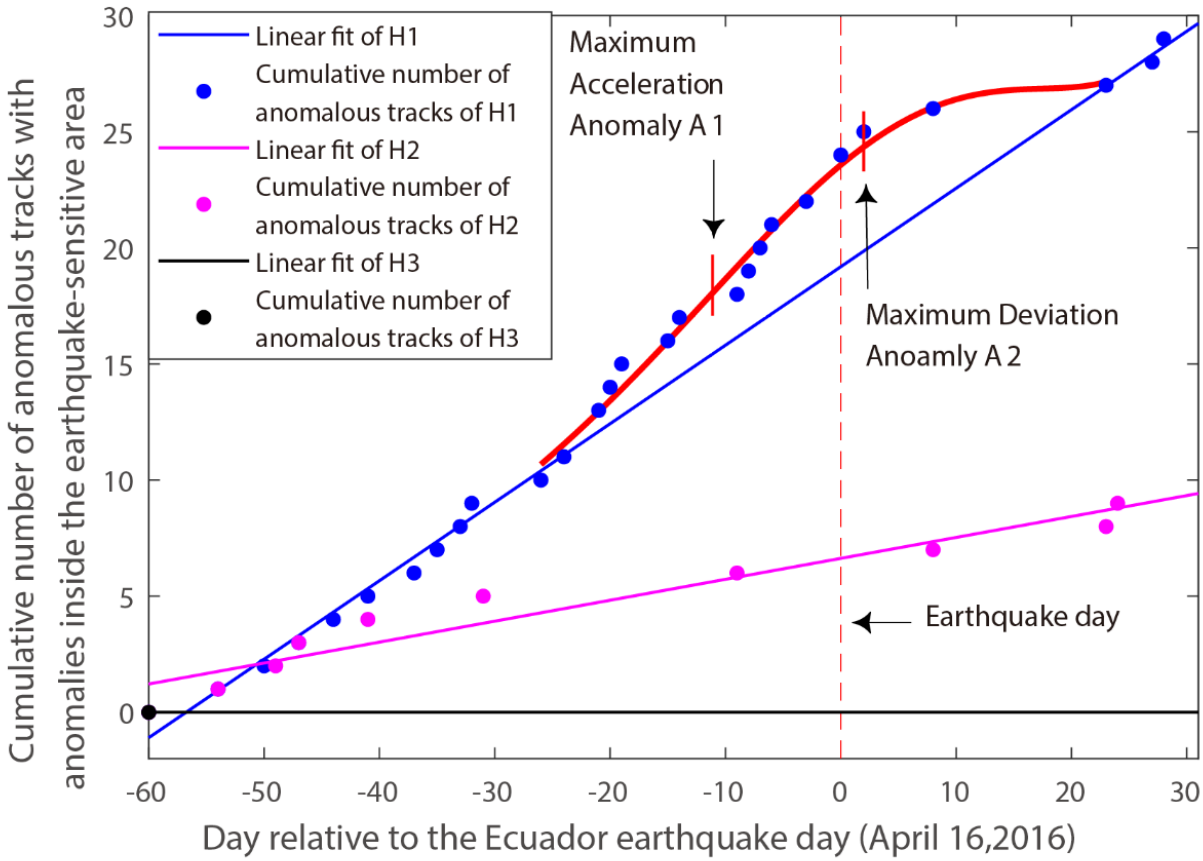
Ionosphere Magnetic Field Precursor Anomalies Extraction Associated with 2016 Ecuador Earthquake using NMF



*Mengxuan Fan[1], Kaiguang Zhu[1], Xiaodan He[1], Kaiyan Li[1], Dedalo Marchetti[2], Chengquan Chi[1], ZINING YU[1]

1. Jilin University, 2. National Institute of Geophysics and Volcanology

Some ionosphere anomalies are found in satellite observations during the preparation phase of earthquakes. In previous earthquake studies, the magnetic field data under strong geomagnetic activity are usually deleted to avoid the influence of the geomagnetic activity, therefore the dataset are reduced. In this paper, we decompose the Swarm satellite time series magnetic field data under all geomagnetic conditions and all local time by Nonnegative Matrix Factorization to study the April 16, 2016 Mw7.8 Ecuador earthquake. The data are decomposed into basic vectors and their corresponding weights, and we find that the energy and entropy of component H1, one of the weight components, are more concentrated inside the earthquake sensitive area than other weight components. The cumulative number of anomalous tracks with anomalies inside the earthquake sensitive area evaluated by component H1 shows accelerated growth before the earthquake and recovers to linear growth after, which obey the power law behavior of a critical system, while for other components H2 and H3 show linear growth before and after the earthquake. Furthermore, the cumulative anomalies of component H1 also correspond to two previous studies which also use the magnetic field data of Swarm satellite, but removed the data or component influenced by the geomagnetic activity. And the test on the anomalous track percentages versus different geomagnetic levels indicates the cumulative anomalies of component H1 are hardly affected by geomagnetic activity. After a confutation analysis of four random low seismicity area cases and two 90 days low seismicity period cases, the cumulative anomalies of component H1 are also confirmed as not obtained by simple chance. Moreover, we find the cumulative result of component H1 has similar growth to the cumulative Benioff strain S around the Ecuador earthquake epicenter, that suggests that the ionosphere magnetic anomalies are associated with the lithosphere activities which are related to the Ecuador earthquake and agrees with the Lithosphere Atmosphere Ionosphere Coupling.

Stress induced from large earthquakes since 1900 and temporal b value change in Nankai trough

Junhyung Lee[1], Ilgoo Kim[1], *Tae-Kyung Hong[1]

1. Department of Earth System Sciences, Yonsei University

The perception of impending great earthquakes may be useful for seismic hazard mitigation. The seismicity is dependent on the stress field as well as medium properties. The Nankai trough is recognized to have a high hazard potental. Large earthquakes occur periodically in the Nankai trough with recurrence intervals of 100-200 years. The influence of fractional stress changes by precedent earthquakes on the induction of forthcoming earthquakes is investigated. We assess the global stress perturbation induced by 1626 earthquakes with magnitudes greater than or equal to 7.0 since 1900. We stack the Coulomb stress changes. The cumulative Coulomb stress changes reach up to an order of tens to hundreds of bars at convergent plate boundaries. Descendant large earthquakes appeared to occur in the regions with large lateral gradients in cumulative Coulomb stress changes induced by precedent earthquakes. The cumulative Coulomb stress changes over a century are comparable among subduction zones. The instability and inhomogeneity in stress field may play an important role in nucleation of great earthquakes. We also determine the temporal variation of the Gutenberg-Richter b values in the slow slip region along the Nankai trough for 40 years. It is observed that the b values were generally bounded between 0.6 and 1.0. The slow slips and associated plate motions accompany micro and small earthquakes, inducing b value increase. The b values increase concurrently at the times of slow slips. The b decay rates after slow slips are observed constant. The consistent b-value decrease rate since 2014 may suggest temporal approaching to a large earthquake.

Microseismicity distribution and inferred fault geometry beneath the western Marmara Sea, Turkey, deduced from long-term ocean bottom seismographic observations

*Yojiro Yamamoto[1], Dogan Kalafat[2], Ali Pinar[2], Narumi Takahashi[3,1], Zeynep Coskun[2], Remzi Polat[2], Haluk Ozener[2], Yoshiyuki Kaneda[4,1]

1. Japan Agency for Marine-Earth Science and Technology, 2. KOERI, Bogaziti University, 3. National Research Institute for Earth Science and Disaster Resilience, 4. Kagawa University

The North Anatolian Fault (NAF) is the transform plate boundary between Eurasian and Anatolian plates. The reginal rate of its dextral strike-slip displacement is about 25 mm/yr. In particular, a part of NAF beneath the Marmara Sea is recognized as a seismic gap for M >7 earthquake during more than 100 years. Earthquake hazard and disaster mitigation studies in Marmara region are sensitive to detailed information on fault geometry and its coupling status beneath the Marmara Sea. However, it is difficult to obtain precise hypocenter location from only onshore permanent seismic stations. Thus, we have started a series of long-term ocean bottom seismographic (OBS) observations beneath the western and central Marmara Sea since 2014. First, we have installed 15 OBSs along the western part of Main Marmara Fault (MMF) from 2014 to 2015. Using these data, Yamamoto et al. (2017) identified a segment boundary of the MMF beneath the central basin of the Marmara Sea (28.05˚E). Besides, they proposed that the zones of no seismicity within the upper crust appear to indicate locked sections of the MMF. In this study, we analyze the second observation data (from 2015 to 2016). The OBS location for first and second observations were almost same. We have conducted the double-difference relocation by using 3-D velocity model obtained by Yamamoto et al. (2017), and obtained 818 relocation results.
The result shows that the feature of hypocenter distribution, including the location of no seismicity zones obtained by Yamamoto et al. (2017), is not changed, suggesting that the coupling status along the fault is almost same during at least two years. The largest no seismicity zone extended over the upper crust is located between 28.45˚E and 28.65˚E, where strong coupling is suggested from seafloor geodetic observation (Lange et al., 2019; Sakic et al., 2016). By combining the relocation result of first and second phases, the detailed fault geometries were clarified. Beneath the Western High and western Central Basin (27.75˜28.05˚E), we found two branch faults whose dip angles are gentler (30˜60) than that of MMF (almost vertical). The cross point of two branch faults and MMF locates about 15 km depth of MMF. Although these faults might relate to the pull-apart or negative flower structure around the Central Basin, we could not find similar structure in eastern Central Basin.

A major earthquake will be followed by many smaller earthquakes and tremors, which are called aftershocks, around its hypocenter in the source area. Omori (1894) discovered that the number of aftershocks generally decreased inversely proportional to the elapsed time from the origin time of the largest earthquake. Later, Utsu (1961) found a simple equation that describes the number of aftershocks n(t) as a function of the elapsed time t: n(t)=K(t+c)^(-p) where p indicates the decay rate of aftershocks and K represents the aftershock activity immediately after a major earthquake. The parameter c controls the retarded time of aftershock activity (Nanjo et al., 2007) and is usually a finite short time. Omi et al. (2015) reported that the parameter p is generally from 0.9 to 1.5 around Japan.

In this study, we focused on aftershock activity of The 2011 off the Pacific coast of Tohoku Earthquake (hereinafter, referred to as the 2011 Tohoku earthquake) and analyzed its p and K values. We then investigated their relationships in space and time with respect to the slip distribution of the 2011 Tohoku earthquake and the regular seismicity before the earthquake.

We analyzed the number of earthquakes on the subducting Pacific plate that occurred from 34.0N to 42.0N in latitude and from 141.0E to 145.0E in longitude during the 16 years from 2003 to 2018. Since it is important that all the earthquakes are detected, earthquakes with a magnitude (M) of 3.0 or larger were used for the analysis. As a result, 24,942 earthquakes were included in the analysis.

The number of daily earthquakes in each area of 0.5 degrees in latitude and longitude was counted and averaged over each month for the period from April 2011 to December 2018. We then deduced values of p and K in the equation of Utsu (1961) that explain the aftershock activity for individual areas, assuming that the parameter c is equal to zero. We obtained values of p and K in the range of 0.07-1.06 and 0.06-400, respectively. Estimated p values were smaller than those derived by Omi et al. (2015), suggesting that the aftershock activity of the 2011 Tohoku Earthquake has been decaying slower than those of other large earthquakes around Japan. We also found that values of p and K had positive correlation. Although these two parameters may not be always independent as suggested by the equation of Utsu (1961), the correlation was significant in taking the estimation error into account.

Focusing on their spatial pattern, values of p and K in the area around the source region of the 2005 Miyagi-oki earthquake were smaller than those in other areas. In addition, these parameters had also smaller values in areas with a large coseismic displacement during the 2011 Tohoku earthquake and in the northern border of its source region. It should be noted, however, that numbers of earthquakes in these areas were relatively small and they might be apparent.

In order to investigate the relationship between the seismicity before and after the 2011 Tohoku earthquake, we finally investigated the spatial pattern of the number of earthquakes N that occurred in 2003 through 2010 and its correlation to the values of p and K of the aftershock activity. We found that values of N and K had a positive correlation. It would be natural to assume that aftershocks take place as a result of the disturbance of shear stress and strength due to a large earthquake and some previous studies

reported a spatial correlation of aftershocks and the coseismic displacement and the change of shear stress associated with a large earthquake. Our results, however, suggests that the spatial pattern of the coseismic slip during the 2011 Tohoku earthquake and of the stress perturbation due to the earthquake may not control the aftershock activity in the study area.

Acknowledgments.

We used the hypocenter data determined by the Japan Meteorological Agency. We would like to express sincere thanks to Dr. Takeshi Iinuma for providing the result of the coseismic slip during the 2011 Tohoku earthquake estimated by Iinuma et al. (2012).

[S-SS09] INDUCED AND TRIGGERED SEISMICITY: CASE STUDIES, MONITORING AND MODELING TECHNIQUES

convener:Luca Urpi, Yusuke Mukuhira(Institute of Fluid Science, Tohoku University), Bogdan Enescu(Department of Geophysics, Kyoto University), Francesco Grigoli(ETH Zurich Swiss Federal Institute of Technology Zurich)

Induced and triggered seismicity occurs in conjunction with human activities such as reservoir impoundments, mining operations, conventional and non-conventional hydrocarbon production, geothermal energy exploitation, wastewater disposal, CO2 sequestration and gas storage operations as well as volcanic and hydrogeological processes. The stability of faults is affected by external solicitations such as pore-pressure diffusion, relaxation effects as well as perturbations related to mass, pressure, temperature and/or volume changes, dike intrusions and earthquake-earthquake interactions. A better understanding of the physical processes governing induced and triggered seismicity is important for the assess the risk of current and future industrial activities.

The study of induced and triggered seismicity is inherently an interdisciplinary problem, which requires the combination of seismological, hydrogeological, geodetic data and a wide range of modeling approaches. This session welcome contributions covering the analysis and modeling of induced and triggered seismicity at different spatial scales and environments.

Relevant topics to be presented include but are not limited to induced seismicity characterization, spatio-temporal variations of physical parameters (including stress, pressure and temperature changes), spatio-temporal patterns of seismicity, modeling strategies and case-studies.

The goal of the session is to cover both theoretical, numerical and experimental aspects of these topics.

Understanding of the physics behind induced seismicity is an important research topic in seismology. Geoscientists have used seismological analyses, numerical simulations, and seismostatistical analyses to investigate the processes occurring in and the behavior of reservoir rock masses upon hydraulic stimulations that frequently led to substantial induced seismicity. Knowledge of the physics related to induced seismicity associated with fluid injections is key to seismic hazard mitigation. In this study, we approach this problem unconventionally, analyzing at high spatial resolution the natural fracture and in-situ stress information inferred from borehole logging, i.e. data available prior to stimulations, while conventional seismological approaches study the waveforms of induced seismicity, which are posterior phenomena. Injection-induced seismicity is primarily caused by an increase of fluid pressure in the existing fractures, which decreases the fracture’ s shear strengths. Using pre-stimulation information, we investigate the potential of induced seismicity by evaluating the state of stress of natural fractures. Then, we try to find the link to the tendency of observed induced seismicity where we got fault plane geometry information from waveform analysis.

In this study we investigate the natural fracture and in-situ stress data sets from the Basel EGS project in Switzerland. The data originates from the lowermost 2.4 km long borehole section through the basement consisting of granitic to monzonitic rocks. The natural fractures were inferred by careful analysis of acoustic borehole logging images (Ziegler et al. 2015), the in-situ stress data was derived from borehole breakout analysis and some well-test constraint (Valley and Evans, 2009; 2015). Ziegler and Evans, (2020) discovered that the orientation of the seismically inferred faults and natural fractures are similar. Based on these findings of the link between the fault to cause induced seismicity and natural fracture from borehole logging, we investigate the physical link between those beyond the geometrical consistency. We estimated various geomechanical parameters such as shear stress, normal stress, apparent shear strength, i.e., critical pore pressure, and slip tendency. We compared the distributions of those parameters estimated from induced seismicity and natural fractures. We try to find the link between those relationships and discuss the preliminary foundings. Then, we will extend our findings to the theory proposed by the conceptual theory of b-value reduction with increasing stress (Scholtz, 1968).

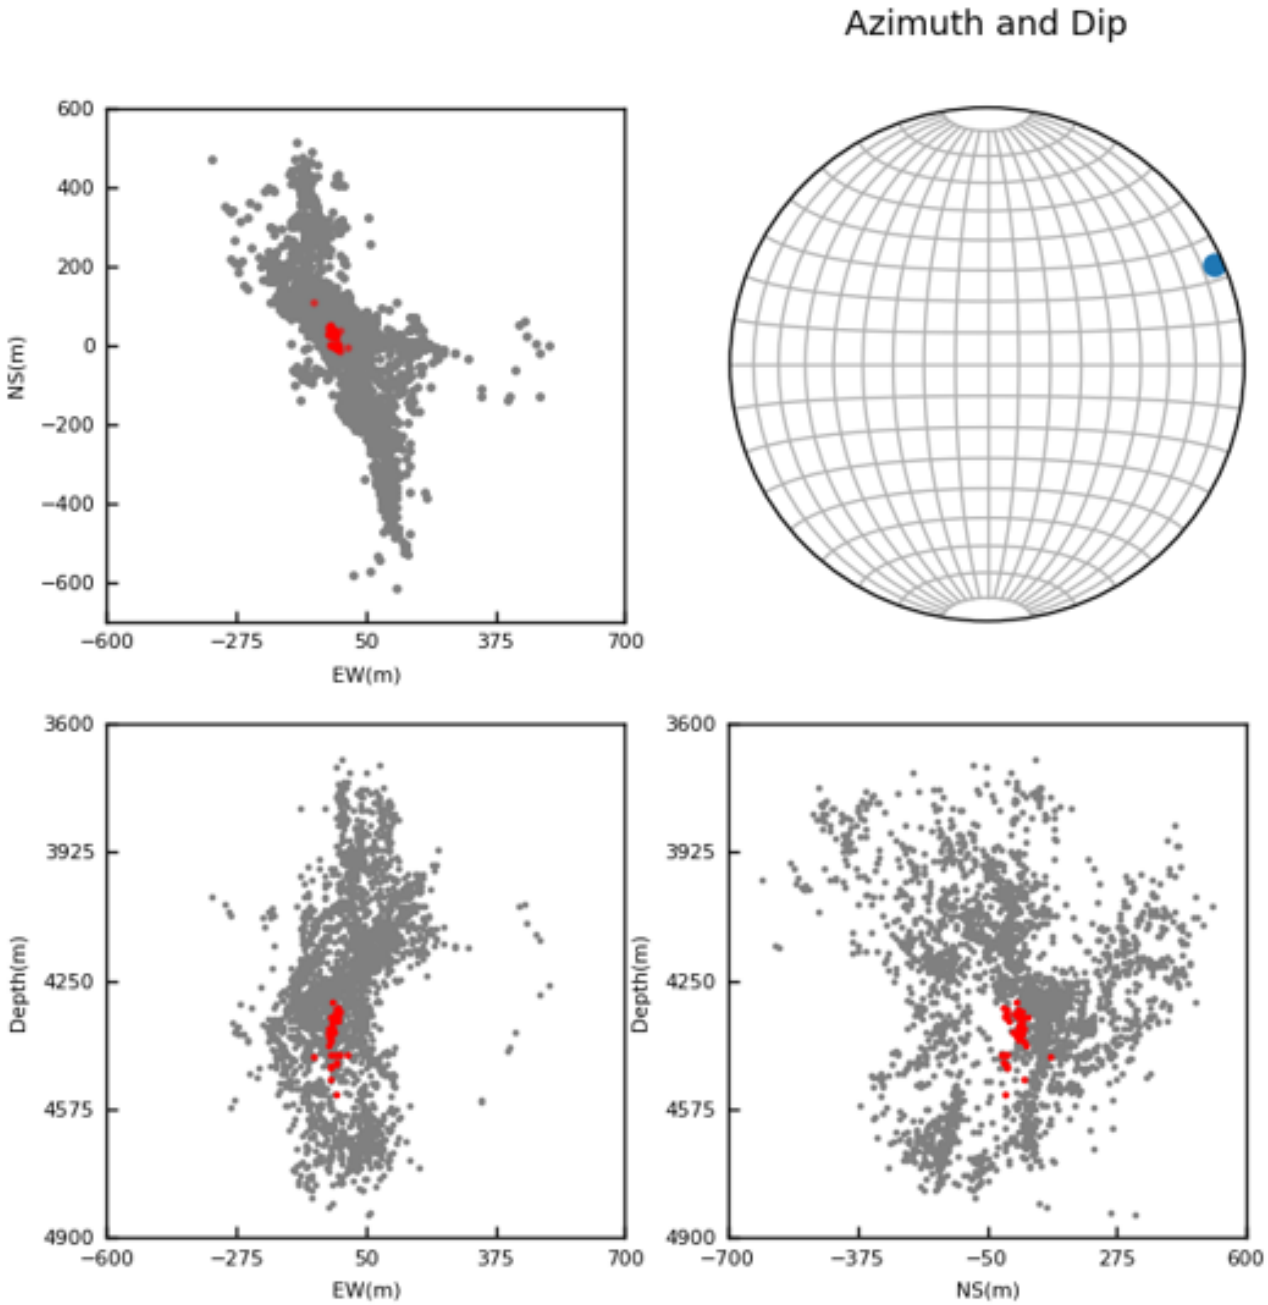
Estimation of focal mechanisms of large number of induced seismicity to understand fracture system in the geothermal reservoir

*Kangnan Yan[1,2], Yusuke Mukuhira[1], Takatoshi Ito[1], Yinhui Zuo[2], Hiroshi Asanuma[3], Markus O Häring[4]

1. Institute of Fluid Science, Tohoku University, 2. State Key Laboratory of Oil and Gas Geology and Exploitation, Chengdu University of Technology, 3. Fukushima Renewable Energy Institute (FREA), National Institute of Advanced Industrial Science and Technology (AIST), 4. Häring GeoProject



Induced microseismicity is a phenomenon often observed in hydrocarbon and geothermal reservoirs accompanying changes in pore pressure due to injection. Estimation of the focal mechanism of induced microseismicity is beneficial to characterize the distribution of the existing fractures in the reservoir. The focal mechanism of microseismicity is often constrained by the polarity information of first P-wave arrivals. However, it’ s difficult to obtain enough P-wave polarities from a limited number of stations due to cost consideration. The new method was proposed to better constrain the focal mechanism of injection induced microseismicity by introducing *in situ* stress magnitude/orientation information and the injection wellhead pressure (Mukuhira et al., 2018). The range of possible focal mechanism estimated by available polarization information was constrained by in situ stress data further.

We have applied this method to 47 microseismicity events with relatively larger magnitude during the hydraulic stimulation in Basel, Switzerland. In this study, we apply our method to more than 2,000 smaller magnitude events of which the orientations of fault are unknown. By estimating more fault orientation, we can understand the entire fracture system of the reservoir.

All the events are divided into 101 groups based on waveform similarity, and assume all group member occur from one single fracture. we choose one group (group 4) based on good linear shape, relatively larger magnitude of members, large number of events and occurrence time during the injection period. We estimate the fault orientation by principal component analysis (PCA) of hypocenter distribution of 54 events from group 4, and then regard this fault orientation as reference. Meanwhile, we also use the first P-wave arrivals polarities and *in situ* stress information to constrain the focal mechanism together. Then, we will compare the two estimates of fault orientation by PCA and our method, and discuss the validity of our method for smaller events. Then, we will apply our method and constrain the focal mechanisms of other groups. Consequently, we will estimate the focal mechanism of more than 2,000 events from Basel, Switzerland using this method. Our work will enhance the validity of our method further and also contribute to better understanding the fracture system in the reservoir in Basel, Switzerland.

Source Mechanism and triggering process for the April 12th and 13th 2014 earthquake doublet in the Solomon Islands

*Calvin Luiramo Qwana[1], Masatoshi Miyazawa[1], James Mori[1]

1. Disaster Prevention Research Institute Kyoto University

On 12th and 13th April 2014, a pair of earthquakes with magnitudes Mw 7.6 and Mw7.4, respectively, occurred near Makira Island (San Cristobal) in the Solomon Islands. The depth of the main event (Mw 7.6) was 27 km and the depth of the second event (Mw 7.4) was 37 km respectively (USGS). The second event occurred 16 hours later after the Mw 7.6, approximately 20 km southwest of the location of the hypocenter of Mw 7.6. The study aims to analyze and evaluate the source mechanism for the two-doublet earthquake Mw 7.6 and Mw 7.4 and evaluates if any interrelation between the main event (Mw 7.6) and the second event (Mw 7.4). To understand “why the Solomon Islands has the highest rate of doublet earthquakes” (Lay and Kanamori, 1979; Schwartz et al., 1989; Felzer et al., 2004, Yamamoto et al., 2002 and Xu and Schwartz, 1993). We utilize the role of static Coulomb stress function to evaluate if the Mw 7.4 earthquake was triggered by the static Coulomb stress changes. Initially, the teleseismic P waveform data were retrieved from more than 20 stations for both events from the Global Seismographic Network from azimuthal coverage distances between 30˚ and 90˚. The retrieved P-waveform data were filtered to obtain the best-fit reduction variant between the observed waveform with the synthetic waveform. The retrieved P-wave form data were filtered separately for each event. The cutoff frequency for P –wave filtered separately between 0.04 Hz - 0.1 Hz. The Green’s function is utilized to determine the slip distribution on the fault planes where the observed seismogram inverted. Based on the presumption that a fault plane with fixed strike and dip angles placed in the region of the earthquake hypocenter and divided into sub faults, a constant rupture velocity of 2.5 km/s is assumed and the synthetic waveforms are calculated at the teleseismic stations according to the dislocations of each sub faults. We calculated the values for the Coulomb Failure Stress function at the hypocenter for the mechanism of the second event and obtained +48.59 kPa for the north dipping fault and south-dipping fault to be +18.24 kPa. Furthermore, the spatial distribution of aftershocks for 16 hours seems to agree with the northern dipping fault for the triggered event. Both cases, however, show an increase of stress changes which encourages the likelihood that the recipient's fault triggered by static Coulomb Stress Changes. We proposed a model that might support the complexity of the region to produce these doublet events.

Ultra-microearthquakes observed at Mizunami Underground Research Laboratory

*Osamu Murakami[1], Yasuhiro Asai[1], Hiroshi Ishii[1]

1. Tono Rearch Institute of Earthquake Science, Association for the Development of Earthquake Prediction

Mizunami Underground Research Laboratory (MIU) was constructed by Japan Atomic Energy Agency (JAEA) in order to achieve these two main goals: establishing technology for investigation, analysis and assessment of the deep geological environment, and developing a range of engineering technology for deep underground application. MIU has two vertical shafts, and has the horizontal galleries and the sub stages at every 100 m depth from 100 m depth to 500 m depth.

We deployed the seismic observation network in MIU. We installed 3 components accelerometers (JEP-6A3-10, Mitutoyo co.) at each station, and continuously recorded the ground accelerations at 10 kHz sampling (SC-ADH10K, Scimolex co.). Because of the high frequency sampling, we succeeded to detect some ultra-microearthquakes occurred around MIU. An ultra-microearthquake occurred at 16:27 (JST) on January 17, 2019. This event was observed at one of the stations installed at 500m depth. Another station (400m depth) also showed the seismic waveform, although we could not find the clear P and S wave arrivals due to the bad signal-to-noise ratio. If we assume that S-P time is 0.05 s at this 500 m depth station, and that the velocity of S wave is 2200 m/s (Okubo et al., 2012) and Vp/Vs is 1.73, we obtain that the hypocentral distance is 150 m. Thus, the depth of this event is 650 m assuming this event occurred just beneath this station.

There is the almost vertical fault (Main Shaft Fault) in MIU (e.g., Tsuruta et al., 2013). The hypocenter of the event is likely to locate in this fault. However, we could not determine the location of the event, because we found the clear P or S wave arrivals at only one station. We will discuss some source parameters of the ultra-microearthquakes observed in MIU.

Acknowledgment: We would like to acknowledge the permission and cooperation to the Tono Geoscience Center, the Japan Atomic Energy Agency and the Mizunami City Office.

Seismoelectromagnetic conversions generated by a double-couple source in
partially saturated media.

*Sheldon Dwight Warden[1], Pascal Sailhac[2], Stéphane Garambois[3]

1. Hyperion Geophysical Services, 7 rue de Châtenois, 67100, Strasbourg, France., 2. GEOPS (Geosciences Paris Sud), Université de Paris Saclay, 15 Rue Georges Clemenceau, 91400, Orsay, France., 3. ISTerre (Institut des Sciences de la Terre), Université de Grenoble Alpes, 1381 rue de la piscine, 38400, Saint Martin d'Heres, France.

Seismoelectromagnetic conversions of electrokinetic origin have triggered new interest since the theory for the coupled propagation of seismic and electromagnetic (EM) waves was reformulated by Pride (1994). Over the last couple of decades, several modelling programs were developed to simulate seismoelectromagnetic propagation. Most of these programs share in common that they only allow to model point sources, well suited to simulate seismic surveys, but inappropriate when attempting to simulate earthquakes, often described using a double-couple source.

In this work, we present a program allowing to model the seismoelectromagnetic waves triggered by a double-couple source, based on the Synthetic Kennett Bouchon Program (SKBP) developed by Garambois & Dietrich (2002); this program is modified to account for partial saturation conditions (Warden et al., 2013) and high salinities (Vinogradov et al., 2010). We implement both M13+M31 and M12+M21 geometries. We validate our program by comparing its results with those obtained by modelling a double-couple source through a numerical derivative and find excellent agreement between both approaches. We then study the symmetry properties of the waves generated by this new source type for a homogenous half-space.

We then perform a sensitivity study considering a simple tabular medium consisting of a homogeneous layer overlying a homogeneous half-space. When considering a source of frequency fpeak=40Hz of magnitude Mw=1, located 4km below the ground surface and 1.5km below the boundary between both media, we model coseismic electric field amplitudes of the order of several

©2020. Japan Geoscience Union. All Right Reserved.

hundreds of μV.m−1. Analyzing these amplitudes in the light of magnetotelluric measurements suggests that even a microearthquake could trigger a coseismic response large enough to be measured at the ground surface.

We also study the characteristics of the interface response (IR) generated at the boundary between the two homogenous media for a M13+M31 double-couple and show that this IR consists of a conversion between an incident S wave and a converted EM wave; its amplitude variations can be approximated by those of a horizontal dipole located at the boundary. We also quantify the contributions of the SH and SV polarizations to the total converted amplitude and find that although the SH waves are coupled to the Transverse Electric (TE) mode, they contribute to the Transverse Magnetic (TM) mode component of the electric field through the IR.

We conclude our study by considering a more realistic model, designed to approximate the context of a geothermal field. We also provide examples of possible coseismic signals observed in electric and magnetic data acquired during geothermal monitoring experiments.

Investigation of the pore pressure sensitivity toward ocean loading influence from seismic ambient noise monitoring

*Rezkia Dewi Andajani[1], Takeshi Tsuji[1,2]

1. Department of Earth Resources Engineering, Kyushu University , 2. International Institute for Carbon-Neutral Energy Research, Kyushu University

Spatial mapping of pore pressure sensitivity toward surface perturbations can be useful to characterize crustal dynamic activities. This is due to pore pressure controls the activity of earthquakes and volcanic eruptions. Recent studies have discussed that the status of pore pressure can be evaluated from ambient noise seismic velocity change. Seismic velocity changes are known to exhibit variations induced by surface perturbations such as rainfall, snow, ocean loading, and atmospheric pressure change. Among these perturbations, the mechanism of the ocean loading influencing seismic velocity changes remain unclear. In regards to this, variations in ocean mass are known to cause inland deformation. We aim to investigate the response of the crustal pore pressure toward perturbations from the ocean by seismic velocity monitoring. We used the estimated seismic velocity in the Chugoku-Shikoku region, Japan. In this study, we used a statistical approach to draw a conclusion. To evaluate the influence of the ocean, we calculate the correlation coefficient between seismic velocity changes and sea-level. We assume a linear model between the absolute correlation and the station distance from the coast. The significance of the linear model is evaluated by considering the probability value. Our result suggests that for a specific period band, the absolute correlation between seismic velocity change and sea-level tends to decrease with the increasing distance from the coast. We conclude that ocean perturbations could spatially influence estimated seismic velocity changes, which might infer inland deformation due to ocean loading.

The character of the Focal mechanisms with Kagan angles in Japan area for the extended 2-D ETAS model

*Maita Eri[1], Jiancang Zhuang

1. SOKENDAI

The original epidemic-type aftershock sequence (ETAS) model which describes how each earthquake produces subsequent events considers only the locations, times, and magnitudes of each event. This time, we explore the possibility of combining the focal mechanisms into the model formulation to increase the estimation accuracy.

To find the suitable conditional intensity (time-varying seismicity rate) of the new form of the ETAS model, we use the F-net data from 1997 to 2017 and select focal mechanism of events with magnitudes . We use the Kagan angles (rotation angles) to transform each focal mechanism, a 3*3 matrix into a vector called a quaternion.

The data calculation leads to the model reconstruction to get the focal mechanism probability densities, under the assumption of a special symmetry, DC4 symmetry with the distribution of the Kagan angle. We also found that the rotation poles are uniformly distributed.

In the background events, the probability density of the focal mechanism or rotation angles, could be independent of any locations in the very small areas. We investigate the Japan area to find the character of .

[S-SS10] Rethinking PSHA

convener:Naoshi Hirata(National Research Institute for Earth Science and Disaster Resilience), Danijel Schorlemmer(GFZ German Research Centre for Geosciences), Matt Gerstenberger(GNS Science), Kuo-Fong Ma(Institute of Geophysics, National Central University, Taiwan, ROC)

The core methods behind probabilistic seismic hazard analysis (PSHA) were first formalized by Cornell in 1968. Since that time, the fundamental components have largely remained unchanged in most applications: 1) a source model, often made up of zones of expected activity, or an active fault model coupled with a smoothed seismicity model based on catalog data, and; 2) empirically based ground motion prediction equations (GMPE) that are based on several basic parameters, such as moment magnitude and distance. The development of the individual components has become increasingly complex in recent years, however the basic structure has largely remain unchanged.
We invite presentations that explore some of the key assumptions currently used in PSHA and their implications for hazard, or alternative PSHA methods that might provide different insight into the hazard. Some examples might be the improved quantification of uncertainty in the source modeling, and moving beyond the typical Poisson-based formulations. How are uncertainties propagated through the model and can they correctly reflect the knowledge. How can non-Poissonian dynamics be best built into time-independent PSHA? How to quantify and use uncertainties in fault and earthquake-catalog source models as well as those in ground-motion prediction? How can fault segmentation be overcome? New types of models (with increasing complexity) are being developed and they will be integrated into PSHA. How can hybrid models be used to improve the forecasting skill of PSHA? Can earthquake simulators contribute to PSHA? What are improvements in GMPEs but also their limits? Is their increasing complexity justified? Or are there viable modeling alternatives for PSHA that can improve current best practice?How can all these potential improvements being tested before they contribute to societal relevant decisions?

[S-EM18] Paleomagnetism and rock magnetism applied to solving geological and geophysical problems

convener:Martin Chadima(Institute of Geology of the Czech Academy of Sciences), Balazs Bradak(University of Burgos, Spain), Daniel Pastor-Galan(Center for North East Asian Studies, Tohoku University), Myriam Annie Claire Kars(Center for Advanced Marine Core Research)

Paleomagnetic studies have provided much key information about the geomagnetic field and plate motions, and rock magnetic methods have considerable potential for detecting and monitoring signals from past and recent environments. Integrated paleomagnetic and magnetic fabric studies, together with structural geology and petrology, are effective tools for increasing our knowledge about sedimentological, tectonic or volcanic processes on various scales. Determining how the geomagnetic field changes (i.e., reversals and paleointensity variations) helps to understand the evolution of Earth's interior, plate kinematics, dynamics of the core and mantle, long-term climate change, and true polar wander. We welcome presentations of innovative studies that make use of paleo-, rock, and environmental magnetic data in relation to geological, geomagnetic, and environmental processes, especially contributions that combine rock magnetic methods or novel approaches to data evaluation. We also solicit contributions from both experimental and theoretical aspects of paleomagnetic reconstructions, acquisition of petrofabrics, characteristic remanences, remagnetizations, polarity reversal records, paleointensity, and environmental magnetic methods.

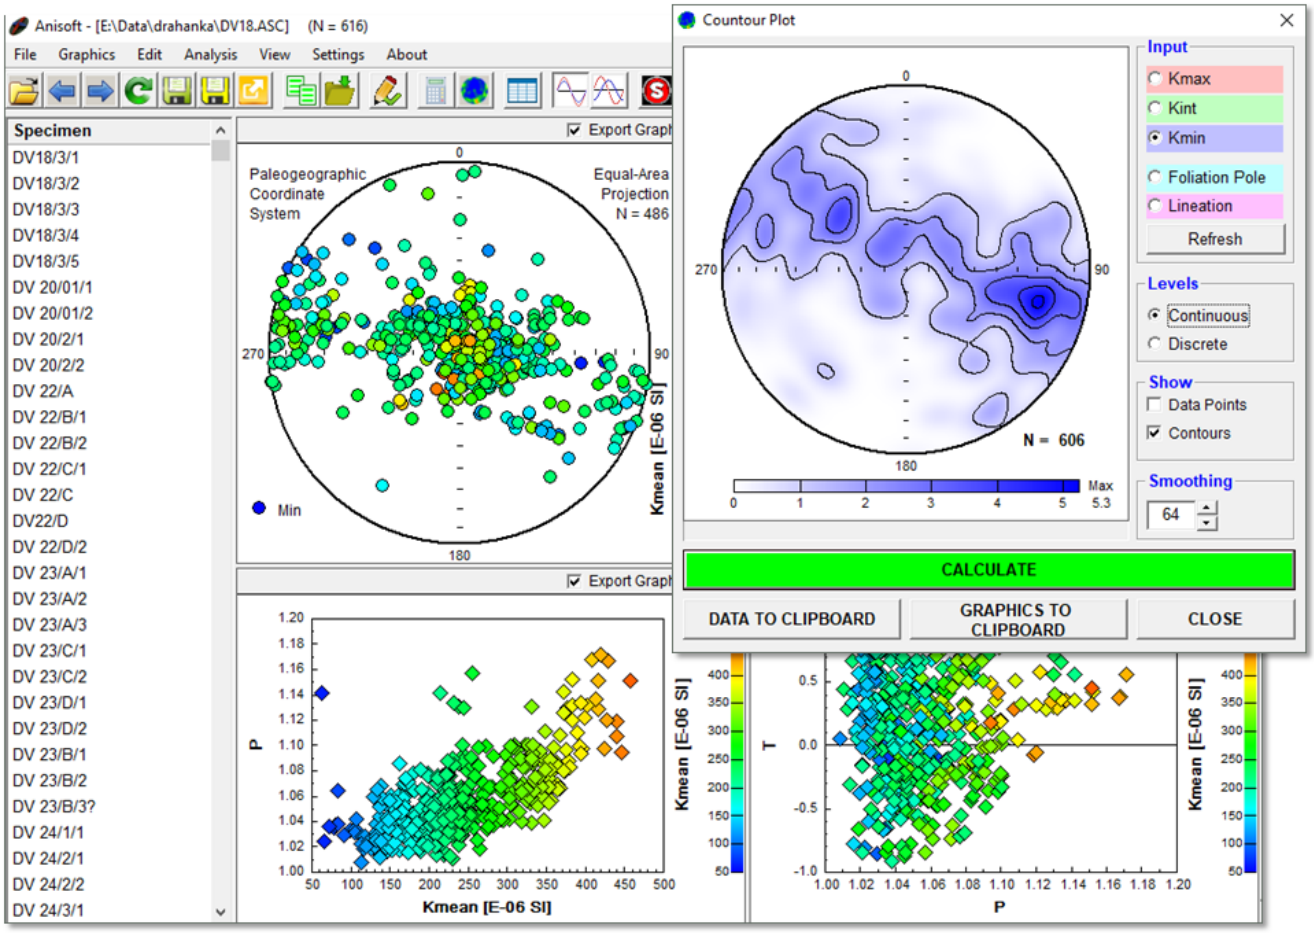
Anisoft –Advanced Treatment Of Magnetic Anisotropy Data



*Martin Chadima[1,2]

1. Institute of Geology of the Czech Academy of Sciences, Prague, Czech Republic, 2. AGICO Ltd., Brno, Czech Republic, e-mail: chadima@agico.cz

Since its first release, Anisoft (Anisotropy Data Browser) has been very well accepted by magnetic fabric community mainly due to its simple and user-friendly interface enabling convenient visualization of magnetic anisotropy data. Here, a major software update is presented transforming a rather simple data viewer into a platform offering an advanced data treatment. The update introduces new data format which stores both in-phase and out-of-phase (if measured) susceptibility tensors (AMS) or tensors of anisotropy of magnetic remanence (AMR) together with their confidence limits. In addition to the tensor data, specimen sampling angles are stored for each record enabling later editing or corrections. Each record also contains an array mesoscopic structural data enabling data transformation into various coordinate systems. Multiple anisotropy files can be combined together or split into several files by manual data selection or data filtering. Anisotropy tensors are conventionally visualized as principal directions (eigenvectors) in stereoplots together with a user’ s choice of quantitative anisotropy parameters presented in histograms or in color-coded scatter plots showing mutual relationship of three variables. For a group of specimens, principal anisotropy directions can be contoured, or a mean tensor and respective confidence ellipses can be calculated using either the Hext-Jelinek statistics or the Bootstrap method. To facilitate the AMR tensor calculation, a simple toolbox is available. The AMR tensors are fitted by a least-square algorithm using a set of pre-selected full-vectors (full-vector method) or their projections to the respective magnetizing directions (projection method). Each graphical output can be exported into several vector or raster graphical formats or, via clipboard, pasted directly into a presentation or publication manuscript. Calculated principal directions or anisotropy parameters can be exported into various types of text files ready to be visualized or processed by any software of user's choice. The software can be downloaded from this link: https://www.agico.com/text/software/anisoft/anisoft.php

Anisotropy of out-of-phase magnetic susceptibility as an alternative proxy for lattice preferred orientation of graphite

*Martin Chadima[1,2], Frantisek Hrouda[2,3], Josef Jezek[3], Štěpánka Mrázová[4], Michal Poňavič[4]

1. Institute of Geology of the Czech Academy of Sciences, Prague, Czech Republic, 2. AGICO, Brno, Czech Republic, 3. Faculty of Science, Charles University, Prague, Czech Republic, 4. Czech Geological Survey, Prague, Czech Republic

Single crystals of graphite are known to exhibit high electrical conductivity and extremely strong conductivity anisotropy. Their AC magnetic susceptibility can be decomposed into a weak negative (diamagnetic) in-phase component and relatively strong out-of-phase component which is due to electrical eddy currents. Anisotropy of magnetic susceptibility (AMS) of graphite is known to be very strong and it is thus expected to be a good proxy for the lattice preferred orientation (LPO) of graphite in a graphite ore.

Here, we present the AMS results of natural graphite ores from the Moldanubian Unit (Bohemian Massif, Czech Republic), which were mined for the pencil industry in the past. The ores are metamorphic in origin and a strong graphite LPO is thus expected.

In-phase susceptibility is very low, in the order of 10^{-6} [SI units], being positive in some specimens and negative in the others. This indicates simultaneous control by graphite and paramagnetic and/or ferromagnetic minerals. On the other hand, the out-of-phase susceptibility is much higher, in the order of 10^{-4}, and no doubt indicates its graphite control. The degree of opAMS is truly high, $P = 2$ to 3, and the opAMS foliation is closely related to the metamorphic foliation created during the Variscan regional metamorphism and associated ductile deformation.

Our results show that the standard AMS, which is in fact the anisotropy of the in-phase component of susceptibility (ipAMS), reflects not only the LPO of graphite, but also the preferred orientation of paramagnetic and ferromagnetic admixtures. On the other hand, the anisotropy of out-of-phase susceptibility (opAMS) indicates LPO of graphite, free of the effects of non-conductive paramagnetic and ferromagnetic minerals and can be used as an alternative proxy for the lattice preferred orientation of graphite in a graphite ore.

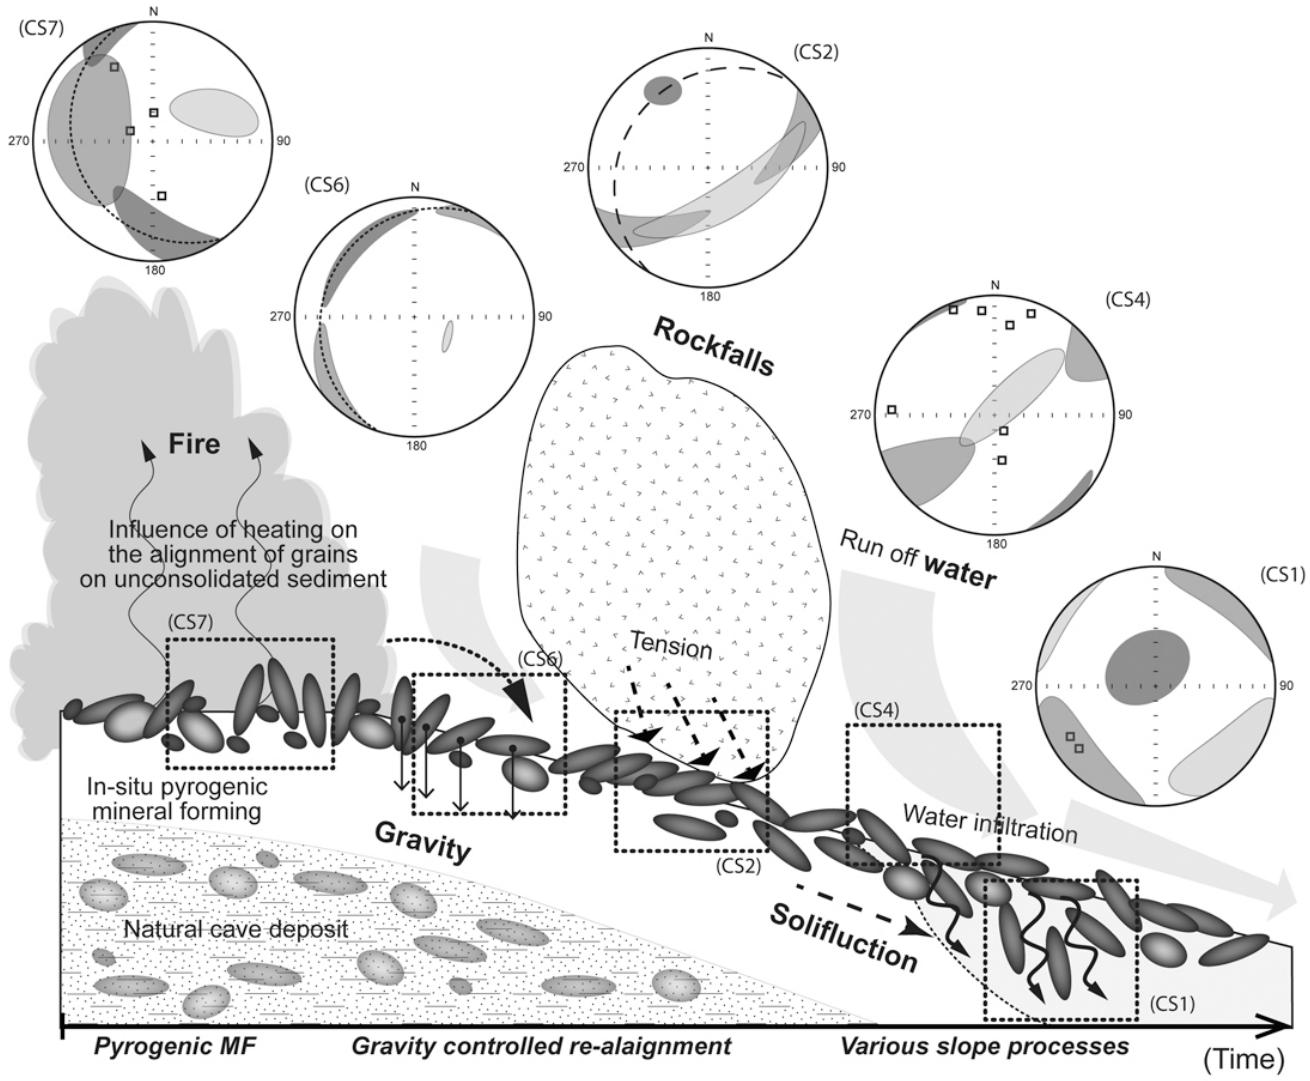
National Museum of Montenegro, Cetinje, Montenegro, 6. Center for Conservation and Archaeology of Montenegro

Rock magnetic and magnetic fabric study has been elaborated on the anthropogenic ash horizons in Crvena Stijena (‘Red Rock Cave’, Montenegro) sediment succession. The study has multiple goals including the identification of mineral forming during burning, alteration after the fire, revelation of the magnetic fabric and its significance in the characterization of cave facies.

Magnetite has been identified as a main ferromagnetic magnetic component of the ash. In addition, a ‘recently unknown’ contributor(s) was found by thermomagnetic experiments (Variable Field Translation Balance - VFTB, Mag Instruments UG, Germany). Various type of minerals are the candidates, such as SD magnetite, siderite and greigite. The forming of all candidates can be described by various processes in cave environment, including burning, post-burning alteration, precipitation from groundwater and so on. But no any theory is supported fully by the rock magnetic results.



The magnetic fabric of the ash was characterized by low field anisotropy of magnetic susceptibility measurements (AMS; KLY-4S Kappabridge, AGICO, Czech Republic). The statistical analysis (Whisker’s box plot) of the basic anisotropy parameters, such as foliation, lineation, degree of anisotropy and the shape parameter, along with the alignment of the principal susceptibilities on stereoplots, revealed varied characteristics of the ash units. The diverse, oblate to prolate, lineated or strongly foliated, horizontally oriented and inverse fabrics of the units like the magnetic contribution. It may indicate multiple processes (on slope), such as orientation by gravity, solifluction, run off water, quasi-vertical migration of groundwater and post-burning/post-depositional alteration of the fabric by the impact of a rockfall (Figure 1).

Bacterial magnetosome morphology in Hiroshima Bay sediments

*Noriko Kawamura[1], Kengo Hiyamizu[2], Toshitsugu Yamazaki[3]

1. Japan Coast Guard Academy, 2. Japan Coast Guard, 3. Atmosphere and Ocean Research Institute, The University of Tokyo

Magnetotactic bacteria play an important role in remanent magnetization acquisition of sediments. Bacterial magnetosome morphology depends on chemical conditions with burial depth in deep-sea sediments, and can be classified into three different groups according to shape: teardrop, elongated, and equant (Yamazaki et al., 2019). In order to clarify reaction time of bacterial magnetosome morphology, the distribution of magnetotactic bacteria in surface sediments was investigated in Hiroshima bay as a reference area. Vertical stratification of the water column in the bay changes throughout the year, and magnetic hysteresis parameters and mineralogy in the bay sediments vary in response to changes in redox conditions of bottom waters (Kawamura et al., 2016). Surface sediments (0-1 cm) were taken using a hand sampler at three stations in February and July 2019. The remanent coercivity/coercivity ratio (Hcr/Hc) of the sediment samples also varies, both spatially and temporally, which reflects changes in magnetic mineralogy. Magnetic minerals were extracted from the dried sediment samples (10.0 g), and were counted using a transmission electron microscope (TEM). They were classified into the groups depended on temperature and nutrient in seawater. From magnetic minerals of February 2019 seen in TEM images, grains in 20~100 m size which seem to have formed by bacteria are rare. In contrast, the equant-shaped chained magnetic minerals are recognized in June 2019 samples at all stations. Seawater temperature and nutrients in July are higher than February. The results imply that magnetotactic bacteria increase in the bay within six months at least.

FORC-PCA analyses of red clay in the Pacific

*Toshitsugu Yamazaki[1], Wei Fu[1], Takaya Shimono[2], Yoichi Usui[3]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. Meiji University, 3. Japan Agency for Marine-Earth Science and Technology

Red clay is widely distributed in deep-sea in mid-latitudes, and potentially preserves long-term paleoceanographic changes, although lack of calcareous and siliceous microfossils and extremely slow sedimentation with numerous hiatuses limit resolution. We conducted a rock magnetic study of some red clay cores in the North and South Pacific in order to identify magnetic mineral components and estimate paleoenvironmental changes. Three piston cores (MR13E02-PC1, KR1402-PC4, and KR1302-PC6) collected from near Minamitorishima Island in the northwestern Pacific and IODP Site U1365 cores in the South Pacific were used in this study. Principal component analyses of FORC diagrams (FORC-PCA) revealed that core KR1302-PC6 contains three main magnetic components (endmembers EM1 through EM3). Two of them, EM2 and EM3, show the features of non-interacting SD, which are interpreted to be biogenic magnetites with lower and higher coercivity, respectively. Combined with TEM observation, EM2 is dominated by magnetofossils of equant ochtahedral shape, while the proportion of bullet-shape magnetofossils is larger in EM3. The other endmenber EM1 showing interacting SD/PSD/MD is interpreted to be a terrigenous component. EM1 contribution suddenly increased upcore at about 3 m in depth, which suggests a significant increase of eolian dust input caused by a global cooling event. The age of this event can roughly be estimated as Oligocene to Eocene from lithostratigraphic correlation with a nearby core having age estimation based on Os isotope ratios (Nozaki et al., 2019; Tanaka et al., submitted). The results of cores MR13E02-PC1 and KR1402-PC4, whose ages are estimated to be Miocene and younger, suggest that eolian input has been kept enhanced since the event observed in PC6. An increase of bullet-shape magnetofossils at a certain depth interval of PC6 suggests that the core had the oxic-anoxic transition zone (OATZ) (Yamazaki et al., 2019), although the core is totally oxidized now and there is no OATZ. The less oxic environment might have been caused by higher biogenic productivity near the equator; the paleoposition of PC6 site calculated with GPlates software suggests that the site was within 5 degrees from the equator between about 70 and 85 Ma. FORC-PCA results of core U1365 show two endmembers, terrigenous (EM1) and biogenic (EM2), respectively. The coercivity distribution of EM2 of Site U1365 is similar to that of EM2 in the North Pacific, while EM1 of Site U1365 includes particles with finer SP grain. Site U1365 also shows a sudden upcore increase of the EM1 component, and its age was roughly estimated to be Oligocene (Shimono and Yamazaki, 2016). Although there are large uncertainties in age estimations, the eolian input increases in the both hemispheres might be a coeval global event. A possible candidate of such an event is the global cooling known to have occurred at the Eocene-Oligocene boundary.

A new $^{40}Ar/^{39}Ar$ age and magnetostratigraphy of the Afro-Arabian Large Igneous Province in the Lima-Limo section erupted in Oligocene

*Yutaka Yoshimura[1], Osamu Ishizuka[2], Toshitsugu Yamazaki[1], Yuhji Yamamoto[3], Hyeon-Seon Ahn[4], Tesfaye Kidane[5], Yo-ichiro Otofuji[6], Naoto Ishikawa[7]

1. Atmosphere and Ocean Research Institute, The University of Tokyo, 2. National Institute of Advanced Industrial Science and Technology, 3. Center for Advanced Marine Core Research , Kochi Univ., 4. Korea Institute of Geoscience & Mineral Resources, 5. School of Agricultural, Earth, and Environmental Sciences, University of KwaZulu Natal, 6. Institute of Geohistory, 7. School of Sustainable Design, University of Toyama

We report new $^{40}Ar/^{39}Ar$ ages on fresh groundmass grains from a 2 km-thick section in the Lima-Limo area of the NW Afro-Arabian Large Igneous Province (AALIP). A succession of seven magnetozones (R4-N3-R3-N2-R2-N1-R1, from top to base) were identified by Ahn et al. (submitted), which are tentatively correlated to Chron C11n.1r (29.477-29.527 Ma) (R4) - C11n.2n (29.527-29.970 Ma) (N3 to N2) - C11r (29.970-30.591 Ma) (R2 to R1) of the geomagnetic polarity time scale 2016 (GPTS 2016; Ogg et al., 2016). A new age was obtained from the R4 magnetozone agrees with the previously reported ages by Coulié et al. (2003) and Hofmann et al. (1997) but has higher precision. From our age and its uncertainty, the R4 magnetozone can be correlated to Chron C11n.1r of the radio-isotopic age model considered for constructing GPTS 2012 (Vandenberghe et al., 2012) rather than the astronomical age model adopted for GPTS 2012. Our correlation is consistent with the two previously proposed magnetostratigraphy (Rochette et al., 1998; Ahn et al., submitted). From the time-interval of 0.12 Myr of C11n.1r for the radio-isotopic age model and the area of ~600,000 km^2 (Mohr, 1983), the average eruption within the R4 magnetozone is estimated to be 5 km^3/yr, which is higher than that of the Siberian LIP.

Institute of Archaeology, Ivane Javakhishvili Tbilisi State University, Tbilisi, Georgia., 5. Hawaii Institute of Geophysics and Planetology, University of Hawaii at Manoa, Honolulu, Hawaii, United States

We present a preliminary archaeomagnetic study carried out in the archaeological site of Grakliani (Republic of Georgia). Samples were taken during two different samplings (2018 and 2019) from nine combustion structures (ovens and possibly altars) and from different pottery fragments with a good age control. The age of all these samples varies between the 12th century BC and the 1st century BC, a broad period with scarce reliable archaeomagnetic data in the region.

We have performed an archeomagnetic and archaeointensity study on these samples at the paleomagnetic laboratory of the University of Burgos (Spain) and at the paleomagnetic laboratory Fort Hoofddijk in Utrecht University (The Netherlands). We carried out directional studies including both thermal demagnetization and stepwise alternating field as well as rock magnetic analyses, consisting in the measurement of IRM acquisition curves, hysteresis loops, *backfield* curves and high temperature thermomagnetic curves. Archaeointensity determinations were carried out with the Thellier-IZZI and Thellier –Coe protocols. They included additional experiments for anisotropy correction of the archaeointensity results.

So far, we have obtained a mean direction for each combustion structure and archaeointensity results for five combustion structures and five pottery fragments of different ages in the studied time range, which provide new full vector and intensity data of the Earth’ s magnetic field variations in the Caucasus. Additional archaeointensity determinations in two other combustion structures are still in progress.

Paleomagnetism.org 2.0: an online multiplatform, open source and FAIR paleomagnetic data management software

Mathijs Koymans[2], *Daniel Pastor-Galan[1], Douwe van Hinsbergen[2], Bram Vaes[2], Cor Langereis[2]

1. Center for North East Asian Studies, Tohoku University, 2. Utrecht University

Scientific communities are placing an increasing emphasis on the implementation of data management protocols concerning data archiving and distribution. For instance, every proposal submitted to the European Horizon 2020 program, as well as to the National Science Foundation in the USA, requires a dedicated section that outlines project data management and accessibility. The widely adopted FAIR data guidelines identify four fundamental principles concerning the Findability, Accessibility, Interoperability and Reproducibility of data. They form a cornerstone of modern data infrastructures and are being increasingly adopted by scientific communities. FAIR data means that data sets are effortlessly searched and discovered, freely downloaded, shared, usable between multiple disciplines, and that derived results and the applied methodology are fully transparent. The wide variety of data formats, the low data volume, and the general lack of a culture of data sharing makes that the paleomagnetic community rarely follows any of the FAIR principles. Most institutions define their own data formats and use inhouse software to analyse their demagnetization data, which are critical to Paleomagnetic research. In this presentation we present the second iteration of Paleomagnetism.org, an online multiplatform open source environment for paleomagnetic data analysis. Paleomagnetism.org provides an interactive environment where paleomagnetic data can be interpreted, evaluated, visualized, and exported. The Paleomagnetism.org application is split in to an interpretation portal, statistics portal, geography portal, and a portal for miscellaneous paleomagnetic tools. In the interpretation portal, principle component analysis can be performed on visualized demagnetization diagrams. Interpreted directions and great circles can be combined to find great circle solutions. These directions can be used in the statistics portal, or exported as data and figures. The tools in the statistics portal cover standard Fisher statistics for directions and VGPs, including other statistical parameters used as reliability criteria, foldtest, bootstrapped common true direction test reversal and correction of inclination shallowing in sediments following TK03.GAD. The geography portal provides a module to visualize VGPs and expected paleolatitudes, declinations, and inclinations relative to widely used global apparent polar wander path models in coordinates of major continent bearing plates. The 2.0 update of Paleomagnetism.org comprises a full overhaul of the application to satisfy the increasingly demanding data management requirements. The application now facilitates a workflow that respects FAIR guidelines by documenting data provenance. All data analysed through the application are easily submitted to a public data library which distributes data and results through an HTTPS web service that lives up to modern data management standards.

Brunhes and Matuyama Chron Paleosecular variation study from dated lava flows erupted from West Maui, Hawaii, USA.

*Emilio Herrero-Bervera[1]

1. University of Hawaii at Manoa

Fifteen sites of oriented basaltic lava flows from the West Maui Volcano series (island of Maui, Hawaii) were selected to improve the determination of the Brunhes and Matuyama time-averaged geomagnetic field between >0.7 and 1.8 and 2.6 Ma respectively. We sampled five flows from the Wailuku Volcanics (ca. 1.97+/-0.96-1.58+/-0.13 Ma), five flows from the Honolua Volcanics (ca.1.50+/-0.13 Ma) and five flows were drilled from the rejuvenated-stage Lahaina Volcanics (ca. <0.610+/-0.012 Ma). Identical Characteristic Remanent Magnetization (ChRM) directions with reverse polarity carried by magnetite were isolated by stepwise alternating-field and thermal demagnetization in 12-15 specimens from each site. The final mean direction points south while the inclination is ~7 degrees lower than the inclination of the geocentric axial dipole (GAD). This offset is reduced after correcting the site latitude for the Pacific plate motion, which has been neglected so far in most studies. The mean corrected direction is almost perfectly antipodal to the Brunhes mean direction derived from the Lahaina Volcanics in the same island of Maui and for the Honolulu Volcanic series (HVS) which are part of the Koolau Volcano on the island of Oahu. After applying the tectonic correction, the inclination remains several degrees larger than the inclination of the axial dipole and cannot be accounted for by a small axial quadrupole which would reverse with the dipole. The mean inclinations of other Hawaiian records (mostly younger than 1 Ma) involving long sequences of lava flows exhibit similar deviations from the GAD which are too large to be accounted for by a small axial quadrupole. Tilting of all sections is difficult to defend for so many localities and persistent secondary components have not been detected. Thus these inclination anomalies would reflect the presence of a long-term standing component under Hawaii but crustal magnetization linked to the volcanic edifice cannot be completely ruled out.

Centennial-resolution terrestrial climatostratigraphy and Matuyama-Brunhes transition from a loess sequence in China

*Masayuki Hyodo[1], Kenta Banjo[2], Tianshui Yang[3], Shigehiro Katoh[6], Shi Meinan[3], Yuki Yasuda[4], Jun-ichi Fukuda[1], Masako Miki[2], Balázs Bradák[5]

Institute of Seismology and Volcanology, Hokkaido University, 5. Department of Physics, EPS, University of Burgos, 6. Museum of Nature and Human Activities, Hyogo

Terrestrial records of the last geomagnetic reversal often have few age constraints. Chronostratigraphy using suborbital-scale paleoceanic events during marine isotope stage 19 may contribute to solving this problem. We applied the method to an 8-m-long, high-resolution paleomagnetic record from a loess sequence in China, and revealed millennial-to-sub-centennial scale features of the Matuyama-Brunhes (MB) transition. All samples were subjected to progressive thermal demagnetization with 14-15 steps up to 650-680˚C. As a result, 96 % of the samples yielded a high-quality remanent magnetization. The MB transition terminated with a 75-cm-thick zone with nine polarity flips. The polarity flip zone, dated at about 779-777 ka, began between the warm events “I” and “J” and terminated at the end of the cooling event coincident with the lowest axial-dipole strength interval. Most polarity flips occurred within 70 years. The virtual geomagnetic poles (VGPs) in the upper polarity flip zone clustered in the SW Pacific region, where the MB transitional VGPs from lavas of the Hawaiian and Canary Islands and lacustrine deposits of Java also clustered. These sites were probably dominated by dipolar fields. The absence of transitional fields across polarity flips implies a short time span for averaging fields due to a thin loess-magnetization lock-in zone. The reverse-to-normal polarity reversal dated at about 778 ka in Lingtai occurred at the end of the SW Pacific VGP zone, an important key bed for MB transition stratigraphy. The reversal is a good candidate for the main MB boundary. We found an excursion at about 766 ka spanning about 1 ka.

Paleomagnetism of sediment cores taken from the Ontong-Java plateau: for better understanding of the role of biogenic magnetite in geomagnetic paleointensity recording

*Jiaxi Li [1]

1. Atmosphere and Ocean Research Institute, The University of Tokyo

We studied sediment cores taken from the Ontong-Java plateau and managed to extract the geomagnetic paleointensity signal from them. Relative paleointensity (RPI) variations are widely used to understand geomagnetic field behavior and to develop age models for sedimentary sequences. Biogenic and detrital magnetic components are considered as the two major components, but for RPI estimations it is conventionally assumed that these two contribute to the remanent magnetization acquisition in an identical manner. However our RPI estimation shows some intriguing results. Normalizations of NRM with different artificial remanent magnetizations yielded inconsistent results; NRM-ARM demagnetization slope plots show curvature whereas NRM-IRM slope plots show a linear relation. It can be interpreted as the coercivity distributions of NRM and ARM are different. Moreover, relative paleointensity normalized by ARM shows artificial downcore decreases, and this may correlate with the variations of the ARM/SIRM ratio, which suggests the increasing proportion of biogenic to detrital magnetite. Then considering that biogenic magnetites have SD particle sizes with higher coercivity, the way biogenic magnetic components contribute to the remanent magnetization acquisition may be different from the way detrital components do. So the varying proportion of biogenic components may have considerable influence on the RPI signal recording in the sediments. The purpose of our research is trying to figure out the mechanism how magnetic minerals derived from different sources contribute to the remanent magnetizations of sediments. Then, it is expected that influences on the relative paleointensity records brought by different proportions between biogenic and detrital components in the sediments are able to be known.

New paleomagnetic data from of Late Cretaceous volcanics of the northern part of the Okhotsk-Chukotka volcanic belt

*Aleksandr Pasenko[1], Ivan Lebedev[1], Florian Lhuillier[2], Baha Eid[2], Vladimir Pavlov[1]

1. The Schmidt Institute of Physics of the Earth of the Russian Academy of Sciences, Moscow, Russia, 2. Department of Earth and Environmental Sciences, Ludwig Maximilians University, Munich, Germany

At the moment, there is an increasing interest in the evolution of the Arctic Ocean and the tectonic history of North-Eastern Asia. The paleomagnetic method can be applied to solve the range of corresponding problems, in particular, to test the hypotheses of the formation and evolution of the eastern part of the Arctic

In the summer of 2019, we sampled an extensive collection of paleomagnetic samples (~ 2000 samples) from 9 remote Late Cretaceous volcanic sections of the central and eastern parts of the Okhotsk-Chukotka volcanic belt (OCVB). At each point, from 7 to 21 volcanic flows were sampled.

The majority of studied rocks contain clear paleomagnetic record, with characteristic remanent magnetization which can be isolated by both AF and thermal demagnetization. The preliminary results which we have obtained when laboratory paleomagnetic treatment of this collection allow to calculate the paleomagnetic pole which is in very good agreement with Late Cretaceous paleomagnetic poles obtained earlier by Stone et al., 2009 for near-located Elgygytgyn region (Chukotka) and by Otofuji et al., 2015 for Magadan region.

In our report we discuss the significance of obtained data for deciphering the history of the Amerasia basin and Arctic Alaska-Chukotka microcontinent.

This work is supported by the Russian Science Foundation under grant №19-47-04110.

[S-EM19] Earth and planetary magnetism: Observations, modeling, and implications on dynamics and evolution

convener:Hirokuni Oda(Institute of Geology and Geoinformation, Geological Survey of Japan, AIST), Futoshi Takahashi(Faculty of Sciences, Kyushu University), Courtney Jean Sprain(University of Florida), Yoichi Usui(Japan Agency for Marine-Earth Science and Technology)

Paleomagnetism and paleointensity are essential tools that are useful in investigating the history of Earth's lithosphere, deep interior, and environment. Likewise, geomagnetic observations, modeling, and dynamo simulations are also important tools that help elucidate the dynamics of the Earth's magnetic field and the core. Beyond Earth, studies on extracting ancient magnetic fields recorded by extraterrestrial materials are increasing, which are improving our understanding of the evolution of other planetary bodies in addition to the solar system. Here, we invite contributions in the broad spectrum of paleomagnetic research with special emphasis on the "Study of the Earth's Deep Interior" (SEDI) that illustrate modern advances and highlight further work to better understand the dynamics and evolution of Earth and other planetary bodies. Topics of interest include (but are not limited to): geomagnetic jerks, secular variation, excursions and reversals, magnetic field modeling and dynamo simulations, geometry of the geomagnetic field, paleointensity and evolution of the core and core-mantle boundary, polarity reversal frequency through time, magnetic shielding and solar radiation effects, evolution of magnetotactic bacteria and magnetic field, in addition to planetary magnetic fields and evolution of solar system.

Archaeological Museum, The International University of Kagoshima, 7. Education Board, Ibusuki City, 8. Research Center for Archaeology, Kagoshima University

Magnetic surveys at an old kiln site cluster in Kagoshima Pref., southwest Japan were conducted, and five magnetic anomalies were detected on the hill slopes, based on a Cretaceous sedimentary rocks. A magnetic anomaly map at one of the sites was drawn and an elongated magnetic anomaly zone, along to the upward direction of the slope with 6 to 8 m length, was found. On the other hand, we obtained the paleomagnetic and rock magnetic results for the samples from an excavated old kiln, located nearby the magnetic anomaly site. Assuming the buried source of magnetic anomaly in consideration of paleomagnetic data, the expected magnetic field on the ground surface is calculated and it is well consistent between the observation and the calculation. It can be concluded that the source of the magnetic anomaly is a floor of an old kiln buried 40cm below the surface, northwardly magnetized. This result can indicate that the paleomagnetic and rock magnetic results provide a validated information about the underground objects in the magnetic surveys.

Paleomagnetic study on the transitionally magnetized volcanic rocks from the Tahaa Island, French Polynesia

*Yuhji Yamamoto[1], Kenneth A Hoffman[2], Myriam Annie Claire Kars[1]

1. Center for Advanced Marine Core Research, Kochi University, 2. California Polytechnic State University

Volcanic rocks collected from the Society Islands, French Polynesia, were systematically investigated in terms of paleomagnetism and geochronology (Yamamoto et al., 2002; Yamamoto and Tsunakawa, 2005; Uto et al., 2007). Some sites were found to be transitionally magnetized, and the follow-up laser-heating $^{40}Ar/^{39}Ar$ dating and additional palaeomagnetic measurements were conducted on samples from these sites in Yamamoto et al. (2007): a lava sequence in the Tahaa Island consisting of the four consecutive lava flows (TA04, 05, 06 and 07) gave the average virtual dipole moments (VDMs) of ~ 5 ZAm2 and the Ar/Ar age of 3.20 +/- 0.03 Ma. This age is consistent with the upper boundary age of the Mammoth reversed subchron in GPTS2012 (3.207 Ma; Ogg et al., 2012).

To further characterize the paleomagnetic behavior recorded in the lava sequence, a follow-up sampling was done in 2014. We collected ~50 new mini-core samples from the sequence, and in addition, 10 new mini-core samples were drilled from a single lava flow of a vicinity lava sequence, which corresponds to the site TA01 in the previous study (K-Ar age of 3.14 +/- 0.06 Ma; Uto et al., 2007). These mini-core samples were cut into specimens and they were subjected to paleomagnetic measurements including the Tsunakawa-Shaw absolute paleointensity experiments. We will report these results together with the previous results which are reanalyzed by a latest scheme.

High resolution paleomagnetic secular variation records from Lake Biwa and its implications on core dynamics

*Hirokuni Oda[1], Yuhji Yamamoto[2], Yoshio Inouchi[3]

1. Institute of Geology and Geoinformation, Geological Survey of Japan, AIST, 2. Kochi University, 3. Waseda University

We have conducted measurements on one of the three piston cores taken from Lake Biwa off Takashima (BWK12-2; length 1633 cm). Sediment comprises of clay intercalated with at least 13 ash layers. Thirteen horizons were dated with 14C using plant pieces giving a maximum age estimate of more than 40 ka. Paleomagnetic cube specimens, u-channel samples and LLchannel samples were taken from the core. Paleomagnetic cube specimens were measured with a SQUID Rock Magnetometer at AF demagnetization steps of 0-80 mT. Results of inclination from the cube samples show an agreement with the paleosecular variation reported by Ali et al. (1999). For example, Inclination show a minimum of ~40 °at 2600 year BP and a maximum of ~58 °at 3400 year BP, both of which can be correlated with a minimum ’h’ at 2400 year BP and a maximum ’i’ at 2900 year BP presented by Ali et al. (1999), respectively. There are reports on "geomagnetic spikes" or "archeomagnetic jerk" from the Near East ca. 980 BC and 890 BC (Ben-Yosef et al., 2009; Shaar et al., 2011). Further, relative paleointensity is estimated from NRM and ARM measurements using discrete and u-channel measurements. Rapid change of paleomagnetic direction and intensity will be discussed in association with the global compilation of paleomagnetic records.

Paleomagnetism around the Cretaceous-Paleogene boundary in the Pacific red clay

*Yoichi Usui[1], Toshitsugu Yamazaki[2], Junichiro Ohta[3,4,1], Honami Sato[4], Akira Ishikawa[5]

1. Japan Agency for Marine-Earth Science and Technology, 2. Atmosphere and Ocean Research Institute, The University of Tokyo, 3. FRCER, The University of Tokyo, 4. ORCeNG, Chiba Institute of Technology, 5. Department of Earth and Planetary Sciences, Tokyo Institute of Technology

Red clay covers a large portion of the Pacific seafloor. These sediments are expected to be good targets for paleomagnetic and environmental magnetic studies, because magnetic minerals in the oxic environment are not affected by reductive diagenesis. However, paleomagnetic data from red clay are often not straightforward, sometimes attributed to oxic diagenesis. More fundamentally, absolute dating of red clay is difficult, and correlation with polarity timescale remains a challenge. In this presentation, we use newly discovered the Cretaceous-Paleogene (K-Pg) boundary in the red clay around the Minamitorishima Island as a tie-point, and discuss the paleomagnetic data from the sediment. This area has been studied intensively, and we have recovered 71 piston cores (~15 m each). The K-Pg boundary was identified in multiple cores by the age constraints from deep sea agglutinated foraminifera, detailed Iridium measurements, and correlation using magnetic susceptibility. We conducted alternating field and thermal demagnetization on two cores. Both methods yielded characteristic remanence, and polarity patterns consistent between the cores were obtained. Lithological observation and chemical mapping revealed sub-horizontal layering, suggesting minor perturbation due to bioturbation or hiatus. The bottom of the core was estimated to be Late Campanian, while the sedimentation rate in the Cretaceous was estimated to be ~1.5 mm/kyr. The successful magnetostratigraphy in the Mesozoic red clay suggests that oxic diagenesis is not the major factor preventing paleomagnetism. Further studies may constrain the paleogeography of the Pacific plate at around the K-Pg boundary. Besides, the Campanian age at ~15 m depth suggests major hiatus somewhere in the Cenozoic. Indeed, acoustic survey showed that the sediment thickness around the Minamitorishima Island varies significantly. These observations imply that Mesozoic red clay can be recovered from wide area by piston coring or multiple short drillings rather than expensive deep drilling, if one carefully conduct geophysical surveys.

Avalonia, get bent! Paleomagnetism from SW Iberia confirms the Greater Cantabrian Orocline

Bruno Daniel Leite Mendes[2], *Daniel Pastor-Galan[1], Mark J. Dekkers[2], Wout Krijgsman[2]

1. Center for North East Asian Studies, Tohoku University, 2. Paleomagnetic Laboratory 'Fort Hoofddijk', Utrecht University

The amalgamation of Pangea formed the contorted Variscan-Alleghanian orogen suturing Gondwana and Laurussia during Carboniferous. From all swirls of this orogen, a double curve stands out in Iberia, the coupled Cantabrian Orocline and Central Iberian Curve. The Cantabrian Orocline formed subsequent to Variscan orogeny (ca. 315-295 Ma). The mechanisms of formation for this orocline are disputed being the most prominent: 1) An Avalonian (Laurussia) indenter at SW Iberia, that would form the Cantabrian Orocline in a sinistral transpressive orogenic phase. 2) A change in the stress field that buckled the orogen. This change in stress would be potentially far-field and linked to subduction of the Paleo-tethys and/or diachronous collision in the Variscan belt.
In contrast, the geometry and kinematics of the Central Iberian curve are largely unknown. Whereas some authors defend both curvatures are genetically linked, others support they are distinct and formed at different times. Such uncertainty adds an extra layer of complexity into our understanding of the final stages of Pangea amalgamation. We have performed a paleomagnetic analysis of several tectonostratigraphic units in SW Iberiat to solve the late Carboniferous Variscan kinematics. Our results show differential counterclockwise rotations, ranging from 20 degrees and up to 70 degrees at late Carboniferous. These results are coincident with the kinematics expected in the southern limb of the Cantabrian Orocline and discard a concomitant formation of both Cantabrian and Central Iberian curvature. The Avalonian portion of Laurussia rotated with the Cantabrian Orocline at both limbs: the northern one (Ireland, Pastor-Galán et al., 2015) and the southern one (South Portugese Zone, this study). The coherent rotation of Avalonia confirms the Greater Cantabrian Orocline hypothesis and discards the Avalonian indenter as a mechanism of formation for the Cantabrian Orocline. The Greater Cantabrian Orocline extended beyond the Rheic Ocean suture affecting both Laurussia and Gondwana margins and probably formed by a late Carboniferous change in the stress field, due to a still unidentified cause.

The Magnetics Information Consortium (MagIC) Data Repository: Status and Future Evolution

*Catherine Constable[1], Nicholas Jarboe[1], Rupert Minnett[2], Anthony A.P. Koppers[3], Lisa Tauxe[1], Lori Jonestrask[1]

1. Scripps Institution of Ocenaography, University of California San Diego, 2. Cogense Inc., 3. Oregon State University

MagIC (earthref.org/MagIC) is dedicated to improving research capacity in the Earth and Ocean sciences by maintaining an open community digital data archive for rock and paleomagnetic data with portals that allow users access to archive, search, visualize, download, and combine versioned datasets. We are a signatory of the Coalition for Publishing Data in the Earth and Space Sciences (COPDESS)'s Enabling FAIR (Findable, Accessible, Interoperable, and Reproducible) Data Commitment Statement and an approved repository for the Nature set of journals. In collaboration with EarthCube's GeoCODES data search portal, we have been adding schema.org JSON-LD headers to our data set landing pages and suggesting extensions to schema.org when needed. Collaboration with the European Plate Observing System (EPOS)'s Thematic Core Service Multi-scale laboratories (TCS MSL) is ongoing with MagIC sending its contributions' metadata to TCS MSL via DataCite records.

Improving and updating our data repository to meet the demands of the quickly changing landscape of data archival, retrieval, and interoperability is a challenging proposition. Most journals now require data to be archived in a "FAIR" repository, but exact specifications for FAIR are still solidifying. Some journals vet and have their own list of accepted repositories while others rely on other organizations to investigate and certify repositories. As part of the COPDESS group at Earth Science Information Partners (ESIP), we have been and will continue to be part of the discussion on the needed and desired features for acceptable data repositories.

We have made continued improvements to MagIC's data validation system and the PmagPy paleomagnetic analysis software suite. Datasets created with PmagPy (earthref.org/PmagPy/cookbook/) or other uploads with the correct method code descriptions can be downloaded from MagIC and viewed using PmagPy. We are actively developing our software and systems to meet the needs of our scientific community. Some current issues are: ensuring coordinated workflows with journals to simultaneously publish the journal article and data in MagIC, sustainability of data repository funding especially in light of the greater demands on repositories due to data policy changes at journals, and how to best share and expose metadata about our data holdings to organizations such as EPOS, EarthCube, and Google.

Department of Earth and Planetary Sciences, University of California, Berkeley, CA, USA

Deciphering long-term variations in the magnetic field has important implications for elucidating the connection between the magnetic field and deep interior processes. However, long-term field variations are difficult to discern because they require large amounts of data globally distributed in both space and time. Despite these challenges, datasets such as these have been accumulated for periods of time throughout Earth history that are thought to represent distinctive geodynamo regimes including superchrons, and periods of hyper-reversal activity. Potential biasing of palaeosecular variation (PSV) due to imperfect spatial and temporal sampling is challenging to determine robustly. Here, we synthesise the results of a major collaboration in palaeomagnetic field behaviour taking place before, during and after the 2017 Nordic Palaeomagnetic Workshop in Leirubakki, Iceland. Specifically, we employ numerical geodynamo models to ascertain whether our previously claimed long-term variations in Mesozoic palaeomagnetic behaviour are robust. We assess the effects of spatial and temporal data distributions on calculated palaeosecular variation behaviour (specifically, the Model G description of McFadden et al., 1988) by downsampling 42 geodynamo simulations, mimicking the spatial sampling for the Cretaceous Normal Superchron, the Middle Jurassic (both from Doubrovine et al., 2019), and the last 10 Ma (Cromwell et al., 2019), and comparing these results to those from a uniform “yin-yang” grid (Kageyama and Sato, 2004). We find that between different spatial sampling, similar distributions of the Model G *a* (characterising dispersion at the equator, similar to equation used in Doubrovine et al., 2019) and field strength (virtual dipole moment, VDM) can be reproduced, but Model G *b* (latitude-dependent dispersion, similar to equation used in Doubrovine et al., 2019) is less well-determined, especially when mid and high-latitude sites are sparse. For all three spatial grids, calculated Model G *b* values were underestimated compared to the uniform grid. These findings add support to the inverse relationship between field strength and reversal rate, recently reassessed in Kulakov et al. (2019), and additionally suggest that the minimal variation observed between Model G *a* between the CNS, Mid-Jurassic, and past 10 Myr is robust (Doubrovine et al., 2019). Although we can say that Model G *b* is likely underestimated in datasets where mid and high-latitude sites are sparse, it is difficult to know the amount by which it is underestimated. Overall, we find that the most robust parameters for determining changes in field behaviour where data are limited are VDM and Model G *a*. It is important to note that for the three time periods assessed here, we cannot presently distinguish between PSV regimes, unlike for median VDM. This suggests that VDM may be a more powerful proxy for reversal frequency than PSV, with implications for studies of Precambrian field behaviour where precise estimates of reversal frequency may be extremely difficult to obtain.

Inferring geomagnetic secular variation using MHD/kinematic dynamo modeling with data assimilation

*Futoshi Takahashi[1], Shin ya Nakano[2], Takuto Minami[3], Hinami Taniguchi[4], Ryosuke Nakashima[4], Masaki Matsushima[5], Hisayoshi Shimizu[6], Hiroaki TOH[7]

1. Faculty of Sciences, Kyushu University, 2. The Institute of Statistical Mathematics, 3. Division of Frontier Planetology, Department of Planetology, Graduate School of Science, Kobe University, 4. Graduate School of Science, Kyushu University, 5. Department of Earth and Planetary Sciences, School of Science, Tokyo Institute of Technology, 6. Earthquake Research Institute, University of Tokyo, 7. Data Analysis Center for Geomagnetism and Space Magnetism, Graduate School of Science, Kyoto University

Secular variation (SV) of the Earth's magnetic field is governed by the advection and diffusion processes of the magnetic field within the fluid outer core. The IGRF (International Geomagnetic Reference Field) offers the average SV for the next five years to come, which has been estimated in various methods. In general, forecasting the evolution of a non-linear system like the geodynamo in the Earth's core is an extremely difficult task, because the magnetic field generation processes are controlled by the complex interaction of the core flows and the generated magnetic field. Data assimilation has been a promising scheme forecasting the geomagnetic SV as demonstrated in literatures (Kuang 2010, Fournier et al. 2015), where time dependency is controlled by a numerical dynamo model. While Ensemble Kalman Filter (EnKF) has been a popular method for data assimilation in geomagnetism, we apply a different data assimilation procedure, that is, four-dimensional, ensemble-based variational scheme, 4DEnVar. Applying the 4DEnVar scheme iteratively, we have derived a candidate SV model for the latest version of the IGRF. In evaluating SV, two forecasting strategies are tested, in which core flows are assumed to be steady or time-dependent. The former approach is favored in Fournier et al. (2015), where the magnetic field evolves kinematically by the flows prescribed to be time-independent in the initialization step. On the other hand, we have adopted linear combination of magnetohydrodynamic (MHD) models to construct a candidate as the best forecast (Minami et al. 2020). It is likely that which strategy is more suitable to forecasting SV depends on assimilation scheme and/or numerical dynamo model. However, we have little knowledge on the issue at present. In this study, we investigate results of MHD and kinematic dynamo runs with a 4DEnVar scheme in order to have a grasp of the properties of the scheme in the 5-year forecast process. Also, MHD and kinematic runs are compared to infer internal dynamics responsible for SV in the geomagnetic field.

Influence of high electrical conductivity heterogeneity at the bottom of the mantle on generation of 2007 geomagnetic jerk

*Hisayoshi Shimizu[1]

1. Earthquake Research Institute, University of Tokyo

Wavelet transform has been used to analyze geomagnetic jerks, sudden change of second time-derivatives of the geomagnetic field components (e.g., [1]). A ridge in wavelet transform allows us to identify a possible geomagnetic jerk and its occurrence time. Character of a geomagnetic jerk is quantified by regularity, which is the gradient of the ridge with respect to dilation. Regularity of geomagnetic jerk depends on the geomagnetic field variation at the surface of the Earth's core and the electrical conductivity of the mantle. Regularity distribution obtained for 1969 geomagnetic jerk implies that its regularity at the CMB is 1.55 and electrical conductivity of the bottom 2000 km of the mantle is about 8 S/m [2].
Geomagnetic jerks somewhat localized in the south Atlantic region were observed around 2003 and 2007 (e.g. [3]). Superposition of fast equatorial Rossby waves at the top of the core [4] and Alfvén wave excited by buoyancy heterogeneity at some depth in the core [5] are proposed as possible cause of the localized geomagnetic jerks. An alternative of the cause is outcome of interaction between sudden variation of the toroidal magnetic field at the CMB and electrical conductivity heterogeneity in the D" region [6].
Regularity of 2007 geomagnetic jerk is expected to provide a clue for discussing the involvement of high electrical conductivity heterogeneity since it would results in higher regularity than the other geomagnetic jerks but different from that due to magnetohydrodynamic waves.
Estimated regularities of magnetic field eastward component at M'Bour (MBO, Senegal) and Chambon la Forêt (CLF, France) around 2007 geomagnetic jerks are larger than that for 1969 geomagnetic jerk at both stations. This is compatible with the scenario of the generation of 2007 geomagnetic jerk by interaction between toroidal field variation and high electrical conductivity heterogeneity while 1969 geomagnetic jerk is purely due to the poloidal field from the core. It seems that the variations are not from simple sinusoidal wave which should result in higher regularity.

The Elsasser number dependence of core surface flow models and its implications for long-term changes in core dynamics

*Masaki Matsushima[1]

1. Department of Earth and Planetary Sciences, School of Science, Tokyo Institute of Technology

Fluid flow in the Earth's metallic liquid core drives dynamo action that generates the Earth's intrinsic magnetic field. The pattern of core flow is likely to influence generation process of the geomagnetic field as well as its spatial and temporal variation. Inversely, information on core flow can be provided by geomagnetic field data. Hence, core flow near the core-mantle boundary (CMB) can be derived from geomagnetic field models. Geomagnetic secular variations at the CMB are assumed to be caused by magnetic diffusion only due to the no-slip boundary condition imposed for the flow there. Inside the viscous boundary layer at the CMB, it is assumed that motional induction, advection and magnetic diffusion contribute to temporal variations of geomagnetic field, and that the viscous force plays an important role in force balance. Below the viscous boundary layer, it is assumed that magnetic diffusion can be neglected as in the frozen-flux approximation, and that core flow is in a tangentially magnetostrophic state.

The effect of core electrical conductivity on core flow modeling has been investigated. It turns out that the ratio of mean toroidal flow to mean poloidal flow decreases with increase of core electrical conductivity. This results from the Lorentz force proportional to core electrical conductivity. This can be extended to investigating the effect of the Elsasser number, which is a non-dimensional measure of relative importance between the Lorentz force and the Coriolis force in the Navier-Stokes equation, on core flow models. The Elsaser number is proportional to core electrical conductivity and inversely proportional to the rotation rate of the Earth and core density. It is conceivable that the rotation rate of the Earth has been decreasing due to tidal friction with the Moon, whereas the core electrical conductivity has been increasing with decrease of core temperature after the core formation. This suggests that the Elsasser number in the past was smaller than the present value; that is, core flow could be more tangentially geostrophic than the present state.

A modern interpretation of magnetic instability

*Ataru Sakuraba[1]

1. Department of Earth and Planetary Science, University of Tokyo

Linear analysis was a basic and tractable methodology in the early stage of planetary dynamo researches. One of such linear problems was a kinematic dynamo in which time development of a small-amplitude magnetic field perturbation was analyzed in the presence of an arbitrary steady fluid motion. This helped us to understand what type of flow structure was effective in magnetic field amplification, what type of magnetic field structure naturally grew, and of course to confirm an MHD dynamo was possible. Another linear study was magnetic instability in which time development of small-amplitude magnetic and velocity perturbations were analyzed in the presence of an arbitrary static toroidal magnetic field. In general, a toroidal field confined in a rotating fluid sphere becomes unstable if the field intensity is strong enough. Early theoretical studies revealed the conditions for ideal instability without electric resistance (e.g. Acheson 1972). However, it is found that addition of a finite but not high resistivity enhances instability (e.g. Fearn 1984). The controlling parameter of the resistive instability is the Elsasser number. The critical Elsasser number is generally about O(10), implying that this gives an upper bound for planetary magnetic field intensity because a higher magnetic field intensity rather destroys the dynamo due to magnetic instability (Zhang and Jones 1994).

These linear studies seem to be inactive in the recent 25 years during which nonlinear self-consistent dynamo simulations become easy. However, we cannot neglect those classical studies because they elucidate fundamental physical processes underlying a complex planetary dynamo. Here I present an idea that magnetic instability plays an important, positive role in the dynamo process. First, the number of convective rolls (the azimuthal wavenumber) in the core is determined by the critical wavenumber of magnetic instability, which is the optimal wavenumber at which the magnetic field and velocity perturbations grow fastest and effectively transport internal heat to the mantle. Second, the growth rate of magnetic instability controls the magnetic field saturation in the core. Magnetic instability is, in some sense, an energy transport process from the axisymmetric to non-axisymmetric parts. Therefore, the energy flow to smaller scales is balanced by the opposite energy flow creating the axisymmetric magnetic field due to dynamo action. There is a possibility that equating two linear growth rates of magnetic instability and a kinematic dynamo gives a relation between the Elsasser number and the magnetic Reynolds number that is the control parameter of a kinematic dynamo problem. I will give a detailed explanation based on my recent numerical results of magnetic instability of axisymmetric toroidal field confined in a rotating inviscid fluid sphere.

[E] Poster | S (Solid Earth Sciences)：S-EM Earth's Electromagnetism

[S-EM20] Electric and Electromagnetic survey technologies and the scientific achievements: Recent advances

convener:Kiyoshi Baba(Earthquake Research Institute, The University of Tokyo), Tada-nori Goto(Graduate School of Life Science, University of Hyogo), Toshihiro Uchida(National Institute of Advanced Industrial Science and Technology), Toru Mogi(Faculty of Science, Tokyo Institute of Technology)

Detailed subsurface images by electric and electromagnetic (EM) surveys are indispensable to investigate the electrical features of the interior of the Earth both for academic and commercial purposes. The technologies, techniques, and methods for surveys, data analysis, and interpretation involve many common aspects that should be solved by scientists and engineers in cooperation since the studies cover a broad range of targets in various spatial-time scales and places on land and seafloor, e.g., natural resource explorations, environment and hazard evaluations, and the crustal and mantle tectonics and dynamics. And the knowledge should be shared in the international community for further development of this field. The session invites papers on recent advances in the electric and EM survey technologies and techniques including instrumentations, the data analysis methods including modeling, inversion, and imaging techniques, and the scientific achievements including novel way of interpretations, from the world.

A tensor measurement with simultaneously transmitted Electromagnetic Accurately Controlled, Routinely Operated Signal System: utilization of distortionless response tensor

*Kuo Hsuan Tseng[1], Yasuo Ogawa[2]

1. Tokyo Institute of Technology, 2. Volcanic Fluid Research Center, Tokyo Institute of Technology

The Electromagnetic Accurately Controlled, Routinely Operated Signal System (EM-ACROSS) is a specially designed system for controlled source electromagnetic investigation. The EM-ACROSS combines with a stable transmitter system and at least one receiver for obtaining the electric and magnetic field at the observation site. The core purpose of this system is a specifically designed signal which is repeatedly transmitted with high accuracy and precision to against the noise.

For obtaining a tensor measurement to solve the galvanic distortion issue, two independent signals were transmitted respectively by the different grounded sources for tensor electromagnetic fields. Two signals were specially designed for different antennas with specifically chosen frequency sets. Which were detectable in the data processing due to its accurately controlled properties. This system provided vector source current at the transmitter and the vector electric field measurements at an observation site without interference, leading to the observation of a “source-current” to “electric-field” tensor response. As the source was precisely controlled, the receiver could get a high signal-to-noise ratio data from the data stacking process.

A forward modeling code was developed for this system by utilizing the finite element method with tetrahedral unstructured meshes. For comparing the calculated electric fields from the forward modeling with those observed, the local distortion effect due to the near surface inhomogeneities was addressed by a new tensor function, which dived out the distortion effect.

This distortionless tensor function was utilized to verify the temporal change in the inversed resistivity models with magnetotelluric (MT) data at Kusatsu-Shirane volcano, Japan. To evaluate the detectability by this tensor system, two 3D resistivity models were prepared. One is the 3D inverted model which inverted from a 2001-2005 MT dataset, and the other is the 3D inverted model from a 2017-2018 MT dataset. For the respective two inverted resistivity models the numerical responses from forward modeling and the observed EM-ACROSS responses (in 2017-2018) were compared by utilizing the distortion-removed electric field tensors. The EM-ACROSS data (2018-2018) fit better with the 3D modeling response using the 2017-2018 MT data than to that using 2001-2015 MT data.

This study provided an alternative method to verify the temporal changes in a volcanic hydrothermal

system with joint time-lapse MT monitoring and controlled source electromagnetic observation. The developed system provides a solution for the environmental noise issue and distortion effect. The final product could be the new conception in future exploration and monitoring in the volcanos.

Pseudo 3-D resistivity model for Geomagnetic Induced Current (GIC) based on 3-D seismic velocity structure

*Tada-nori Goto[1], Kota Hori[1]

1. Graduate School of Life Science, University of Hyogo

Geomagnetic Induced Current (GIC) is a natural hazard due to a huge geomagnetic storm, whose large current amplitude makes severe troubles on the electric power grid, pipe lines and other metallic elongated infrastructure. For prevention of this new-typed disaster, three-dimensional (3-D) resistivity structure of the crust and mantle is necessary for evaluation of degree of GIC. Magnetotelluric (MT) survey is effective for obtaining such deep resistivity structures. However, artificial noise around highly populated areas restrict the MT survey and no resistivity structures are obtained. Other geophysical information such as 3-D seismic velocity structures has been obtained in such populated areas. If the relationship between the crustal/mantle seismic velocity and resistivity can be found, the subsurface resistivity structure can be inferred from the 3-D velocity structure.

In this study, an integrated analysis of the subsurface resistivity structure and seismic velocity structure is attempted to find the correlation between these two physical properties and to promote quantitative understanding of the deep crust and the uppermost mantle. The target region is the east Hokkaido, where the GIC was observed together with the geomagnetic storm. The two-dimensional (2-D) resistivity structure by MT survey (Sato et al., 2001) and the 3-D seismic velocity structure deduced by seismic tomography (Matsubara et al., 2019) are used in this study. We first focus on the correlation between two different physical property with cross-plots, and approximately express the correlation at each geological area. We found a positive correlation of resistivity and P-wave velocity at the mantle depths. Based on a rock physics model, the feature can be interpreted with porosity distribution with fluid (magmatic material). On the other hand, negative correlations are often found at the crustal depths. It cannot be well fitted by the simple-pore model, but could be explained by the presence of conductive minerals such as graphite. Although the relationship between resistivity and seismic velocity is not simple, we try to construct a pseudo-resistivity model based on 3-D seismic velocity distribution. Finally, we compare the predicted GIC at the eastern Hokkaido area with the observed one.

Sensitivity of local electromagnetic response functions from Sq field to the electrical conductivity in the upper mantle

*Xiaoli WAN[1,2], Hisayoshi Shimizu[2], Hisashi Utada[2]

1. Tongji Univ., 2. Earthquake Research Institute, the Univ. of Tokyo

Solar quiet daily variations of the Earth’ s magnetic field, Sq field variations, are composed of externally inducing electric current system in the ionosphere and internally induced current system within conductive Earth. Spherical harmonic analysis of magnetic field on quiet days showed that dominant spherical harmonic modes are those with spherical harmonic degree n=p+1 and order m=p for a period 24/p hours up to p=4. Schmucker (1999a) named them as the principal modes of Sq. It is possible to separate the scalar magnetic field potential at each of these periods into external and internal parts by spectral and spherical harmonic analyses, and the responses obtained from them may be used to study the electrical conductivity in the upper mantle. Ratios of the internal to external coefficients, q-response, of the spherical harmonic expansion, global responses, may be useful when Earth is radially symmetric. However, for a realistic three-dimensional (3-d) Earth, one external spherical harmonic mode generates various internal modes due to lateral heterogeneities like land-ocean distribution and heterogeneity in the upper mantle, and each internal term has to be related to all existing external terms. This implies that a global response such as the q-response is difficult to apply for estimating 3-d structure (Schmucker, 1999b). In this study, we consider local electromagnetic responses such as Bz/Bx, Bz/By, magnetotelluric (MT), and corresponding quantities, where x, y and z are northward, eastward and vertically downward components, respectively. We investigate the sensitivity of these responses with respect to the electrical conductivity of the upper mantle by forward modeling of electromagnetic field.

Here theoretical responses were evaluated at the depth of seafloor in order to apply the results on the electromagnetic field observed there. We first examine the sensitivity of the response functions for 1-d radially symmetric conductivity structure modified according to Olsen (1998). The responses for the Sq's principal modes are calculated using a method based on Banks (1969). In addition to showing the responses have sensitivity to 1-d structure, apparent resistivity calculated from Ex/By and Ey/Bx due to the principal modes are compared with those calculated assuming source field with spherical harmonic mode of n=1 and m=0 to discuss the influence of source field that has spatial structure. Then, we evaluate the influence of 3-d conductivity structure on the responses using forward modeling code by Uyeshima and Schultz (2000). Influence of land-sea conductivity contrast on the responses are shown. Also, sensitivity of the responses to a rectangular heterogeneous body (in a spherical coordinate) in the upper mantle is discussed by evaluating the responses by changing the size, depth, and conductivity of the heterogeneous body.

The sparse inversion of the magnetic data to recover subsurface blocky structures.

*Mitsuru Utsugi[1]

1. Aso Volcanological Laboratory, Institute for Geothermal Sciences, Graduate School of Science, Kyoto University

Magnetic inversion is one of the popular method to obtain information about the subsurface structure. However, this method has a serious problem, that is, the linear equations to be solved become ill-posed, under-determined, and thus, the uniqueness of the solution is not guaranteed. As a result, several different models fit the observed magnetic data with the same accuracy. To reduce the non-uniqueness of the model, conventional studies introduced regularization method based on the quadratic solution norm. However, these regularization methods impose a certain level of smoothness, and as the result, the resultant model is likely to be blurred.

To obtain a focused magnetic model, Utsugi (2019) introduced a combination of the conventional L2 norm penalty (which is equivalent to the first order Tihkonov penalty) and L1 norm penalty. As is widely known, L1 norm regularization promotes sparseness of the model. Utsugi (2019) showed that, by introducing the L1-L2 norm penalty into the magnetic inversion, a model which is not overly blurred, and not excessively concentrated can be derived.

To facilitate the model interpretation, some of recent inversion studies focused on to recover the sharp boundary and block structure. However, L2 norm penalty is very simple and favorable because of its convexity, the ability to recover the sharp boundaries seems to be not enough when it is used with L1 norm penalty. Therefore, in this study, I tried some variations of the penalties which is used as the combination with the L1 norm penalty, such as fused-lasso penalty (Tibshirani, 2005), TSV (Total Squared Variation) penalty (Kuramochi et al.,2018), and will discuss about the best combination of the penalty which has good ability to recover the blocky structure, and is easy to implement.

Understanding Unzen volcano magmatic system by broadband Magnetotelluric observation

*Agnis Triahadini[1], Koki Aizawa[2], Keita Chiba[2], Kanta Miyano[1], Yuto Yamamoto[1], Kazunari Uchida[2], Tasuku Hashimoto[1]

1. Department of Earth and Planetary Sciences Graduate School of Science Kyushu University, 2. Institute of Seismology and Volcanology Faculty of Science Kyushu University

The magma system of Unzen volcano are believed to be sourced from under Chijiwa bay, 15 km west of Shimabara Peninsula, Nagasaki. Most of the magma chamber models of Unzen are derived from ground deformation measurement, i.e Kohno et al (2008) who used deformation data before and several years after 1991-1995 eruption. According to them, four pressure source models are proposed which located below the intensive smarm zone before eruption reported by Umakoshi et al (2001). Among the pressure sources, the most intensive sources are pressure source D which situated about 15 km under Chijiwa bay and pressure source C is located 5-6 km west of the active dome (Fugendake and Heisei-shinzan) at about 6 km depth. The D source explains why in the surround area underwent ground uplifting after the eruption ceased while the C source experienced deflation during eruption. After considering petrology data by Sugimoto et al (2005), these pressure sources are later concluded as deep basaltic magma reservoir and shallow crust dacite chamber respectively. Thus, more than one magma chambers related to Unzen volcano are expected below Shimabara Peninsula. During December 2019, we installed 23 MT sites consisted of 7 sites to record both E-field and B-field and 16 sites for E-field only. The sites were distributed across Minami-Shimabara and Obama area, around the suspected area of D and C pressure source. The distance of each sites are approximately 2-4 km where the recording period is 4-14 days depends on the site. Our purpose of study is to determine magmatic system of Unzen in correlation with pressure sources D and C. If they are existed than they are possibly detectable using MT. Because MT method is highly sensitive to conductive zone such as fluid rich zone or melt rich magma. Currently, we are processing the acquired data. At glance, the phase tensor and tipper at longer period > 100s are roughly aligned toward Southwest direction. For the inversion, we will include the MT data from several stations located in 2 km west of the summit, previously obtained by Triahadini et al (2019). Thus, we will present more complete analysis of the resistivity structure in the JPGU meeting.

[S-IT23] Property and role of liquids inside terrestrial planets

convener:Tatsuya Sakamaki(Department of Earth Science, Tohoku University), Yoichi Nakajima(Kumamoto University, Priority Organization for Innovation and Excellence)

Liquids of silicates and metals inside of terrestrial planets play important role in the physical, chemical, and thermal evolutions of planets. This session aims at understanding the physical and chemical properties of liquids from shallower to deep parts of terrestrial planets, which are strongly related to the long history of those planets from the planetary accretion to the present-day dynamics. In addition, we call for presentations by researchers from various backgrounds of geochemical, experimental, theoretical/computational, and seismic/geodynamical ones, who investigate the physical and chemical properties of liquids and the behaviors and roles inside of terrestrial planets. Relevant topics include, but are not limited to, partial melting and melt extraction, liquid-solid partitioning, high pressure experiments on melts, and seismic detections of mantle melts and outer core anomaly.

Behavior of high-pressure silicate melts, which is controlled by their physico-chemical properties, is crucial to understand the magmatism in the deep Earth. Particularly, the H_2O content significantly affects the properties, such as density (e.g., Matsukage et al. 2005; Sakamaki et al. 2006) and viscosity (e.g., Poe et al. 2006; Suzuki et al. 2011). Since such physical properties can be largely determined by the atomic structure, there are considerable interests in revealing how the structure changes with increasing pressure.

Here, structures of dry Na_2O-8/3SiO_2 (NS8/3) melts and hydrous ones with 5 wt% (NS8/3-H5) and with 9 wt% H_2O (NS8/3-H9) were determined under high pressure and temperature by means of the in-situ X-ray diffraction (XRD). The in-situ XRD study was carried out using a cubic-type multi-anvil apparatus MAX80, which is installed at the AR-NE5C beamline of Photon Factory, KEK at Tsukuba, Japan. The experimental *P*-*T* conditions were about 1.4–6.7 GPa and 900–1060 ˚C, respectively.

The obtained total structure factors, *S*(*Q*) of dry NS8/3 and NS8/3-H5 melts show that the position of the first sharp diffraction peaks (FSDP) monotonically shift to higher-*Q* with pressure. In contrast, the pressure dependence of the FSDP for NS8/3-H9 melt has a minimum around 4 GPa. This minimum indicates the intermediate-range order structure of the melt extends up to 4 GPa and shrinks at higher pressure. The reduced radial distribution functions, *G*(*r*) of NS8/3-H9 melt indicate different pressure evolutions in the average Na-O bond lengths, showing a sharp elongation between 3 and 4 GPa. This implies an enlargement of the -Na-O-Na- domain (Greaves 1985; Noritake 2017), and so this elongation can explain the decrease of the FSDP position up to 4 GPa. With increasing pressure,the O-O and Si-Si lengths in NS8/3-H9 melt remains constant, whereas these lengths in dry NS8/3 melt monotonically decrease. The difference in this behavior to the pressure increase can be explained that the Si-O-Si angle dominantly bends in polymerized melts with increasing pressure, while modifier cations mainly work as a cushion and the Si-O-Si angle does not shrink accordingly in depolymerized melts (Wang et al. 2014).

Nitrogen in the core from sound velocity measurements of liquid Fe-N at high pressure

*Asaki Iwamoto[1], Yoichi Nakajima[1,2], Daisuke Kinoshita[1], Yasuhiro Kuwayama[2,3], Kei Hirose[3], Daisuke Ishikawa[2,4], Alfred Q.R. Baron[2]

1. Kumamoto University, 2. RIKEN MDL, 3. The University of Tokyo, 4. JASRI

The Earth’ s liquid outer core is mainly of iron, alloying with ~5wt.% nickel and ~10wt.% some light elements [1]. Geochemical observations show that the silicate mantle is depleted in nitrogen relative to primordial meteorites which are believed to have similar composition of the bulk earth. This indicates that a large portion of nitrogen in bulk earth can be stored in the core [2,3]. In order to examine the possibility of nitrogen in the core, it’ s benefit to compare the sound velocity of liquid Fe-N alloy under high-pressure and –temperature corresponding to the core conditions with seismological observations. In this study, we have performed inelastic X-ray scattering (IXS) measurements to determine the longitudinal velocity of the liquid Fe-N alloy under high-pressure and –temperature conditions.
We carried out IXS measurements up to 76 GPa and 2200 K, using a laser-heated diamond-anvil cell (LH-DAC) at the RIKEN Quantum NanoDynamics beamline BL43LXU of SPring-8 [4]. We used a Fe80N20 foil as a starting sample and single crystal Al2O3 discs as thermal insulator. We judged the sample melting based on X-ray diffraction measurements during heating, and then measured IXS of the liquid sample. The IXS spectra was collected in a momentum transfer range of 3-5.7 nm-1 with an energy resolution of ~2.8 meV at 17.94 keV. The longitudinal sound wave (P-wave) velocity of liquid Fe80N20 was determined from the dispersion relation of the longitudinal acoustic phonon mode of the sample. We fit the P-wave velocity data for liquid Fe80N20 with an equation of state, which enabling to extrapolate the present velocity date to core pressures and also calculate the destiny and bulk modulus under high pressure conditions . Compared with pure Fe [5], the P-wave velocity of liquid Fe80N20 is faster by ~10% and the density is lower by ~8% in the present experimental conditions. By extrapolating the present results to the Earth’ s outer core conditions and then comparing with seismological observations, we found that the upper limit of nitrogen is ~3.3 wt% in the outer core.

Sound velocity of liquid Fe-P alloy at high pressure

*Yoichi Nakajima[1,2], Daisuke Kinoshita[3], Yasuhiro Kuwayama[4], Kei Hirose[5,4], Asaki Iwamoto[3], Daisuke Ishikawa[6], Alfred Q.R. Baron[2]

1. POIE, Kumamoto Univ., 2. RIKEN MDL, 3. Grad. School Sci. Tech., Kumamoto Univ., 4. Dept. Earth Planet. Sci., Univ. Tokyo , 5. ELSI, Tokyo Tech. , 6. JASRI

The compositions and physical properties of planetary cores are of great importance to understand the core formation processes, the thermal and chemical evolutions, and the present-day core dynamics. Terrestrial planets such as Mercury, Mars, as well as Earth are believed to have molten cores that consist of Fe alloys with lighter components such as hydrogen, carbon, nitrogen, oxygen, silicon, phosphorous, and sulfur [1]. Therefore, the physical property of liquid Fe alloys with possible lighter elements at high pressure relevant to the core conditions is key to understanding the planetary cores. Phosphorous is one of the candidates for the light elements in planetary cores because iron phosphorous alloys such as schreibersites (Fe_3P) and allabogdanite (Fe_2P) are often found in chondrites and iron meteorites [2,3]. Here we report the P-wave velocity of liquid Fe-P up to 96 GPa based on inelastic X-ray scattering (IXS) measurements.

We performed IXS measurements at the Quantum NanoDynamics beamline (BL43LXU) [4] of the RIKEN SPring-8 Center. The sample of $Fe_{75}P_{25}$ together with single crystal Al_2O_3 thermal insulators was compressed by a diamond-anvil cell (DAC), and then melted using the laser-heating system installed at the beamline. The longitudinal acoustic phonon mode of the liquid was measured in a momentum transfer range of 3-6 nm^{-1}. The P-wave velocity of liquid $Fe_{75}P_{25}$ was determined up to 96 GPa based on the phonon dispersion relation obtained at each pressure condition. Based on the P-wave velocity determined at high pressures, we constructed the equation of state for liquid $Fe_{75}P_{25}$. We found that the influence of phosphorous on the sound velocity of liquid Fe [5] is almost negligible under the present experimental pressure conditions, while the phosphorous reduces the bulk modulus and density of liquid Fe.

[S-IT24] MAGMA AND FLUID TRANSPORT IN THE EARTH'S INTERIOR

convener:Bjorn Mysen(Geophysical Laboratory, Carnegie Inst. Washington), Eiji Ohtani(Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University), Dapeng Zhao(Department of Geophysics, Tohoku University), Michihiko Nakamura(Division of Earth and Planetary Materials Science, Department of Earth Science, Graduate School of Science, Tohoku University)

The principal mass and energy transport agents in the Earth's interior are magma and fluids. The objective of the proposed session is to combine experimental data, observations, and theoretical modeling to describe the transport properties and processes.
Melting, crystallization, and devolatilization occur across temperature intervals within which the distribution of mass between melts, fluids, and crystals is established. Element partitioning between melts, crystals, and fluids is needed to describe these processes. Physical properties of melts and fluids are controlled by their chemical composition, temperature, and pressure. The mass transfer processes depend on the property information. Magma aggregation at depth and ascent toward the surface are direct functions of density contrasts and permeability and depends on temperature, pressure, chemical composition and concentration of volatile components.
The mass transfer processes are imaged globally and locally by geophysical observations such as seismic tomography and electrical conductivity profiles. Magma sources in the deep mantle and the crust are also imaged by these geophysical tools. The mass transfer to the surface can be observed as the volcanic eruption in which phase separation of magma and fluid, and crystallization during the magma ascent control the type of eruptions. These are processes imaged with geophysical methods with which a three-dimensional structure of magma and fluid plumbing systems can be described, and in the geological records of earlier phenomena.
The proposed session will focus on those phenomena including laboratory experiments, numerical modeling, and observations using geophysical, seismological and geochemical approaches. These include physical and chemical properties and process of magma and fluid, near surface processes of volcanic eruptions, and geophysical imaging of various scales from locally to globally. Contributions to any of these subjects are encouraged.

Viscosity of silicate network phase-separating from aqueous fluid

*Takehito Koyama[1]

1. Institute of Industrial Science, the University of Tokyo

Silicates and aqueous fluids are fundamental to multi-spatiotemporal-scale geodynamics on Earth. An important phenomenon of their mixtures is phase separation or phase demixing (Hack et al., 2007), creating different liquid phases; This is significant for magma differentiation (Kawamoto et al., 2012) as similar as crystallization, for magmatic dynamics from the crustal deep to the surface (Allabar and Nowak, 2018), and maybe, for crustal activities (Koyama, JpGU [2012, 2019]). To these time-consuming processes, viscous dynamics of the silicate phase slower than that of the aqueous one is crucial, but almost unknown. We have to consider the thermodynamic relations between the components in the non-equilibrium process, when using usual flow mechanism as the base.

This mechanism in melt silicate network, although still debated, can basically be interpreted as the conformation change through diffusion of the formers, Si, bridging O, Al, etc. (Mysen & Richet, 2005, Stebbins, 2016). In mixing hydrous melts, the increasing H_2O drastically lowers the viscosity; The modifier H with its non-bridging O makes the network variable through the dissociation and polymerization as the terminal OH and free H_2O, and through the inter-strand hopping as the OH (ibid.). However, these softening actions of H (OH & H_2O) through the reactive former-modifier collisions must be realized under the entropic mixing. Then, in coexisting melts of silicate network (formers) and aqueous fluid (modifiers) under SiO_2-H_2O demixing, are the actions of H the same as that in the mixing or not? Here, I expect to be not, or rather to be the opposite. This is because that the enthalpic demixing, overcoming the entropic mixing with the “both-like-both” one, leads to the “likes-like-likes” situation for both groups; The H_2O and OH, favoring themselves more than the network, must prevent the dissociation but promote the polymerization. Under this preferential polymerization the network shrinks with the strand tension instead of the fracturing to demix from the fluid. The tension must suppress the strand vibration creating the inter-strand collision for the OH hopping and for the network-former diffusion itself. Thus, these “inert” actions of H on the network in the demixing must be the hardening or the viscosity and solidity increasing, even in the highly hydrous situation, contrasted with the softening in the mixing. This state must be transient under the intense demixing in the early stage (transient gel: Tanaka, 2017; Koyama & Tanaka, 2018). Further, the hardening will be assisted by the actions of other modifiers, Na, K, Mg, etc., similar to that of H and by the enthalpy overwhelming the entropy in lower temperature and pressure.

Although having to be verified theoretically and experimentally, these qualitative results of the asymmetric behaviors of the silicate network and aqueous fluid in thier demixing will connect to magmatic and seismic processes: the convection suppression due to the elastic resistance of the demixing network in the chamber and the explosive eruption to the surface through the brittle fructuring of the network under rapid volatile expansion; a hypothetic phase-separating continental lower crust of the shrinking-network and diffusing-fluid for compressive and fluid-concerned intracrustal seismicity (Koyama, JpGU [2012, 2019]).

Structure and density of H_2O-rich Mg_2SiO_4 melts at high pressure from *ab initio* simulations

*Gerd Steinle-Neumann[1], Liang Yuan[1,2], Akio Suzuki[2]

1. Bayerisches Geoinstitut, Universitaet Bayreuth, 2. Department of Earth Science, Tohoku University

Water has a strong effect on silicate melt properties, yet its dissolution mechanism in depolymerized melts, typical for mantle composition, remains poorly understood. Here we report results of first-principles molecular dynamics simulations of hydrous Mg_2SiO_4 melts with 6 wt.%, 16 wt.% and 27 wt.% H_2O at pressure and temperature conditions relevant to the upper mantle and mantle transition zone. The results show that hydrogen not only bonds to network-forming cations Si, but also to network-modifying cation Mg which - nevertheless - remains the most important network modifier. There is no evidence to support the hypothesis inferred from experimental data that water may cause an increase in the melt polymerization for ultramafic magmas; the ratio of non-bridging oxygens per Si increases with the addition of the oxygen from H_2O. The partial molar volume of water is independent on concentration in our simulations which allows us to examine the density of hydrous melt systemmatically. The critical water content - at which melts are neutrally buoyant compared to the surrounding mantle - is ~4 wt.% H_2O for a pyrolite melt, much lower than the high water content (>10 wt.%) observed in petrological experiments and estimated thermodynamically for low-degree partial melts formed in the vicinity of the mantle transition zone.

A three-dimensional electrical conductivity model of the crust beneath the southern Tohoku district, NE Japan

Aoi Motoyama[1], *Masahiro Ichiki[1], Yasuo Ogawa[2], Makoto Uyeshima[3], Koichi Asamori[4], Toshihiro Uchida[5], Takao Koyama[3], Shin'ya Sakanaka[3,6], Hideaki Hase[3,8], Koki Aizawa[3,7], Yusuke Yamaya[3,5]

1. Graduate School of Science, Tohoku University, 2. School of Science, Tokyo Institute of Technology, 3. Earthquake Research Institute, The University of Tokyo, 4. Tono Geoscience Center, Japan Atomic Energy Agency, 5. National Institute of Advanced Industrial Science and Technology, 6. Graduate School of International Resource Science, Akita University, 7. Graduate School of Science, Kyushu University, 8. Geothermal Energy and Development Co. Ltd.

This study reports a three-dimensional electrical resistivity distribution model in the crust beneath the onshore southern Tohoku district, NE Japan. The southern Tohoku district here contains southern Yamagata prefecture, southern Miyagi prefecture, eastern Niigata prefecture, and northern Fukushima prefecture. This resistivity analysis aims three-fold. (1) To delineate fluid distribution in the crust beneath the onshore forearc of southern Tohoku district: The seismic swarm beneath around Iwaki city has been active since the 2011 off the Pacific coast of Tohoku Earthquake. The seismicity is interpreted as being induced by fluid migration from the deep crust. We investigate if conductive body in the crust elongates northwards from beneath Iwaki city. (2) To detect whether outstanding crustal fluid distributes beneath the onshore backarc. (3) To reveal a finer three-dimensional crustal conductivity distribution model beneath Ou-backbone range in southern Tohoku district, which we expect to give the interpretation of genesis of the volcanoes and of another seismic swarm occurring beneath around Yonezawa-city.

We compile the magnetotelluric (MT) and geomagnetic transfer function (GDS) data which were acquired by Uchida (2004), Umeda et al. (2008), Asamori et al. (2011), Uyeshima (private comm.) and Ogawa (private comm). The 118 observation sites locate in the study area. Both MT and GDS frequency response is used to model three-dimensional resistivity distribution. The period range is 0.03 to 652 second.

The resultant resistivity model reveals no conductor beneath the onshore forearc in Fukushima prefecture. The model rather shows resistor there with over several-thousand Ωm, which corresponds to the Abukuma batholiths. Thus, our model indicates that the area only around Iwaki-city is peculiar forearc, where fluid migrates upward from deep crust. Neither exists an outstanding conductor beneath backarc of the study area. However, a few local shallow conductors (down to 5 km depth) lie beneath the backarc. The bottom boundary of one of the conductors around Iide-Mountain area clearly bounds the local seismicity there. Although the cut-off depth of seismicity shows distinct undulation beneath regional backarc of the study area, the resistivity distribution shows no correspondence to the cut-off depth undulation. The outstanding crustal conductors are found beneath Ou-backbone range in the study area. We find the clear correspondence between deep low frequency events (20-40 km depth) and the conductor beneath Bandai-Azuma volcanoes. This image is similar with the relation of low velocity and deep low frequency event (Niu et al., 2018; Chen et al., 2019). The conductor beneath Ou-backbone range delineates the hot-finger image. The conductor branches at about 20 km depth.

Experimental constraint on the fluid connectivity in an olivine–H_2O–CO_2–NaCl system in subduction zones

*Yongsheng HUANG[1], Takayuki Nakatani[1], Michihiko Nakamura[1], Catherine McCammon[2]

1. Graduate School of Science, Tohoku University, 2. Bayerisches Geoinstitut, University of Bayreuth

In subduction zones, the circulation of slab-derived aqueous fluid through a mantle wedge plays a key role in arc magma genesis and global material cycling. Their presence can be detected by geophysical observations because of their remarkable influence on the physical properties of overlying plate. Recently, high electrical conductors have been detected by magnetotelluric observations beneath some fore-arcs and are believed to store voluminous slab-derived fluids. This implies that the mantle wedge at fore-arc depths is permeable for aqueous fluids. At high temperature and high pressure condition, dihedral angle is an important parameter to control the fluid connectivity in a fluid-bearing rock. The subduction zone fluid is now gradually recognized as a multicomponent fluid that is composed of the H_2O, salt (NaCl), nonpolar gas (CO_2) and dissolved solid components. However, the effect of multicomponent fluid on dihedral angle is still unclear, which restricts our understanding for realistic fluid circulation model in subduction zones. In this study, we experimentally constrain the dihedral angle in olivine–H_2O–NaCl–CO_2 systems at 1–4 GPa and 800–1100 ˚C to understand the combined effect of salt and nonpolar gas on the connectivity of aqueous fluids in the mantle wedge. Results in H_2O–CO_2 system show that CO_2, contrast to NaCl, tends to increase the dihedral angle at 1 GPa and 800–1100 ˚C, and 2 GPa and 1100 ˚C. However, it can reduce the dihedral angle even below 60˚ at relatively high pressure and low temperature conditions where olivine partly reacts with CO_2 to form magnesite and orthopyroxene. Results in the multicomponent system suggest that the effect of NaCl on dihedral angle is much more significant than that of CO_2. In addition, strikingly, the dihedral angles in the multicomponent system are the smallest among all investigated systems and much smaller than 60˚ under the presence of magnesite and orthopyroxene. Therefore, the multicomponent fluid can infiltrate into the forearc mantle wedge through the interconnected fluid network, which can account for the high electrical conductivity anomalies detected in the forearc region. This work was supported by the JSPS Japanese-German Graduate Externship.

Anomalous structural dynamics of basaltic melt at mantle conditions: Implications for superplumes and magma oceans

*Arnab Majumdar[1], Min Wu[2,1], Yuanming Pan[1], Toshiaki IITAKA[3], John S Tse[1]

1. University of Saskatchewan, 2. Zhejiang University of Technology, 3. RIKEN

Transport properties such as diffusivity and viscosity of melts determined the evolution of the early Earth’ s magma oceans. They also govern many present-day processes of the Earth, from mantle convection to plate tectonics, magma migration and volcanic activity. Unfortunately, carrying out experimental measurements of melt diffusivity and viscosity at most mantle conditions are rendered impossible due to technical challenges. In this theoretical work we report the structure, density, diffusivity, electrical conductivity, and viscosity of a model basaltic ($Ca_{11}Mg_7Al_8Si_{22}O_{74}$) melt. The calculations have been performed using first-principles molecular dynamics simulations at temperatures from 2200 K (0 to 80 GPa) to 3000 K (40-70 GPa) and 4000 K (120 GPa). There is good agreement between our results on the melt structure and viscosity at low pressure with that of experiments and previous theoretical predictions. A significant finding is that, although the density and coordination numbers around Si and Al increase with pressure, however, the Si-O and Al-O bonds become more weak and ionic. The temporal atomic interactions at high pressure are fluxional and fragile. Thus, making the atoms more mobile and reversing the trend in transport properties at pressures close to 50 GPa. The reversed melt viscosity under lower mantle conditions allows new constraints on the timescales of the early Earth’ s magma oceans. It also provides the first tantalizing explanation for the horizontal deflections of superplumes at ~1000 km below Earth’ s surface.

[S-IT25] Structure and Dynamics of Earth and Planetary Mantles

convener:Takashi Yoshino(Institute for Planetary Materials, Okayama University), Takashi Nakagawa(Department of Earth Sciences, The University of Hong Kong), Dapeng Zhao(Department of Geophysics, Tohoku University)

Interdisciplinary approach can lead to a better understanding of the dynamics and evolution of the deep interiors of the Earth and planets. We welcome any submissions of recent results in observational, theoretical and experimental studies on seismology, geomagnetism, mineral physics, dynamics of deep interiors, and any other relevant fields from researchers in many countries. The integration of such results is also welcome. In particular, we encourage any contributions focusing on "plate and mantle dynamics in Earth and terrestrial planets". This session will be organized as the main session of the SEDI-J group in the Solid Earth Section of JpGU. We encourage all participants concerning the deep planetary interior to submit this session.

The viscosity structure of the low-viscosity zone of the Moon derived from the tidal response

*Yanxia Tan[1], Yuji Harada[1]

1. State Key Laboratory of Lunar and Planetary Sciences, Macau University of Science and Technology

The effect on the tidal response of the low-viscosity zone at the deep interior of the Moon is investigated, in particular from the viewpoint of its possible viscosity structure on a few simple assumptions of some hypothetical temperature profiles. Based on the Love number theory, the tidal parameters are computed numerically in order to demonstrate their structure dependences on the low-viscosity zone as well as the frequency dependence. Unlike the earlier consideration, the viscosity structure of the low-viscosity zone here is not assumed to be fully uniform any longer but linked with either a couple of temperature profiles, namely, the thermal boundary layer model or the convective layer model. The calculations show that the latest observational ranges of the frequency-dependent quality factors can be satisfied only by the convective layer model with some viscosity value for the interlayer but not by the thermal boundary layer model for any structure. The approximate viscosity solution is estimated to be 3.3×10^{16} Pa s. If considering also the observational ranges of the Love numbers together with those of the quality factors, the solution of the outer radius of the low-viscosity zone is approximately 560 km. These solutions are almost identical to those based on the previous uniform model. It is concluded that in the Maxwell model the thermal state of the bottom layer of the lunar mantle is predicted to be mainly controlled by the local convection, and possibly maintained by the energy balance between convective cooling and tidal heating, as previously suggested.

2D Visco-elasto-plastic numerical modeling of buckling and uplift on passive margin under compression: implications for topography of SE Korea and the East Sea (Japan Sea)

*Seok-Hyeon Do[1]

1. Kangwon National University

The continental margin, which shows prominent topographical structures such as buckling, uplift, and fault, is categorized into the active and passive margins. Although the passive margins are considered geophysically stable, it is likely to be reactivated into the active margins such as subduction zone due to external forces and its own gravitational weight. Previous studies, based on geophysical observations (e.g., seismic reflection, tomography, gravity anomaly, and marine terrace uplift), suggested that the EW compression exerting on SE Korean Peninsula induced a buckling structure with ~60-70 km wavelength and uplift rate of ~0.3 m/ky. In this study, we reproduced the Korean passive margin associated with buckling and uplift structures, and found the clear correlation between the strength of oceanic lithosphere and wavelength of buckling structure. We developed the passive margin model with 2D visco-elasto-plastic finite element method in the Lagrangian manner. Due to the lack of available geophysical data for inferring rheological structure beneath the Korea Peninsula and the East Sea (Japan Sea), we performed a parametric numerical simulation with a wide range of rheology. In the reference model, the domain composed of the mantle, oceanic and continental (upper and lower) crusts is compressed horizontally by constant velocity boundary condition (i.e., ~3-6 cm/yr). The reference model exhibits a buckling structure with ~200 km wavelength on oceanic crust and uplift rate of ~0.6 m/ky on continental crust. We experimented with varying the variables using the strength of oceanic lithosphere as a variable. Our model showed that different strength of oceanic lithosphere caused the buckling with different amplitude to that of the reference model. The stronger strength of oceanic lithosphere, the buckling structure becomes bigger. We suggest that the Korea passive margin with buckling and uplift structure has developed due to the combination of young oceanic lithosphere and EW compression.

Development of 3-D Lagrangian Free Subduction Model: Implications for Surface Process of the Earth

*Jae-Yoon Keum[1], Byung-Dal So[1]

1. Kangwon National University

Variation of surface curvature along trench which is geodetically observed is ubiquitous in modern subduction zones on Earth. Global reference frame suggested differential trench motion in the one subduction zone. Its resultant trench shape has been explained by tectonic mechanism such as heterogeneities in ages of the plate at trench, slab width and overriding plate. However, relationship between the trench motion and sedimentation which is fundamental surface process of the Earth (e.g, climate, eustatic sea level change, amount of supply and erosion due to vertical topography change) relatively has been poorly understood. In this study, we developed 3-D thermo-mechanical free subduction model using viscoelastic material based on Lagrangian finite element method. We quantitatively evaluated relationship between trench shape along strike direction and sediment thickness by implementing realistic rheology including brittle, diffusion, and dislocation creep. We suggest that if sedimentary accumulation vary gradually along trench axis, differential trench rollback rates could be obtained and various trench shpae including oblique subduction could occur. Our results, including the geodynamic implication that the Earth’ s surface process contributes to subduction physics, are expected to improve the understanding of the structure of deep subduction.

Application of Parker-Oldenburg Algorithm to map Moho Discontinuity using Gravity Data in Western North America Cordillera

*Mohammad Shehata[1,2], Hideki Mizunaga[2]

1. Department of Geology, Faculty of Science, Port Said University, Egypt, 2. Department of Earth Resources Engineering, Faculty of Engineering, Kyushu University, Japan

Parker–Oldenburg algorithm was applied to airborne gravity data in the western USA to map the Moho discontinuity. F-H Parasnis method was also applied to the gravity data to estimate the Bougeur reduction density for calculation of the Bougeur gravity anomaly. The inversion process uses the Oldenburg equation (Oldenburg, 1974), which is a rearrangement of Parker’ s equation (Parker, 1973), to estimate the depth to the undulating interface from the gravity anomaly by means of an iterative process. These formulas are shown as follows,

The resulted Moho depth map shows depths ranging from 9 km to 50 km. Moho anomalies showed good spatial correlation with the major physiographic provinces in the study area. The subduction trench of the Farallon remnants (Juan de Fuca and Gorda) was mapped at the north of the Mendocino Triple Junction (MTJ). The subducting plates show north-east dipping direction with low dipping angle. The effect of the subduction appears in the structure at the northern part (i.e. Cascade Mountain, Walla-Walla plateau and Northern Rocky Mountains), whereas the southern part is affected by the transform movement of the Pacific Plate yielding a set of basins (Central Valley, Great Basin and Wyoming Basin). Results of this research, in conjunction with other information of the area, provide a new information for the analysis of the tectonic framework of the western North-America.

Multi-mode surface wave phase speed distribution in North America

*Hitoshi Matsuzawa[1], Kazunori Yoshizawa[2], Fan-Chi Lin[3]

1. Graduate School of Science, Hokkaido University, 2. Faculty of Science, Hokkaido University, 3. The University of Utah

The recent deployment of high-density broadband seismic networks in continental regions enables us to investigate the detailed seismic images of the continental upper mantle using seismic surface waves. Making the most of such seismic arrays, we have recently developed two-step array-based methods for (1) the multi-mode phase speed measurements based on a *f-k* analysis with a long-linear array, and (2) the modal waveform decomposition for the centroid location of array, based on the linear Radon transform (Matsuzawa & Yoshizawa, GJI, 2019). Such array-based multi-mode phase speed measurements are expected to be of help in enhancing the vertical resolution of 3-D S-wave speed models.

We applied the method (1) to an extensive data set from the Transportable Array stations of USArray, and mapped phase speed distributions in North America (Matsuzawa & Yoshizawa, AGU Fall Meeting 2018). We could obtain preliminary phase speed maps of the fundamental-mode and the first four higher-mode surface waves. Although the large-scale anomalies (i.e., fast phase speeds in cratons in the stable eastern US., slow phase speeds in the tectonically active western US.) could be identified, the lateral resolution of the phase speed maps was limited, compared with earlier tomography models using inter-station and single-station measurements. This suggests that the small-scale tectonic features tend to be blurred and averaged out due to the long linear array (2000–4000 km).

To overcome this problem, we apply the inter-station dispersion analysis (Hamada & Yoshizawa, GJI, 2015) and the eikonal tomography method (Lin *et al.*, GJI, 2009) to the decomposed modal waveforms of the fundamental-mode derived from the method (2). In the eikonal tomography, the phase speed distributions can be retrieved by calculating the gradient of the phase traveltime field without any inversion processes.

The resultant fundamental-mode phase speed maps of Rayleigh and Love waves exhibit enhanced lateral resolution, showing some small-scale tectonic features in the inland of the US. The results indicate that the decomposed modal waveforms at the centroid of the linear array represent the average phase speeds in a relatively small area of several-hundred kilometers, which is equivalent to the wavelength of the fundamental-mode surface waves. Such decomposed fundamental-mode seismograms can be further used to enhance the quality of higher-mode measurements through the mode-stripping of the fundamental-mode from the observed seismogram.

Mapping azimuthal anisotropy in the Australasian upper mantle with multi-mode surface waves

*Kazunori Yoshizawa[1,2], Yuka Nishimura[2]

1. Faculty of Science, Hokkaido University, 2. Graduate School of Science, Hokkaido University

Azimuthal anisotropy in the upper mantle from seismic surface waves provides us with the information of mantle dynamics, such as the present-day mantle flow and the remnant of past deformation in the lithosphere. The Australian plate is currently the fastest-moving tectonic plate including a large continent, encompassed by the intensive seismicity, particularly in its north (Indonesia) and east (Tonga-Kermadec to New Zealand). Thus, the entire continent can be covered by dense ray paths utilizing broad-band seismic stations deployed throughout the continent. This unique tectonic setting of the Australian plate allows us to reconstruct high-resolution tomography models in the Australasian region.

In this study, we construct azimuthally anisotropic phase speed maps of multi-mode surface waves incorporating azimuthal anisotropy, which are then used to construct three-dimensional S wave models with azimuthal anisotropy. We employ the database of path-specific multi-mode phase speeds for the fundamental mode and up to the fourth-higher modes surface waves by Yoshizawa (2014), which has been measured by using the non-linear waveform fitting method (Yoshizawa & Ekstrom, 2010).

The results suggest that the fast-axis of azimuthal anisotropy in the upper mantle is nearly parallel to the absolute plate motion (APM) in the oceanic area, but is more complicated in the continental area. The azimuthal anisotropy beneath the Australian continent above 150 km depth reflects the past deformation frozen in the lithosphere, which is characterized by the E-W oriented anisotropy. However, below 150 km depth, azimuthal anisotropy tends to represent the present-day shear flow in the asthenospheric mantle beneath the cratonic lithosphere, which moves to the north. Beneath the Tasman Sea between New Hebrides Trench and New Zealand, we can see the circular pattern of azimuthal anisotropy, especially at a shallower depth above 200 km.

The thickness of the Australian lithosphere becomes thinner toward the eastern margin of the continent, which is well reflected in the cross-sections of the azimuthally anisotropic S wave model. The agreement between APM and azimuthal anisotropy can be observed at the depth below the lithosphere-asthenosphere transition estimated from the isotropic S wave speed model, indicating the effects of mantle flow under the fast drifting Australian continent.

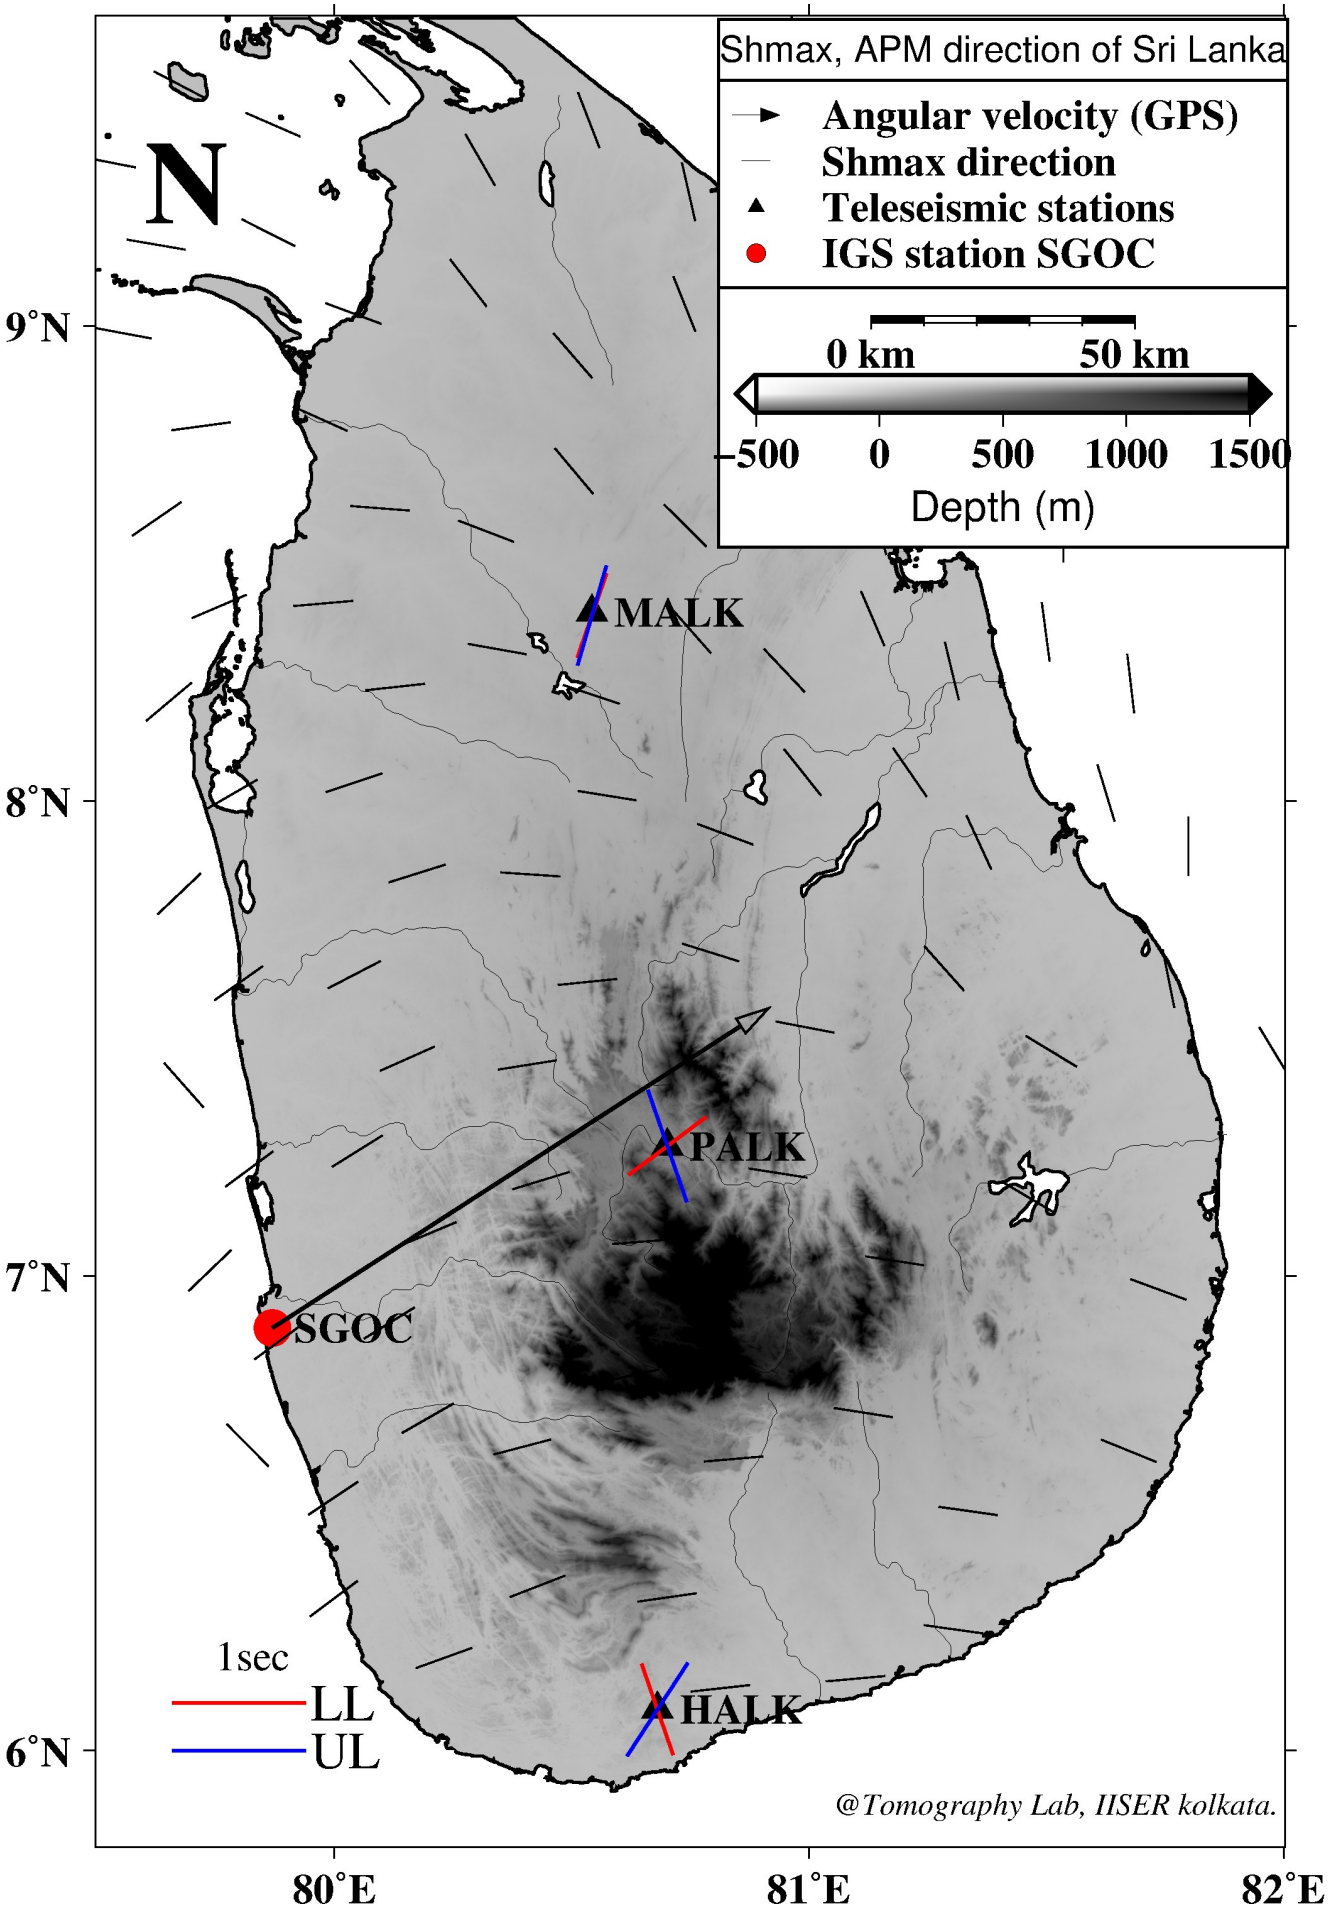
Upper mantle anisotropy beneath Sri Lanka region using shear-wave splitting analysis



*Shivam Chandra[1]

1. Undergraduate student member

Anisotropy in the Earth’ s upper mantle is a signature of past and present deformation. Seismic anisotropy beneath a seismic station can be inferred by analyzing core-refracted (SK(K)S, PK(K)S) seismic phases. In this study, upper mantle anisotropy is investigated using shear wave splitting of SK(K)S phases at 3 stations in Sri Lanka. Sri Lanka consist of four main lithological units, viz., the Highland Complex (HC), the Wanni Complex (WC), the Vijayan complex (VC) and the Kadugannawa complex (KC). Shear wave splitting measurements were done for ~30 high-quality waveforms recorded in the region, using rotational correlation (RC), minimum energy (SC) and eigenvalue techniques. The result of the shear-wave splitting measurement shows the presence of two anisotropic layers in the upper mantle, viz., the upper layer with fast polarization direction (Φ): NW-SE and delay time (δt): 0.4-0.5 s, and the lower layer with Φ: NE-SW and δt: 0.6-0.8 s. Our study suggests that fast axis direction of lower layer with an average delay time of 0.6 s depicts a ~67 km thick anisotropic layer with 4% anisotropy beneath Sri Lanka region. Comparison of Absolute Plate Motion (APM) direction with fast directions infer that the Simple Asthenospheric Flow (SAF) model prevails in this region. On the other hand, Comparison of Maximum Horizontal stress (S_{hmax}) and the Global Positioning System (GPS) with the fast direction infer that there is partial contribution from lithospheric mantle. So, the anisotropy in Sri Lanka is mainly governed by asthenospheric flow, and partially due to lithospheric mantle.

Lattice preferred orientation of akimotoite deformed in the D111 Kawai-type multianvil apparatus

*Longli Guan[1], Daisuke Yamazaki[1], Noriyoshi Tsujino[1]

1. Institute for Planetary Materials, Okayama University, Misasa, Japan

Seismic anisotropies are one of the key factors for understanding the mantle dynamic and have been observed near Tonga subducted slabs in the mantle transition zone and the uppermost lower mantle (mid-mantle) (e.g. Chen & Brudzinski, 2003; Vavryčuk, 2006; Nowacki et al.,2015). Spatial variation of seismic anisotropy in the Tonga subduction zone was reported by Vavryčuk. (2006). The stagnant slab above 660 km of northern segment shows that *P*-waves propagate more slowly in the direction normal to slab interface, while they propagate more slowly along the slab sinking direction in the penetrated slab below the 660 km of southern segment. The seismic anisotropy, in general, can be often caused by lattice preferred orientation (LPO) of elastically anisotropic minerals. LPO of akimotoite (ilmenite-structured (Mg, Fe) SiO_3) is plausible to interpret these seismological observations because it has a strong elastically anisotropic feature and it is one of main constituting mineral at the mantle transition zone and the uppermost lower mantle. Although pioneer works investigated the slip system of akimotoite (Cordier, 2002; Shirashi et al., 2008), it has not been fully determined yet. In this study, therefore, we conducted well-controlled deformation experiments at high pressure and temperature to observe LPO of akimotoite developed during deformation. The starting material of akimotoite aggregates was synthesized from $MgSiO_3$ glass at ~21 GPa and 1400℃, in the Kawai-type multianvil apparatus. Subsequent deformation experiments were conducted on the akimotoite aggregates at 21-23 GPa and 900-1200℃ by using high-pressure deformation apparatus, so-called D111 type apparatus, installed at Institute for Planetary Materials, Okayama University. Total strain and average strain rate were determined to be 0.08-0.19 and 2.63×10^{-5}-5.76×10^{-6} s^{-1}, respectively for the uniaxially deformed sample and 0.4-2.1 and 1.06×10^{-5} -6.03×10^{-5} s^{-1}, respectively for the sheared sample. All LPO patterns at experimental temperature ranged from 900 to 1200℃ indicate the c-axis of akimotoite is preferentially sub-parallel to the compression direction, suggesting a dominant slip plane on (0001). The variation of *P*-waves anisotropy observed in Tonga subduction zones at depths of the mid-mantle can be explained in terms of the LPO of akimotoite induced by different stress field between northern and southern slab segments. The LPOs of northern and southern slabs are mainly caused by the simple shear deformation with σ_2 perpendicular to the advance direction (slip direction) and along the slab and uniaxially compression with σ_1 parallel to the downdip direction, respectively. Our preliminary conclusion is consistent with geophysical observations (Bonnardot et al., 2009).

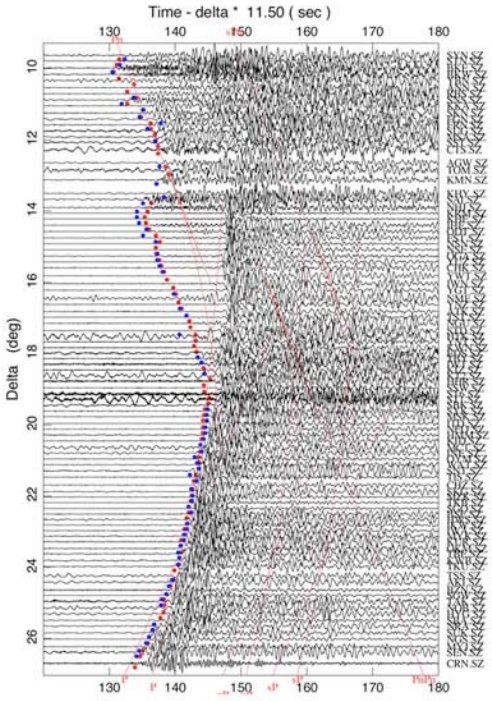
Mantle discontinuities oceanward of the Krile - Honshu slab



*Masayuki Obayashi[1], Junko Yoshimitsu[1], Yoshio Fukao[1]

1. Japan Agency for Marine-Earth Science and Technology

Triplication waveforms of the 410-km discontinuity (the 410) and 660-km discontinuity (the 660) recorded on Hi-net (High Sensitivity Seismograph Network in Japan) from Kuril earthquakes are analyzed to investigate seismic structures of the discontinuities. The first P-waves of which ray paths bottom depths well above the 410 arrive much earlier than expected by any standard spherical velocity model because they propagate through the dipping Pacific fast slab. However, such fast arrivals are well predicted by our tomography model GAP_P4 (Obayashi et al., 2013) (Figure 1). On the other hand, the later phases of the mantle discontinuity triplication are less affected by the dipping slab. Figure 2 shows the region of interest indicated by the ray paths grazing the discontinuities located oceanward the Kurile-Honshu slab. Figure 3 shows the square of envelope waveforms stacked for 11 earthquakes after equalizing the focal depths to a common depth of 120 km. This equalization was made using a representative slowness value of 11.5 or 9.7 (sec/deg) to emphasize the retrograde branch of the 410 or 660 triplication. The retrograde branches of the 410 and the 660 are clearly observed as shown by yellow thick lines in Figure 3. The retrograde branch for the 660 is consistent with the theoretical travel time predicted by IASP91 model. However, the retrograde branch for the 410 arrives later by 2 or 3 seconds and its slowness is larger than the prediction, suggesting slow anomalies atop of the 410. We will show a spherical model that explains the characteristics described above.

Tomography Model Using Singular Value Decomposition

*Jun Su[1,2], Christine Houser[2], John William Hernlund[2]

1. Department of Earth and Planetary Sciences, Tokyo Institute of Technology, 2. Earth-Life Science Institute

We apply a singular value decomposition (SVD) solution for the inverse problem in tomography and compares model results with a least-squares (LSQR) method which uses first difference radial and lateral smoothing parameters for regularization. Taking advantage of the increased computing power and efficient algorithms, we are now able to introduce the SVD method to solve a non-sparse matrix inversion like three-dimensional global mantle tomography. This study finds the k value for truncated SVD can serve as a unique regularization parameter and produce models with similar spectral power to the LSQR solutions.

We examine the SVD method using the same dataset as the tomographic model HSML06: long-period travel time residuals downloaded from the Incorporated Research Institutions for Seismology Data Management Center from 1976 to 2005. When employing a least-squares inversion, changing the smoothing parameters requires an entire re-calculation of inversion. However, the SVD solution provides a less computationally expensive way to regularize tomographic models by increasing or decreasing the number of singular values that contribute to the solution. Structures of small scale and fluctuations of short wavelength contribute smaller singular values and correspond to the later part of the singular matrix according to its descending property. We evaluate the SVD tomographic models to determine the necessary contribution of the smaller singular values to retain seismic structure resolved using the least-squares technique. The SVD solutions are desirable since they require negligible computation time and the resulting resolution operator provides a quantitative means for comparing tomography with geodynamics models.

Whole-mantle P-wave tomography beneath East Asia

*Yu Katayama[1], Dapeng Zhao[1], Genti Toyokuni[1]

1. Research Center for Prediction of Earthquakes and Volcanic Eruptions, Graduate School of Science, Tohoku University

The geological structure and tectonics of East Asia are characterized by the India-Asia collision in the southwest and subduction of the Pacific plate and the Philippine Sea plate from the east. The Pacific slab exists as a stagnant slab in the mantle transition zone, which is closely related to intraplate volcanism in NE Asia. Volcanoes in mainland China, such as those in Changbai, Datong, Ashikule and Hainan are intraplate volcanoes, which are quite different from the volcanoes in subduction zones and mid-ocean ridges. The origin of magmatic fluids associated with the formation of the intraplate volcanoes and causal mechanism of large earthquakes in the continental region have been investigated by many previous tomographic studies (e.g., Zhao et al., 2011; Ma et al., 2019). However, the detailed crustal and mantle structures under the intraplate volcanoes and the slab structures are still not very clear. In this study, we investigate these issues by conducting whole-mantle P-wave tomography beneath the East Asian region.

We use a large number of P-wave arrival time data of earthquakes selected from the ISC-EHB catalog and Annual Bulletin of Chinese Earthquakes. The events are relocated using depth phase data. To select a best set of earthquakes, we divided the crust and mantle into small cubic blocks and only selected an event in each block that had the maximum number of arrival-time data and the smallest error in the hypocentral location. The events are selected so that they have a uniform distribution in the study region.

We use the multiscale global tomography method (Zhao et al., 2013, 2017), which can prevent the over-dense grid nodes arranged at higher latitudes. A denser 3-D grid is arranged in East Asia, whereas a coarser 3-D grid is arranged in the surrounding whole globe.

Our new tomographic model shows the following features.

(1) Low-velocity anomalies are generally revealed in the whole mantle under the Hainan region, which may reflect the whole-mantle Hainan plume.

(2) Very heterogeneous structures are revealed under the Tibetan region, which may reflect the complex subduction of the Indian plate beneath the Eurasian plate.

(3) Slab tear is revealed under the marginal seas, which is consistent with the recent result obtained by Ma et al. (2019).

Seebeck coefficient measurement of olivine by dual heating system and its application to the redox kinetics of the subducted slabs

*Ran Wang[1], Takashi Yoshino[1]

1. Institute for Planetary Materials, Okayama University

Subduction plays an important role in the plate tectonics of the Earth and is closely related to many activities such as water transport, volcanism and mantle convection. In addition, the subducted slabs can also influence the redox state of the Earth’ s interior because the descending slabs are always colder and more oxidized compared with the surrounding mantle. Since thermal boundary layer is likely to develop around the cold slab, the heat conduction could produce the electrical potential gradient by the Seebeck effect. The Seebeck coefficient is a parameter to define the type of the dominant charge carrier inside the materials under thermal gradient. Positive value of seebeck coefficient means the charge carriers have positive valence such as electron holes (small polarons) and protons. When the value is negative, electrons or metal vacancy are potential charge carriers.

To determine the Seebeck coefficient under high pressure, we established the cell design with dual heating systems on the 6-axis apparatus. Two disk TiB_2 heaters were placed in the octahedral cell to make two insulated heating systems. Temperature differences were produced on the two sides of the sample by dual heaters and the temperatures were measured by separated thermocouples on each side of the sample. In addition, the electromotive force (voltage difference) of the sample was measured by high resolution multimeter. Therefore, we could easily obtain the seebeck coefficient from the formula, $S = \Delta V / \Delta T$. To check the reliability of the method, we use two types of P-type silicon single crystals with different boron doping concentrations as the test materials. The results are quite consistent with previous experimental and calculation results obtained at ambient pressure.

In order to better understand the redox kinetics of the subduction zones, olivine, the dominant phase in the upper mantle, is the most important mineral to control the redox condition. We measured the Seebeck coefficient of olivine under high pressure. The Seebeck coefficient of the sintered Fo_{90} aggregates was measured at 5 GPa. The Seebeck coefficient is positive and decreases with increasing temperature. The positive to negative transition of the charge carrier occurred at around 1100-1200℃. Thus, we can assume that the temperature of the overlying mantle at about 150 km is above 1350℃, and then olivine would behave as N-type semiconductors. In contrast, olivine in the cold slab behaves as P-type semiconductor, suggesting that the cold slab will be oxidized itself by the Seebeck effect.

High-pressure generation to 150 GPa in multianvil apparatus using the 6-8-2 system with nano-polycrystalline diamond anvils.

*Takehiro Kunimoto[1], Masayuki Nishi[1], Tetsuo Irifune[1]

1. Geodynamics Research Center

The pressures available in Kawai-type multianvil apparatus (KMA), using second-stage anvils of tungsten carbide (WC) or sintered diamond (SD), have been limited to about 30 GPa and 60 GPa, respectively [e.g.1,2]. Recent efforts in introductions of new WC and SD materials and improvements in cell assemblies significantly expanded these limits to 60 GPa for WC anvils and 120 GPa for SD anvils [3,4,5]. An attempt has also been made to the harder nano-polycrystalline diamond (NPD) as the second-stage anvils demonstrated the potential importance of this noted ultra-hard material for KMA, but the available pressures have been limited to ~90 GPa because of the limitation in the size of the NPD anvils [6].

Kunimoto and Irifune (2010) introduced a newly-designed cell assembly for 6-8-2 type cell with NPD as third-stage anvils, and reported generation of pressures up to 125 GPa [7], but it was difficult to produce further higher pressures. So, we have been trying to improve the cell assembly for the 6-8-2 system to generate the pressure equivalent to the Earth’ s core-mantle boundary (CMB), for better understanding of this heterogeneous region using advantages of KMA over competing diamond anvil cell.

In situ X-ray experiments were conducted using the KMA (SPEED-Mk.II) at SPring-8, BL04B1. We used sintered polycrystalline $MgSiO_3$-perovskite (Pv) synthesized in a KMA as a starting material. Generated pressures were determined from the unit cell volumes of Au and MgO using adequate equation of state [8,9]. Upon compression, the X-ray diffraction profile showed the $MgSiO_3$-Pv changed to an amorphous-like phase above ~70 GPa at the room temperature. Eventually, we reached pressures of about 150 GPa in two independent runs, which are the highest pressure ever reported in KMA, although we were unable to identify the crystal structure of the sample due to amorphization. The pressure achieved in these runs completely cover the entire D” region (approx. 125-135 GPa), and some attempts have also been made to produce high temperatures under such pressures.

[S-IT26] Interaction and Coevolution of the Core and Mantle in the Earth and Planets

convener:Kenji Ohta(Department of Earth and Planetary Sciences, Tokyo Institute of Technology), Tsuyoshi Iizuka(University of Tokyo), Kenji Kawai(Department of Earth and Planetary Science, School of Science, University of Tokyo), Taku Tsuchiya(Geodynamics Research Center, Ehime University)

Recent observational and experimental investigations have significantly advanced our understanding of the structure and constituent materials of the deep Earth. Yet, even fundamental properties intimately linked with formation and evolution of the planet, such as details of the chemical heterogeneity in the mantle and light elements dissolved in the core, remain unclear. Seismological observations have suggested a vigorous convection in the lower mantle, whereas geochemistry has suggested the presence of stable regions there that hold ancient isotope signatures. The amounts of radioactive isotopes that act as heat sources and drive dynamic behaviors of the deep Earth are also still largely unknown. We provide an opportunity to exchange the achievements and ideas, and encourage persons who try to elucidate these unsolved issues of the core-mantle evolution using various methods, including high-pressure and high-temperature experiments, high-precision geochemical and paleomagnetic analyses, high-resolution geophysical observations, geo-neutrino observations, and large-scale numerical simulations. Papers stimulating an interdisciplinary collaboration relating to establishment of the Japan-SEDI community are also welcomed.

Density of Fe^{3+}-bearing magma at high pressure

Rintaro Ban[1], *Akio Suzuki[1], Tatsuya Sakamaki[1]

1. Department of Earth Science, Graduate School of Science, Tohoku University

Previous studies indicate the high concentration of Fe_2O_3 in the lower mantle. Even though the partial molar volume of Fe_2O_3 has become essential for discussing the magma in the deep mantle, there is no data of partial molar volume of Fe_2O_3 at high pressure and temperature. This study is aimed to obtain partial molar volume of Fe_2O_3 in silicate melts under high pressure. Fe^{3+}-rich starting material was compressed by a Kawai-type multi-anvil apparatus at high pressure of above 4 GPa and high-temperature of above 1800 ˚C. We determined the third-order Birch-Murnaghan equation of state of melts from results of sink-float method. By combining the compression curves of melts and the equation of state of silicate melts proposed in Wakabayashi and Funamori (2013), partial molar volumes were yielded between 8 and 22 GPa and 1800 ˚C. These results indicate that compressibility of Fe_2O_3 is much higher than that of FeO within the range of 8 GPa to 22 GPa.

Quantitative evaluation of the geochemical correlation length within the single granitic body, toward the error estimation of geoneutrino flux from the Japanese crust

*Kenta Ueki[1], Minami Kazuki[2], Akimichi Taketa[2], Tsuyoshi Iizuka[3], Sanshiro Enomoto[4], Nozomu Takeuchi[2], Hiroyuki Tanaka[2]

Geoneutrino observation at anti-neutrino observatory "KamLAND" (Kamioka, Hida City, Gifu Prefecture) allows us to estimate the total abundance of Uranium and Thorium in the deep Earth. By subtracting the crustal contribution from the KamLAND observation, it is possible to estimate the flux of mantle-derived geoneutrino. As ~50% of the observed geoneutrino flux at KamLAND is derived from the nearby Japan crust, precise estimations of geoneutrino flux from the Japan crust and its error are essential to estimate the flux of mantle-derived geoneutrino accurately. For this purpose, we have established a stochastic estimation method for crustal chemical composition. Based on the stochastic compositional model, we have calculated the geoneutrino flux from the Japan crust. At present, the estimated values of geoneutrino flux from the Japanese crust exhibit a considerable uncertainty because of the difficulty in handling spatial correlations (in other words, compositional similarities within each geological unit).
In this study, dense sampling was performed in a single granite body (Inada granite, Kasama City, Ibaraki prefecture) to quantitatively understand the spatial correlation of rock chemical composition. By analyzing the compositional differences between samples at various distances, the spatial correlation length of the compositions was evaluated. Based on the analysis, the "typical composition of a km-scale rock body," which excludes small (cm-m) spatial-scale composition variations, was estimated with an uncertainty. Under this proper correlation modeling, geoneutrino flux estimation errors from the Japan crust would be reduced. We also discuss the magmatic processes that derived the geochemical variations of granite, based on the differences in spatial correlation depending on the elemental species.

Re-evaluation of thermal data in the Japanese Islands for better estimation of the temperature structure in the crust

*Makoto Yamano[1], Akiko Tanaka[2], Hideki Hamamoto[3], Shusaku Goto[2], Takumi Matsumoto[4]

1. Earthq. Res. Inst., Univ. Tokyo, 2. Geol. Surv. Japan, AIST, 3. Center Environ. Sci. Saitama, 4. Nat. Res. Inst. Earth Sci. Disaster Resilience

For investigation of the structure and composition of crust, we need to combine various geophysical data with estimated subsurface temperature stricture as well as geological and petrological information, since physical properties of rocks depend on temperature. Surface heat flow is the most fundamental data for estimation of subsurface temperature structure. However, published heat flow data on land in the Japan have been rather sparse and not evenly distributed owing to the limitation of boreholes available for temperature measurement.

Borehole temperature profiles have been measured in observation wells for the Hi-net seismograph network, which are densely and evenly distributed over the Japanese Islands. Temperature measurements have been conducted in groundwater monitoring wells located in and around large cities as well. Although these data can be valuable sources of new heat flow data, the most of the wells are shallow, 50 to 150 m, and subject to influence of ground surface temperature (GST) variation. We selected temperature profile data in relatively deep wells, over 150 m, in the central part of Honshu and attempted to evaluate the influence of GST variation on subsurface temperature structure.

After eliminating data apparently affected by groundwater flow, we reconstructed GST history in the past at each well through inversion analysis of the temperature profile data, taking account of the layered subsurface structure based on borehole lithological column information. GST histories for the last 300 years were successfully reconstructed at several sites in Kanto and Tokai regions and the obtained GST variations are similar to each other. It suggests that we may be able to determine an average GST history for each region in Japan, which can be used for analysis of shallow well temperature data in the region.

For determination of heat flow values, we need to know thermal conductivity of formations through which temperature gradient is measured. At many stations, however, it is difficult to obtain rock/sediment samples for thermal conductivity measurement. Aiming for better evaluation of surface heat flow, we have been conducting measurement of thermal conductivity of core samples collected from Hi-net wells and boreholes drilled for volcano observation. We used an optical scanning instrument, TCS (Thermal Conductivity Scanner), which enables nearly continuous measurement along the core, as well as a conventional box-type probe, QTM (Quick Thermal Conductivity Meter). High-density data with TCS provide valuable information on small-scale heterogeneity in thermal conductivity. For most of the samples we measured, the average of values obtained with TCS is consistent with the value with QTM.

A new version of database "Thermal Data Collection in and around Japan" was released by Geological Survey of Japan in March 2019. It contains updated compilations of heat flow data in the northwest Pacific area (0 to 60 ˚N, 120 to 160 ˚E) and geothermal gradient data in and around Japan, and a new collection of thermal conductivity values measured on rock samples from boreholes in Japan. These datasets, in combination with data from Hi-net boreholes and groundwater monitoring wells, would serve as a basis for modeling thermal structure of subduction zones around the Japanese Islands.

Outer core flows and dynamo induced by heterogeneous growth of the inner core of the Earth

*Shin-ichi Takehiro[1], Youhei SASAKI[2]

1. Research Institute for Mathematical Sciences, Kyoto University, 2. Department of Architecture/Institute of Fundamental Sciences, Setsunan University

Recent seismological observations suggest longitudinal heterogeneity of seismological wave velocity of the inner core of the Earth, which stimulates a discussion that phase change at the inner core boundary (ICB) does not occur uniformly in the horizontal directions. One of the mechanism explaining heterogeneous growth of the inner core, is that hydrodynamic instability of the inner core surrounded by the phase boundary causes translational motion inside the inner core. The expected amplitude of the motion is 5e-10 m/s,
which is one order of magnitude larger than that of the velocity of uniform growth of the inner core. This suggests that heterogeneous component of the inner core growth dominates the uniform one if this mechanism actually operates in the core of the Earth, However, almost numerical simulations of geodynamo performed so far assume homogeneous buoyancy condition at ICB. In this study, we investigate the characteristics of outer core flows and dynamo action when the inner core grows heterogeneously. By performing numerical experiments of MHD rotating spherical dynamo, the effects of heterogeneous buoyancy condition at ICB are examined, as well as those of the rotation of the inner core. The governing equations of the numerical model is those for MHD Boussinesq fluid. The radius ratio of the inner and outer spherical boundaries is fixed to 0.35, the Ekman number is 1e-4, compositional and magnetic Prandtl numbers are 1, the modified Rayleigh number is 0.075. The compositional boundary conditions at ICB is
either uniform or Y_1^1 spherical harmonics type. The inner core either co-rotates with the mantle, rotates faster than the mantle, or slower. The results of time integrations show that the magnetic field is maintained when the inner core is co-rotating while it decays when the inner core is rotating faster or slower than the mantle. The obtained the magnetic field is dipolar in the case of uniform compositional boundary condition, whereas the magnetic field localizes in the case of Y_1^1 type ICB condition.

Earthquake Research Institute, University of Tokyo

The upper inner core of the Earth has quasi-hemispherical heterogeneity [Tanaka and Hamaguchi, JGR 1997]. A region that occupies a smaller area, called as 'East', has higher P-wave velocity and attenuation and smaller anisotropy compared with the rest, which is called as 'West'. To determine the boundary between these two regions at high latitudes, we analyze waveforms from Central America earthquakes observed at temporal broadband seismic network in Thailand (Thai Seismic Array; TSAR) [Tanaka et al., *Bull. Earthq. Res. Inst. Univ. Tokyo*, 2019]. Rays from C. America earthquakes to the network pass in the inner core, and have their turning points near 180˚E in the north polar region, which is close to the supposed boundary by several seismic studies. We pick differential traveltimes between PKPbc, which turn in the lower outer core, and PKIKP, which turn in the inner core, on the waveforms, and obtain differential residuals relative to ray-theoretical values predicted by PREM. The observed residuals are compared with those for global models and regional inner core models which represent 'East', 'West', and the South Pole. The residuals are also compared with residuals of South America earthquakes observed in Japan, which sample the 'western' upper inner core.

Deformation experiments of lower mantle minerals using D111 type press

*Noriyoshi Tsujino[1], Daisuke Yamazaki[1], Yu Nishihara[2]

1. Institute for Planetary Materials, Okayama University, 2. GRC, Ehime University

One dimensional viscosity models of the Earth’s mantle proposed by geophysical observations suggested that the lower mantle had the largest viscosity in the Earth’s mantle. In order to understand mantle dynamics in the Earth’s interior, it is important to know the viscosity of the Earth’s lower mantle. However, there are large variations of viscosity in the lower mantle between suggested models because of limitation of locations for geophysical observations. Therefore, it is important to determine viscosity of lower mantle minerals by high pressure experiments in order to discuss mantle dynamics. Bridgmanite would be the most abundant mineral in the lower mantle. This mineral could dominate the lower mantle viscosity at low strain conditions. In addition, ferropericlase, which would be the second abundant mineral in lower mantle and considered to softer than bridgmanite, might dominate the lower mantle viscosity with large shear strain condition. In this study, we conducted in-situ stress-strain measurements of uniaxial deformation experiments of bridgmanite aggregate and shear deformation experiments of post-spinel phase using D-111 type high pressure apparatus.

In-situ measurements were conducted using MAX III with D111 type guide block at PF-AR NE7A beam line. Mg-pure bridgmanite aggregates and Mg-pure post-spinel phase aggregates, which is bridgmanite and periclase mixture with 1:1 molar ratio, were used as starting material for uniaxial and shear deformations experiments, respectively. Experimental conditions are 1473-1673 K and 24-27 GPa. WC second cubic anvils with cone (6°) to take 2D X-ray diffraction, was used along X-ray path. Largest strain ε of uniaxial deformation experiments of bridgmanite reached approximately 0.3. We changed strain rate and/or temperature conditions within one uniaxial deformation experiment to determine stress-strain relationship and temperature effect precisely, respectively. Based on obtained stress exponent n and activation enthalpy H^* in this study, dominant deformation mechanisms would be dislocation creep. At normalized strain (10^{-5} /s), the creep strength of bridgmanite in this study is the largest in constituent mantle minerals reported by D-DAI apparatus. At shear deformation experiments, maximum shear strain reached around 1, which was much larger than the strain at which the hint of strain weakening of bridgmanite was observed in Girard et al. (2016) while stress of bridgmanite were almost constant until maximum strain. The obvious stress weakening of bridgmanite was not observed until shear strain ~ 1 in this study.

Chromium isotopes of basalts from the Ontong Java Plateau and Samoan Ocean Islands: Implications for the core-mantle interaction

*Yuki Hibiya[1], Tsuyoshi Iizuka[2], Katsuhiko Suzuki[1], Shigekazu Yoneda[3]

1. Japan Agency for Marine-Earth Science and Technology, 2. The University of Tokyo, 3. National Museum of Nature and Science

Introduction: Basaltic rocks from large igneous provinces (LIPs) and from ocean islands (OIBs) are thought to be derived from the deep-rooted mantle upwelling. Recent studies have shown that some of these rocks, including OIBs from Samoa and Hawaii, are characterized by ^{182}W deficits that are well resolved from the ambient upper mantle [1, 2]. This negative ^{182}W signature has recently been proposed to originate from the outer core which has a μ^{182}W of −220 [3-5]. If so, the ^{182}W anomaly may be accompanied by deficits of ^{53}Cr, a decay product of a short-lived radionuclide ^{53}Mn, because Cr is more siderophile than Mn at high temperature [6, 7]. However, the Cr isotope variations of LIPs and OIBs are still poorly known. Here, we report the mass independent Cr isotopic data for basaltic rocks from the Ontong Java plateau (OJP) and Samoan OIBs, to further examine the core-mantle interaction that can cause the systematic isotopic variability between LIPs and OIBs.

Results & Discussion: We prepared OJP drill core samples provided by the Ocean Drilling Program and basalt samples from the Samoan Island of Tutuila. The chemical separation and purification of Cr from the samples were made following the procedure described by [8]. The recoveries of Cr were 90-100% for all samples. We have measured Cr stable isotope compositions of the samples processed through the separation scheme by thermal ionization mass spectrometry (TIMS). The external reproducibilities achieved here were ±5 ppm and ±11 ppm for ^{53}Cr and ^{54}Cr, which are markedly smaller than isotope variation among planetary materials (^{53}Cr ~1 ε ; ^{54}Cr ~2 ε). The Cr isotope analyses so far yielded ε^{53}Cr = 0.03 ±0.05, ε^{54}Cr = 0.02 ±0.10 (2SE) for the OJP basalts, and ε^{53}Cr = 0.03 ±0.05, ε^{54}Cr = −0.03 ±0.11 ~ 0.05 ±0.11 for the Samoan basalts. The results for both the OJP and Samoan basalts reveal that there is no resolvable $^{53, 54}$Cr excess or deficit in their source. Our results suggest that there' s no systematical contribution to Cr isotope signatures in the source of OJP and Samoan islands from the material with the anomalous Cr isotope compositions. Therefore, the chemical interaction between the core and the LIPs and OIBs sources is not detectable in terms of the Cr isotopes. This implies that, unlike W, the difference in the Cr concentrations of the core and the mantle might not be so large, or that Cr in the core does not necessarily diffuse in the mantle.

The tungsten isotopic compositions of kimberlites: constraints on material circulation in the deep Earth

*Otaro Kobayashi[1], Tsuyoshi Iizuka[1], Hatsuki Enomoto[1]

1. Department of Earth and Planetary Science, Graduate School of Science, The University of Tokyo

The short-lived ^{182}Hf-^{182}W isotopic system (^{182}Hf $\rightarrow$ ^{182}W + β -) has been widely used to probe early differentiation events (*e.g.*metal-silicate segregation and silicate differentiation). Since ^{182}Hf has a short half-life of 8.9 Myr (Vockenhuber *et al.*, 2004), it decayed into ^{182}W during the first 60 Myr of the solar system's history. Given that W is moderately siderophile, it preferentially partitioned into the Earth's core during its segregation. Hf, in contrast, is lithophile and is retained in the silicate portion of the Earth. As a result, the ^{182}W/^{184}W ratio of the Earth's core is estimated to be ~220 ppm lower than the terrestrial mantle (Touboul *et al.*, 2012). In addition, early silicate differentiation could have also created the variation in ^{182}W/^{184}W ratios. Since W is more incompatible than Hf, an "early depleted reservoir" may have an excess in ^{182}W and, in contrast, its complementary "early enriched reservoir" (EER) may have a deficit in that value.

Mundl *et al.* (Mundl *et al.*, 2017) reported negative μ^{182}W (deviations in ppm from the ^{182}W/^{184}W isotopic composition of the terrestrial standard) values in oceanic island basalts (OIB) which negatively correlate with ^{3}He/^{4}He. This result suggests that there exist early-differentiated reservoirs in the present-day deep mantle, since OIB are considered to have their sources in the lower mantle. Several processes have been proposed to explain the deficits in ^{182}W, for example, core-mantle interaction and the contribution from the EER. However, none of the hypothesis can satisfy geochemical constraints. This study provides new constraints on this issue by investigating plume-derived rocks, kimberlites.

In this study, we performed ^{182}W isotope analysis of kimberlites from South Africa, China and Brazil with MC-ICP-MS (*Thermo Fisher Scientific* Neptune Plus). Kimberlites are ultrabasic rocks that are presumed to have their origin deep in the Earth like OIB. On the other hand, globally distributed kimberlites have relatively undifferentiated isotopic compositions close to those of bulk silicate Earth (BSE), whereas OIB have relatively differentiated values. From these results, kimberlites are considered to originate from an isotopically primordial reservoir like the Earth's primitive mantle (Woodhead *et al.*, 2019).

All measured ^{182}W/^{184}W values of kimberlites were within analytical error of a terrestrial standard, which is considered to have the value of the modern accessible mantle. The present result indicates that the depletion of the present-day upper mantle in incompatible elements has occurred after ^{182}Hf was no longer extant, as there is no difference in ^{182}W values between the primordial mantle and the already depleted mantle. In addition, given that OIB show μ^{182}W negative anomalies (Mundl *et al.*, 2017), whereas kimberlites didn't show any anomalies, the source mantle of OIB is considered to be more strongly affected by the core-mantle interaction or the EER than that of kimberlites.

In situ X-ray and neutron diffraction studies of hcp iron hydride

*Sho Kakizawa[1,2], Hiroyuki Kagi[2], Chikara Shito[2], Hiroyuki Saitoh[3], Yuji Higo[4], Yoshinori Tange[4], Asami Sano-Furukawa[5], Takanori Hattori[5], Katsutoshi Aoki[2]

1. Hiroshima University, 2. Geochemical Research Center, The University of Tokyo, 3. National Institutes for Quantum Radiological Science and Technology, 4. Japan Synchrotron Radiation Research Institute, 5. J-PARC center, Japan Atomic Energy Agency

The internal structure of the Earth can be divided into a” rock mantle” and a “metallic iron core”. The mantle is mainly composed of silicate minerals, but experimental studies suggested the presence of metallic iron in the Earth’s mantle [e.g., Frost et al., 2004; Rohrbach et al., 2007]. Metallic iron has been discovered as an inclusion in diamond and peridotite originating from the deep Earth [Jones et al., 2008; Ishimura et al., 2009]. Therefore, considering that there is a metallic core below the mantle, metallic iron exists all over the deep Earth. In addition, one of the major features of the Earth is the presence of water. Water is thought to exist not only as surface seawater but also as OH ions in the deep Earth minerals. Hydrogen can be partition into metallic iron than silicate minerals [e.g., Shibasaki et al., 2009]. Therefore, it is expected that metallic iron existing the deep Earth is hydrogenated.

The phase diagram changes abruptly when pure metallic iron is hydrogenated. In the case of pure metallic iron, fcc (face-centered cubic) or hcp (hexagonal closed packing) phase can be present under deep Earth conditions. On the other hand, fcc or dhcp (double hexagonal close packing) phase appear in the case of iron hydride. The hcp phase of iron hydride is a metastable phase. Conventional phase diagram of iron hydride has been determined only in experiments under hydrogen saturated conditions. However, our recent studies have revealed that hcp iron hydride is stable under low-concentration hydrogen condition [e.g., Machida et al., 2019]. Therefore, experiments under low-concentration hydrogen condition are important to discuss iron hydride under the deep Earth.

We conducted in-situ neutron diffraction experiments under high pressure and high temperature at J-PARC MLF BL11 to determine hydrogen-induced volume expansion coefficient of hcp-FeD_x. Deuterated Ammonia borane (ND_3BD_3) was used as hydrogen source This material decomposed to D_2 and BN at high pressure and high temperature conditions. The experimental conditions were 10-12 GPa, 300-900 K. Hydrogen content was controlled to D/Fe = 0.45. In addition, we conducted in-situ X-ray diffraction experiment under high pressure and high temperature at SPring-8 BL04B1 and BL14B1 to determine P-T-x phase diagram, especially maximum hydrogen content of hcp-FeH_x at a high pressure and high temperature condition. The experimental conditions were 3-16 GPa, 300-1100 K. Hydrogen content was controlled to D/Fe =0.5-0.8.

In the in-situ X-ray experiments, we observed coexistence of hcp and fcc-FeH_x. The hydrogen content is x = 0.4 and 0.7 for hcp and fcc-FeH_x at 15 GPa and 700 K, respectively. There is an immiscibility gap between hcp and fcc-FeH_x. In this presentation, we will discuss hcp iron hydride based on the results of neutron diffraction experiments.

Ab initio lattice thermal conductivity of (Mg,Fe)O ferropericlase at the deepest mantle

*Haruhiko Dekura[1], Taku Tsuchiya[1]

1. Geodynamics Research Center, Ehime University

Determination of lattice thermal conductivity (κ_{lat}) of lower mantle (LM) minerals is a key to understanding the dynamics and evolution of the earth’ s deep interior. (Mg, Fe)O Ferropericlase (Fp) is believed to be the second most abundant LM mineral after (Fe, Al) bearing $MgSiO_3$ bridgmanite and postpervskite (PPv). Recent experimental and theoretical studies under LM pressures showed that κ_{lat}) of MgO is substantially reduced by Fe incorporation (Ohta *et al.*, 2017; Hsieh *et al.*, 2018; Song *et al.*, 2019). However, the temperature condition is limited to a low temperature of 300 K, which is far from the actual LM condition. Therefore, the role of FP on the heat transport at the deepest mantle is still poorly understood. In this study, we determined κ_{lat} of FP at the LM pressure and temperature conditions, based on the *ab initio* anharmonic lattice dynamics techniques with fully solving the phonon Boltzmann transport equation (Dekura and Tsuchiya, 2017; 2019) combined with the internally consistent LDA+*U* technique for more precisely describing the Fe-O bond (Wang *et al.*, 2015). Calculations demonstrate strong negative solid solution effects (~-70-80% for ~13-19 mol% FeO) of low-spin Fe on κ_{lat} of MgO owing to decreases both in phonon group velocity and lifetime. An effective κ_{lat} of the lowermost mantle is then estimated for pyrolytic aggregate (FP+PPv) with pyrolytic ratio to be ~4 $Wm^{-1}K^{-1}$, which produces a net heat flow from the core to mantle ~6-7 TW. This value is more than ~50% smaller than that estimated from the core with high thermal conductivity of iron (~15 TW). This discrepancy could be reconciled by the thermally or chemically stratified layer at the top of the outer core observed seismologically (Helffrich and Kaneshima, 2010) if subadiabatic temperature gradient exists there.

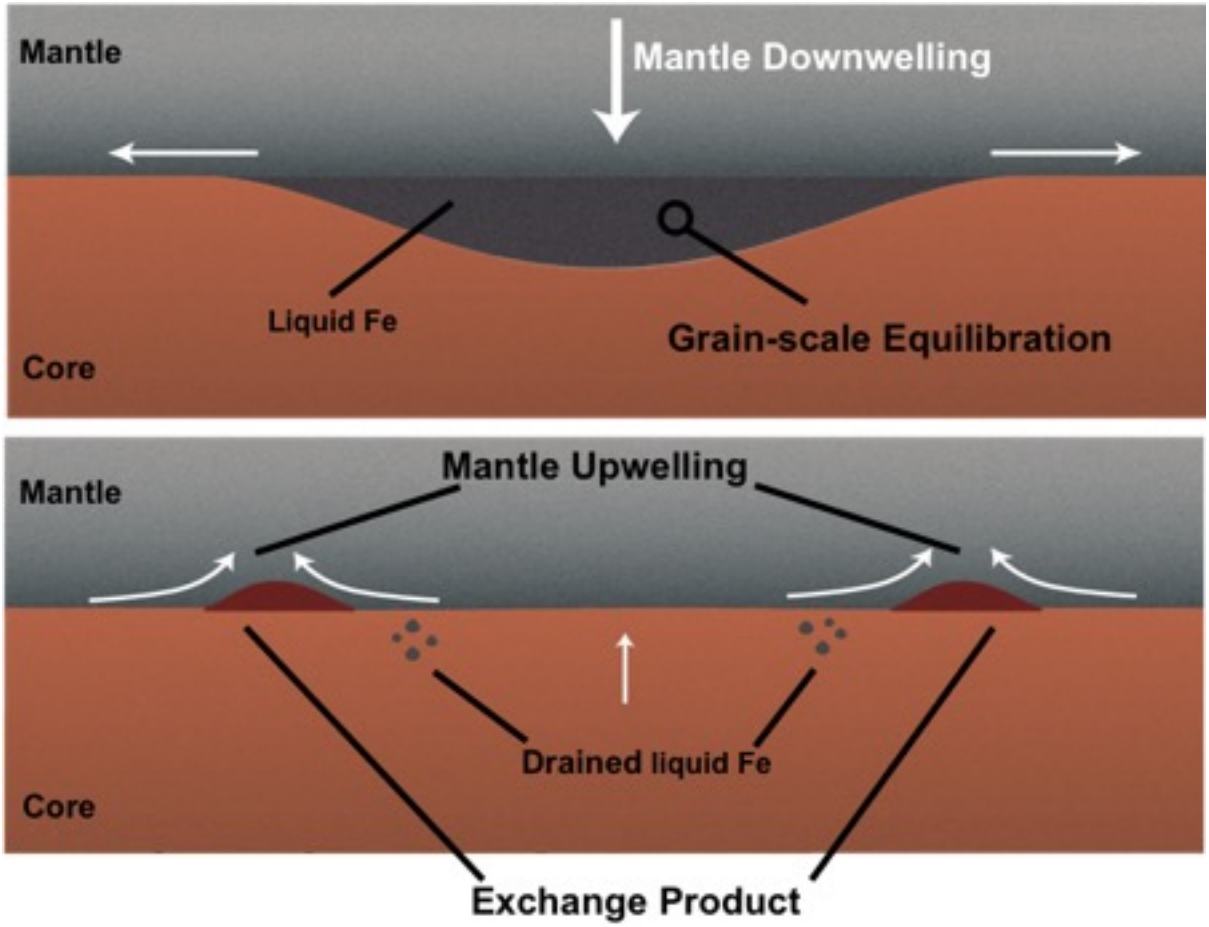
Soft Core-Mantle Boundary: A Mechanism for Chemical Interactions Between the Core and Mantle



*Kang Wei Lim[1], Irene Bonati[1], Scott D Hull[2], John W Hernlund[1]

1. Earth-Life Science Institute, Tokyo Institute of Technology, 2. Earth and Environmental Sciences, University of Rochester

A recent study measuring global isotopic compositions in ocean island basalts (OIBs) combined with geochemical mixing models suggested that to explain the negative correlations between μ^{182}W values with $^{3}He/^{4}He$ values, there should be at least three mantle reservoirs present, two of which are primordial and preserved in the deep mantle. One of the primordial mantle reservoirs is hypothesized to contain material at the core-mantle boundary (CMB) that is chemically and isotopically equilibrated with the core, such that it records core-like isotopic signatures. Although there have been discussions on the possibility of core metal being entrained in mantle material, there is a lack of evidence of correlated enrichment in siderophile elements in OIBs. This raises doubts as to whether the unique isotopic signatures are a manifestation of interactions between the core and lowermost mantle. We propose a mechanism involving metal intrusion to explain how it is possible for mantle rock to obtain core-like isotopic signatures without the presence of metal itself: In the vicinity of mantle downwellings, deviatoric stresses at the CMB deform the boundary to produce a dynamic topography that depresses into the liquid core. At the high pressure-temperature conditions, the metal intrudes between the solid grains and “wets” the grain boundaries. Combining with the excess fluid pressure head induced in topographic lows, this drives intrusion of metal into the basal mantle rock. The intrusion of metal rheologically weakens the metal-rock mixture, promoting lateral gravitational spreading which draws additional material downwards. This enhances the circulation into the mixed layer and “softens” the lower boundary condition for mantle convection. During lateral spreading, liquid metal is squeezed out of pore spaces due to viscous compaction and falls back into the core. This can allow dense, reacted rocks to accumulate away from downwelling flows that contain isotopic signatures from the core without any trace of siderophile elements. As a first order approximation, we assume that the infiltration of metal into submerged rock occurs on timescales much shorter than the residence time of mantle rocks at the CMB, and the subsequent compaction of the mixture and expulsion of metal occurs on similarly short timescales. Next, we assume that the intruded layer is sufficiently thin such that the thin-layer approximation for a viscous fluid can be applied. To obtain a rough idea of the dynamics involving the rock-metal mixture, we incorporate the thin-layer approximation at regions with negative dynamic topography in a numerically simulated 2D Cartesian mantle convection model. This model assumes that the mantle is an isoviscous, incompressible, Boussinesq fluid. The addition of the thin layer at the CMB generates a boundary-driven flow which superimposes on the buoyancy-driven one in the mantle. Initial results show that the viscosity contrast between the submerged layer and reference mantle has a significant effect on which flows dominate: for the thin layer at sufficiently low viscosities, the boundary-driven flows dominate the dynamics and impede the movement of downwellings. This is accompanied by the increase in temperature of the mantle from the bottom-up as the secondary flow field spreads warm material from the CMB towards the top, thereby reducing the heat flux through the CMB. In addition, we observe that as Rayleigh number increases, the average amplitude of the dynamic topography and gain (the ratio between the flux of material into the layer due to the boundary-driven flow to that of the buoyancy-driven one) decreases.

Electrical conductivity measurement of water-bearing bridgmanite using an externally heated diamond anvil cell

*Yoshiyuki Okuda[1], Kenji Ohta[1], Yu Nishihara[2], Hiroyuki Kagi[3], Kei Hirose[3,4]

1. Tokyo Institute of Technology, 2. Ehime University, 3. University of Toyko, 4. Earth-Life Science Institute

The presence of water strongly affects the structure, phase relation and physical properties of the Earth's deep mantle minerals (Chen et al., 2020; Chang et al., 2017). Since electrical conductivity is sensitive to the water content of minerals, the electrical conductivity inferred from the analysis of electromagnetic induction brings the spatial distribution of water in the Earth's interior. Previous studies have estimated the actual water content of the Earth's upper mantle and the mantle transition zones by comparing the geophysically inferred electrical conductivity with the experimentally measured water content dependence of the electrical conductivity of mantle minerals (e.g., Karato, 2011). However, so far, the water content dependence of the electrical conductivity of lower mantle minerals have never been reported. Bridgmanite is the most abundant mineral in the Earth's lower mantle. Its water solubility is yet controversial, which varies from 5~4000 ppm (Litasov et al., 2003; Murakami et al., 2002), implying that studies on water solubility of bridgmanite is not sufficient to constrain the actual water distribution in the lower mantle. Here we measured the electrical conductivity of $Mg_{0.88}Fe_{0.14}Al_{0.11}Si_{0.91}O_3$ bridgmanite containing 500 ppm H_2O at high *P-T* conditions using an externally heated diamond anvil cell. We used a quasi-four terminal method for electrical conductivity measurements. Water content of our sample was estimated by Fourier transform infrared spectrometer (FTIR). From our results, we will discuss the water content of the Earth's lower mantle.

Mechanisms of the post-perovskite transformation in $NaNiF_3$

Koyumi Yamashita[1], *Tomoaki Kubo[1], Yoshinori Tange[2], Yuji Higo[2]

1. Kyushu Univ., 2. JASRI

Strong seismic anisotropy has been observed in the D" layer at the bottom of the lower mantle. This is possibly attributed to lattice preferred orientation (LPO) of bridgmanite (pv) and/or post-perovskite phase (ppv) induced by mantle flow, however their interpretations are still under debate. In particular, the ppv transformation exhibits topotaxy (having crystallographic relationship between pv and ppv) at least a certain condition in analogue material ($NaNiF_3$), which may cause LPO transition, and thus should be considered when interpreting seismic anisotropy (Dobson et al., 2013). However, topotaxy in the ppv transformation has been found in the single crystalline sample only at large overpressure and low temperature condition that is far from the equilibrium boundary. It is likely that the transformation proceeds near the equilibrium boundary in the D" region, where incoherent grain-boundary nucleation and growth mechanism may be dominant without topotaxy. In this study, we conducted the ppv transformation experiments in polycrystalline $NaNiF_3$ to investigate the dominant transformation mechanisms in the D" layer.

The starting material is equi-granular polycrystalline $NaNiF_3$ pv (~5-10 μm grain size) that was synthesized from a powder mixture of NiF_2 and NaF at 2 GPa and 750-800℃ for 40-60 min using a DIA-type high-pressure apparatus (MAX 90D) at Kyushu University. Transformation experiments were carried out by using Kawai-type high-pressure apparatus with the quenching method at Kyushu University (QDES) and with in-situ X-ray observation method at BL04B1 of SPring-8 (SPEED 1500). In the latter case, the phase transition was observed by time-resolved X-ray diffraction measurement using the energy dispersive method. Au was used as a pressure marker, and the overpressure (dP) of the phase transition was estimated based on the equilibrium boundary determined by Shirako et al. (2012). Transformation textures in the recovered samples were examined by SEM and EBSD.

In the case of the in-situ X-ray observation, we observed the transformation during the isothermal pressurization (~2.8 GPa/h) at 400˚C, 600˚C, 800˚C, and 1000˚C. The dP needed for the initiation of the transformation drastically increases with decreasing temperature. For example, the transformation started at dP of 1.5 GPa and 1000℃, however it did not occur even at the dP of 15 GPa and 400℃. Dobson et al. (2013) reported the intracrystalline lamellar nucleation of ppv phase in single crystalline pv with having crystallographic relationships at 700℃ and dP of ~9 GPa. Our study demonstrated that the ppv transformation can proceeds at much smaller dP conditions. We observed lamellar textures implying topotaxy in the recovered samples even at such small dP conditions. This is a typical feature for the ppv transition that is not seen in the olivine-spinel and post-garnet transformations. This may suggest that topotaxy generally occurs in the D" region. On the other hand, the lamellar spacing and width drastically increases with decreasing dP. We found that, after the nucleation stage at high T and small dP conditions, the ppv phase largely grow in the a-axis direction outside the parental pv grain, resulting in the formation of large rod-like crystal over the parental grains. The fast growth by rod-like ppv crystals likely occurs by the migration of incoherent interface, which may erase the texture induced by topotaxy.

[S-IT27] Oceanic lithosphere and asthenosphere

convener:Nozomu Takeuchi(Earthquake Research Institute, University of Tokyo), Ban-Yuan Kuo(Institute of Earth Sciences, Academia Sinica), Rob L Evans(Woods Hole Oceanographic Institution), Younghee Kim(Seoul National University)

The oceanic lithosphere/asthenosphere system (LAS) is one of the most fundamental features of plate tectonics. In recent years, the elucidation of the oceanic lithosphere/asthenosphere system has become one of the hot topics in solid earth science. New data from the ocean floor are being extensively obtained under the Pacific Array initiative (http://eri-ndc.eri.u-tokyo.ac.jp/PacificArray/) and others, and a great variety of views are proposed and discussed. In this session, we will discuss on observation technologies, views of the oceanic lithosphere/asthenosphere system, the strategies for interpretation of the observations (including seismic and/or electrical conductivity anisotropy), constraints/ideas on the role and abundance of water/melt in the mantle (including the transition zone), and other related topics for elucidating this enigmatic system. We call for contributions from diverse fields, including but not limited to seismology, magnetotellurics, petrology/mineralogy, dynamical modelling, and mineral physics.

There remain a lot of unresolved problems that limit our understanding of the physical nature of the lithosphere-asthenosphere system (LAS), although nearly 60 years have passed since the concept of plate tectonics was born. In-situ measurement of the physical property distributions in the mantle by seafloor geophysical array observations in all over the age will be one of the keys to reveal these problems, and the Pacific Array concept has been proposed. The Pacific Array has been launched in 2018, by deployments of two seafloor arrays, one by a US group and the other by a Japan-Korea collaboration. In this presentation, the scientific perspective and the observation report of the latter are shown. We selected the oldest part (the mean age of about 170 Ma) of the Pacific Basin for the first deployment of the Pacific Array. In the study area, the seafloor isochron suggested by magnetic lineations is seen to converge to a small triangle which shows the shape of the Pacific plate when it was born in the middle Jurassic. One of the scientific purposes of this Oldest array is to reveal the early evolution of the Pacific LAS by estimating the anisotropic seismic structure from analysis of the BBOBS data. We also intend to examine the relation between the seafloor depths and mantle geotherms that might be recorded in the mantle to answer the long-lasting question why older seafloors are flat.

The deployment cruise was conducted from October 30 to November 9, 2018, by R/V Isabu (Korea Institute of Ocean Science and Technology: KIOST), started from and returned to Guam, USA. 12 sets of broad-band ocean bottom seismometers (BBOBSs) and 7 sets of ocean bottom electro-magnetometers (OBEMs) were deployed in the study area. The recovery cruise was performed between October 26 and November 9, 2019, by using another KIOST’ s R/V Onnuri, with the same route of the deployment. Although the weather and sea condition during the recovery cruise was severe, all BBOBSs and OBEMs were recovered with healthy data, except one BBOBS that was troubled in the deployment with the broadband sensor unit and recorded the DPG data only. Preliminary analysis results both of seismic and electro-magnetic data are individually presented in this meeting by Takehi Isse and Hogyum Kim, respectively.

The Electrical Conductivity Structure of The Oldest Pacific: Preliminary Results from Magnetotelluric Observation Data of Pacific Array, Oldest-1

*Hogyum Kim[1], Kiyoshi Baba[2], Hisashi Utada[2], Sang-Mook Lee[1], Hitoshi Kawakatsu[2], YoungHee Kim[1]

1. School of Earth and Environmental Sciences, Seoul National University, 2. Earthquake Research Institute, The University of Tokyo

With the complex regional history from the creation between Izanagi-Farallon-Phoenix plates system to the oldest crust of the Pacific over 180 Ma, the west Pacific basin between Northern Mariana, Marshall Islands, and Micronesia has been considered as an ideal place to study the anisotropy structure related with the crustal evolution and the thermal history of oceanic lithosphere-asthenosphere system (LAS). As an element of the international collaboration Pacific Array project, which aims to deploy “array of arrays” over the entire Pacific, a joint research group of Japan-Korea scientists conducted in-situ ocean bottom geophysical observation of the Oldest-1 region for a year from 2018 to 2019. 12 ocean bottom seismometers and 7 ocean bottom electromagnetometers (OBEMs) provided by Earthquake Research Institute, The University of Tokyo, has been deployed and recovered on vessels (RV Isabu and RV Onnuri, respectively) of Korea Institute of Ocean Science and Technology (KIOST).

Here we report the preliminary analysis of magnetotelluric data from 7 OBEMs of the Oldest-1 array. After the initial processing to correct anomalous peaks in time series, shift of internal clocks, and the effect from bathymetry/land-sea distribution, we estimated a 1-D regional mean profile of electrical conductivity. In the context of the thermal evolution process of oceanic LAS, the 1-D electrical structure represents the oldest end member of the Pacific basin.

P Velocity Heterogeneities in the Upper Mantle beneath the Northwestern Pacific

*Nozomu Takeuchi[1], Hitoshi Kawakatsu[1], Hajime Shiobara[1], Takehi Isse[1], Hiroko Sugioka[2], Aki Ito[3], Hisashi Utada[1]

We previously conducted waveform inversion of P waveforms recorded by our BroadBand Ocean Bottom Seismometers (BBOBSs) deployed in the Northwestern Pacific. We could reveal the depth profile of the P velocity of the oceanic upper mantle, which has not been well resolved by previous surface wave or receiver function analysis. The resulting P model shows higher and lower velocities in the lithosphere and the asthenosphere, respectively, and the velocity contrast was approximately 2/3 of that in the previous S models. However, the observed waveforms appear to show regional variations, and the validity to discuss using 1-D models was not very clear.

In this study, we investigated to reveal regional variations of P structures within the Northwestern Pacific. We defined two data bins so that the raypaths belonging to each bin sample similar regions with similar azimuths. The observed waveforms of each bin are coherent, which shows plausibility to compare obtained 1-D models. The preliminary results showed significant differences both in the lithosphere and the asthenosphere. The observed differences in the lithosphere (~4%) are consistent to the azimuthal anisotropy in the uppermost mantle reported by previous exploration studies. However, the differences in the asthenosphere (~2%) are unlikely to be explained by azimuthal anisotropy by olivine LPO because the angles to the plate motion direction are similar. This may suggest some mechanism to produce larger-scale (~1000 km) lateral heterogeneities in the asthenosphere.

Seismic velocity structure beneath the oldest region of the Pacific ocean basin from multiscale finite-frequency traveltime tomography

*Hyunsun Kang[1], Younghee Kim[1], Shu-Huei Hung[2], Pei-Ying Patty Lin[3], Takehi Isse[4], Hajime Shiobara[4], Hitoshi Kawakatsu[4], Sang-Mook Lee[1], Hisashi Utada[4], Nozomu Takeuchi[4]

1. Seoul National University, 2. National Taiwan University, 3. National Taiwan Normal University, 4. Earthquake Research Institute, The University of Tokyo

The 12 broadband ocean-bottom seismometers (BBOBS) and 7 electro-magnetometers (OBEM) were deployed in Oct-Nov 2018 for a duration of 12 months on the 7˚x7˚ area of the oldest (~170 Ma) Pacific basin, where the mantle structure below is poorly constrained (Becker et al., 2014). This experiment (Pacific Array) was conducted as a collaboration between South Korea and Japan to investigate an early evolution of the Pacific lithosphere-asthenosphere system. In this study, we perform multiscale finite-frequency traveltime tomography to elucidate the lithospheric-scale seismic structure from the 12 BBOBS data. We extract teleseismic waveforms with earthquake magnitudes greater than 5.5 within an epicentral distance of 30-98 degrees from the array, and measure relative traveltime residuals of P waves in high-frequency (8-16 s) and low-frequency (16-32 s) bands by multichannel cross-correlation method (VanDecar and Crosson, 1990). The relative traveltimes measured at the two different frequency bands are sensitive to seismic velocity structures with different length scales and allow better recovery of the velocity perturbations in tomographic models (Hung et al., 2004). We apply data adaptive, multiscale parameterizations based on wavelet transforms, which can account for variability in data coverage and provide a tomographic model with spatial-varying resolutions (Hung et al., 2010). We plan to show preliminary P-wave velocity structure of the upper mantle below the Pacific Array region with the checkerboard resolutions test results to confirm the reliability of the obtained tomographic images.

[S-IT28] Mantle dynamic from thermochemical imaging from observable to numerical modeling

convener:Walid Ben Mansour(Macquarie University), Yosuke Aoki(Earthquake Research Institute, University of Tokyo)

Mantle plays a key role on the present-day topography. If the temperature is one of the key parameters, the chemical composition of the mantle is also very important. In the last 20 years, different approaches tried to bring new information on the thermochemical structure of the mantle. The development of high-performance computational infrastructures (HPCI) and new algorithms to manage the processing of big data brings new opportunities to produce high-resolution images and better understanding of mantle dynamics. This session wishes to bring together contributions from experimental geophysics and computational geochemistry to large scale geodynamics, which are aimed at imaging and modeling thermochemical structure on different time scales. Presentations of new methods combining multiple observations of geophysical and geochemical datasets with regional to global geophysical modeling are particularly encouraged.

[SIT28-P01] Constraints on the composition of LLSVPs from seismic properties of lower mantle minerals

Constraints on the composition of LLSVPs from seismic properties of lower mantle minerals

*Kenny Vilella[1], Thomas Bodin[2], Charles-Edouard Boukare[3], Frederic Deschamps[4], James Badro[5], Maxim Ballmer[6], Yang Li[7]

1. Hokkaido University, 2. Laboratoire de Geologie de Lyon, 3. Ecole Polytechnique Federale de Lausanne, 4. Institute of Earth Sciences, Academia Sinica, 5. Institut de Physique du Globe de Paris, 6. ETH Zurich, 7. Institute of Geology and Geophysics, Chinese Academy of Science

Seismic observations have suggested the presence of two LLSVPs in the lowermost mantle. These two reservoirs are likely to be chemically distinct from the ambient mantle and to influence the dynamics of the whole Earth. Several studies have tried to constrain the compositions explaining their seismic properties with the hope that it may help to identify their formation mechanism. In particular, compositions enriched in iron (10 wt%) and bridgmanite (Bm, 90 vol%) are good candidates. These compositions are somewhat consistent with the reservoirs produced by the solidification of a primitive magma ocean, except that the iron enrichment (>20 wt%) is much larger. Here, we provide a reappraisal of the potential compositions for LLSVPs based on an improved mineralogical model including, for instance, the effect of alumina and spin state transition. We have also investigated systematically the effects of six parameters: FeO and Al_2O_3 content, proportion of $CaSiO_3$ and Bm, oxidation state and temperature contrast between ambient mantle and LLSVPs. From the 81 millions cases studied, only 166 thousands cases may explain the seismic observations. Nevertheless, these successful cases involve a large range of parameters with, for instance, FeO and Al_2O_3 content between 12–28 wt% and 5–19 wt%, respectively. A principal component analysis (PCA) is then applied to our results. The PCA has highlighted two robust results:
(i) the proportion of ferropericlase (Fp) should be low (<6 vol%);
(ii) the formation of Fe^{3+}-bearing Bm is much more favorable than other iron-bearing phases.
Following these results, we have identified two end-member compositions: one Bm-rich and one CaPv-rich. Each end-member can then be associated with various temperature contrasts, although a low temperature contrast (<500 K) is more favorable, and various FeO contents, provided a certain proportion between oxidation state, FeO and Al_2O_3 content is maintained. As a last step, we discussed different scenarios for the formation of LLSVPs. In particular, the solidification of a magma ocean may produce reservoirs with FeO and Al_2O_3 content similar to the ones we found but their proportion of Fp is too large. From a broader perspective, constraints on the mineral proportion of LLSVPs are probably the best to discriminate between different formation mechanisms.

[S-IT29] New perspectives on East Asia geodynamics

convener:Jonny Wu(University of Houston), Asuka Yamaguchi(Atomosphere and Ocean Research Institute, The University of Tokyo), Kyoko Okino(Atmosphere and Ocean Research Institute, The University of Tokyo), Timothy B Byrne(University of Connecticut)

East Asia is one of the most tectonically active regions on Earth and includes the Eurasian continental margin, the western Pacific subduction zones and many of Earth's marginal seas. The region has a long history of subduction, collision, backarc basin opening and closing, and other plate boundary interactions. In recent years, a wide range of new observations have been collected from the land, oceans and Earth interior, including detailed geologic data, zircon age spectra, earthquakes, high resolution crustal to mantle imaging, and Big Data. These new data show the detailed space-time evolution of subduction zones, mountain building, slab stagnation, crustal deformation, continental dynamics, backarc spreading, and other East Asian geodynamics cannot be fully explained by classic theories; new perspectives are needed. Here we seek to share new insights on the geologic history, paleomagnetism, and geophysical character of East Asia since the Paleozoic. We also invite geodynamic models that integrate diverse datasets into a more holistic view of this dynamic environment.

Early Miocene zircon U-Pb ages in the Hidaka Supergroup of the Tomuraushi area, Hokkaido : Ridge subduction or marginal basin magmatism?

*Michiru Inoue[1], Hayato Ueda[1]

1. Department of Geology, Niigata University

Abstract

The Hidaka Supergroup in central Hokkaido has been regarded as a Paleogene accretionary complex. It consists mainly of deformed sedimentary rocks, and is also known to contain MORB lavas and dolerites, which erupted on and intruded in unconsolidated trench sediments (in situ MORB). It has thus been considered to suggest ridge subduction in the Paleogene period. Tomuraushi area is one of the most typical localities of the in situ MORB in the Hidaka Belt. However, limited and indirect age data have been so far available for the age of MORB eruption.

Based on field mapping, we divided the Hidaka Supergroup in the Tomuraushi area into six lithological units in structurally ascending order as unit A (black mudstone), unit B (muddy turbidites), unit C (basalts and dolerites with black mudstones) , unit D (red, green and black mudstone), unit E (sandy turbidites) , and unit F (black mudstone). Successions from units A to C and from D to E are regarded as conformable, and the boundaries between units C and D, and between E and F as reverse faults. Therefore, the Hidaka Supergroup in this area consists of at least three thrust sheets.

We determined detrital zircon U-Pb ages for six samples of sandstone and tuff collected from units B, C, and E. Zircons from each tuff sample shows a single age cluster with weighted mean of 18-20 Ma. Zircon U-Pb ages from sandstone samples showed the youngest clusters about 22-26 Ma.

Based on the results above, sedimentary ages of units B and C is considered as 18-20 Ma, and of unit E younger than 22 Ma. The age of N-MORB eruption is contemporaneous with the unit C deposition in the Early Miocene, significantly younger than the timing of subduction of the Izanagi-Pacific Ridge along the Eurasian margin assumed in 50-60 Ma (Seton et al., 2015; Wu & Wu, 2019). Instead, the ages are coeval with zircon U-Pb ages of granulite facies metamorphism (Usuki et al., 2006) and of MORB-type gabbro (Kemp et al., 2007) in the Hidaka Metamorphic Belt to the south of the Tomuraushi area. Because the Oligocene-Early Miocene Hidaka intrusive and metamorphic events are attributed to back-arc rifting and spreading of the Kuril and Japan basins by these authors, the Tomuraushi in situ MORB could also be formed along with the same events.

Subduction and exhumation history of the early metamorphic rocks of southern Kamuikotan Zone, Hokkaido, Japan.

*Yuki Furukawa[1], Hayato Ueda[1], Megumi Ozawa[2]

1. Niigata University, 2. Asano Taiseikiso Engineering Corporation

The Kamuikotan Zone is a Cretaceous to Paleogene low-temperature and high-pressure metamorphic belt that extends from north to south in the central part of the Sorachi-Yezo belt in Hokkaido. The Iwashimizu Complex in the southern part of the Kamuikotan Belt is considered as a Lower Cretaceous accretionary complex, in which the Pirashuke Unit near the structural top show the oldest metamorphic age in the belt as well as amphibolite blocks in serpentine melanges. It is expected that these rocks tell us the timing, thermal structure, and its temporal change just after the subduction initiation. Therefore, we focus on the Pirashuke Unit and surrounding rocks in the Iwashimizu complex.
In the Shizunai-Niikappu area, the Pirashuke Unit is subdivided into units 1 (basalt), 2 (chart, siliceous mudstone, sandstone), 3 (basalt, chert), 4 (lapilli tuff), and 5 (chert) in structurally ascending order, and the top parts are covered by mid-Cretaceous and younger sediments.
Based on equilibria of pumpellyite (P), actinolite (A), alkali pyroxene (N), epidote (E), and sodic amphibolite (R), rocks in this area are classified into PAN type and PNR type. The PAN type rocks occur in the northeastern and southwestern parts, and also locally in the northwestern parts as a wedge. The PNR type rocks occur as a zone between the PAN type rocks from the northwest to the southeast. The PAN type rocks are considered to lie in the structurally higher horizons than PNR type rocks. The Schreinemarker’ s bundle analysis suggests that the PAN type quilibrium are formed in lower pressure or higher temperature than the PNR type. In the further east (structurally lower), lawsonite-bearing assemblages instead of epidote occurs suggesting lower temperature than both PAN and PNR types.
U-Pb ages were measured for detrital zircons extracted from a sandstone and tuffeceous siliceous mudstone. In the sandstone, the youngest peak peak of ~127 Ma was found in a cluster ranging 120-150 Ma as the older limit of its sedimentary age. Pi-129 zircons showed a single peak with the weihted mean age of 123 Ma as a sedimentary age. Time interval from the sedimentary ages to the metamorphism (~25 km at 125 Ma) for the Pirashuke Unit was no greater than 2 m.y., leading a estimate of the vertical velocity of subduction faster than 10 mm/y. Assuming the minimum slab dip as 45 degrees based on the destance from the Kamuikotan Zone to the eastern margin of the Idonnappu Zone (as the trench site), the subduction velocity of >14 mm/y can also be estimated. The time interval from metamorphism at ~125 Ma to surface erosion with unconformity at 110-105 Ma suggests an exhumation rate of 1–2 mm/y. In the structurally lower Shizunai Unit, vertical subduction rate of ~1 mm/y vertical subduction rate is estimated based on the youngest sedimentary age (~125 Ma) and the metamorphic depth and ages (15-20 km at 110 Ma). The Pirashuke Unit rocks were subducted with a velocity as fast as general plate velocity, while the Shizunai Unit rocks were subducted at a velocity one order of magnitude slower. Therefore, the Pirashuke rocks were probably underplated after subduction together with the slab, while the Shizunai rocks were detached from the slab at shallow levels and then slowly subducted.
Occurrences of higer-temperature PAN-type rocks structurally overlying the PNR type suggest that the hanging-wall wedge mantle was still hot immediately after the subduction initiation. Hornblende cryustals in amphibolite blocks of serpentinite melange in adjacent area are commonly mantled by actinolite and rimmed by sodic amphibole. This zoning can be correlated with the map-scale zonation of PAN and PNR types. Taking occurrences of lawsonite also into account, the subduction zone was probably deastically refrigerated from amphibolite-grade to lawsonite-grade temperatures in a short period contemporaneously with accretionary growth of the Iwashimizu subduction complex.

Examination of hiterland based on clastic rock composition and zircon U-Pb age in the Nikoro Group, Tokoro Belt

*Komei Nara[1], Yuta Akutsu[2], Hayato Ueda[1]

1. Niigata University, 2. Kowa co.Ltd

The Tokoro Belt in eastern Hokkaido consists of accretionary complexes of the Cretaceous Nikoro Group and the Paleogene Yubetsu Group, and the overlying forearc basin sediments of the Late Cretaceous Saroma Group. It is widely accepted that the Tokoro belt rocks were formed along the southern margin of the Sea of Okhotsk. Although the Sea of Okhotsk occupies a large portion of NW Pacific and is important to make a comprehensive oceanic plate reconstruction, component and origin of its submerged crust has not been well understood. In this paper we present clastic composition and detrital zircon age of the Nikoro Group clastic rocks, which were supplied from the crust of the Sea of Okhotsk.
The Nikoro Group consists of basalt, chert, limestone, red mudstone and volcanolithic sandstone. We divided the group in western parts of the belt into clastic-dominant Unit I and basalt-dominant Unit II. Unit I is an imbricate stack of sedimentary sequences from chert to mudstone and sandstone. Unit II is a structural pile dominantly of basalt and chert.
Sandstones in the Nikoro Group are lithic wacke composed of volcanic rock fragments as well as plagioclase and clinopyroxene particles. Both chemical composition of volcanic rock fragments and detrital clinopyroxene suggest clastic supply from a volcanic arc.
Zircons extracted from a trachyte yielded ~152 Ma[u1] age suggesting the age of subducted oceanic crust. Detrital zircons from sandstone range from 80 to 154 Ma. A tonalite lens in sheared red mudstone yielded zircons of ~147 Ma, implying that the adjacent crust was juvenile rather than cratonic.
Precambrian zircons first appear in the Paleocene sandstone of the Yubetsu Group. In the Nikoro Group and Saroma Group sandstones, detrital zircons are quite scarce, and no Paleozoic or Precambrian zircon is so far found.
The clastic composition and detrital zircons ages are in general agreement with dredged volcanic and plutonic rocks from the Sea of Okhotsk floor. Since no zircons older than Jurassic are found, and no dredged rocks older than Triassic has been reported, the Sea of Okhotsk crust probably originated from Mesozoic island arc rather than a continental arc or rifted continental margin.

Zircon U-Pb ages and felsic volcanic clasts in the Lower Cretaceous Rebun Group, Hokkaido

*Nozomu Suzuki[1], yusuke Sugiyama, Hayato Ueda[1]

1. Niigata University

The Rebun - Kabato Belt, is characterized by Early Cretaceous arc volcanic and volcaniclastic rocks. The belt extends to the Harachiyama Formation of NE Honshu (Kitakami Mountains) in the south and Moneron Island offshore Sakhalin in the north. The Rebun –Kabato belt has been assumed to be a clastic source for the Sorachi Group, which comprise an accreted or trapped ocean basin in central Hokkaido. Thus, history and composition of volcanic activity in the Rebun-Kabato Belt is important to reconstruct oceanic plate configuration offshore Japan in the Early Cretaceous. This study examines stratigraphy, age, and clastic composition of the Rebun Group in Rebun Island and discusses on the cryptic basement on which the arc volcanic activity occurred.

We divided the Rebun Group into seven stratigraphic units (J, US1, and UN1 to UN5). The lowermost unit J is composed of thin-bedded volcaniclastic turbidites and massive volcaniclastic conglomerates, The overlying units are composed of volcaniclastic sandstone and conglomerate, and partly with tuff breccia and lapilli tuff. US1 unit consists both of conglomerate and sandstone. UN1, UN3 and UN5 unit are gravelly, and the UN2 and UN4 units are dominated by sandstone.

Bulk-rock silica contents of 26 volcanic clasts were diverse ranging from basaltic andesite to rhyolite, in spite that no felsic rocks have been known to occur in the Rebun Group. All the volcanic clats are subalkaline and tholeiitic. They can be subdivided into high-Ti and low-Ti groups. The high-Ti group show a typical tholeiite trend with evidently increasing TiO2 and FeO along with differentiation. The low-Ti group show increasing SiO2 and decreasing TiO2 and FeO somewhat similar to calc-alkaline rocks. The felsic clasts are metaluminous.

We obtained zircon U-Pb ages from a tuff bed in unit J. Concordant ages ranging from 110-142 Ma shows a skewed peak of probability density suggesting a mixture of two age groups averaging 123 Ma and 136 Ma. The younger and more dominant 123 Ma group is considered to represent the sedimentary age. The older group zircons probably originated either from xenocrysts inherited in the magma chamber or accidental grains involved during eruption and/or transportation. In both cases, the older zircons suggest an age of the host crustal rocks in which the felsic magma developed and erupted.

Occurrences of felsic rock clasts from the lowermost unit of Rebun Group imply that the underlying crust had already been more or less mature until 123 Ma. The crust was probably dominated by juvenile igneous rocks because of metaluminous composition of rhyolites and the absence of old inherited zircons in the tuff. The underlying crust could be oceanic because the belt neighbors the Sorachi-Yezo Belt in the east, where oceanic basalts are also overlain by arc-derived detritus. On the other hand, felsic magma in the Harachiyama Formation as a southern extension of the Rebun –Kabato Belt is considered to have developed within the underlying Jurassic accretionary complex of Eurasian margin, because some rhyolites are peraluminous and contain inherited zircons of Precambrian ages presumably originated from the host sandstone. These contrasting occurrences suggest that the Rebun-Kabato-Harachiyama arc was formed crosscutting previous plate boundary between Eurasia and the Sorachi ocean basin.

Paleozoic accretionary complex in the Khangai-Khentei belt, central Mongolia, and stratigraphy of Devonian chert

*Tomohito Nakano[1], Yukio Isozaki[2], Uyanga Bold[2], Otgonbaatar D[3], Yukiyasu Tsutsumi[4]

1. Department of Earth and Planetary Science, The University of Tokyo, 2. Department of Earth Science and Astronomy, Multi-disciplinary Sciences - General Systems Studies, Graduate School of Arts and Sciences, The University of Tokyo, 3. Institute of Paleontology and Geology, Mongolian Academy of Science, 4. Department of Geology and Paleontology, National Museum of Nature and Science

The Khangay-Khentei belt (KKB) in central Monglia is composed of Devonian-Carboniferous accretionary complexes (ACs), which were formed in one of the convergent plate boundaries within the Paleo-Asian ocean (PAO) between Siberia and North China continental blocks. This belt extends for more than 1200 km in NE-SW and 300 km wide in central Mongolia, of which main distribution is located in the Khangai Mtns. Preliminary researches were sporadically performed for basic mapping, and radiolarian dating. Nonetheless, vast areas still remain unmapped/undated. In order to document the essential characteristics of AC, i.e., ocean plate stratigraphy, we conducted detailed field mapping and sample collection of bedded cherts and sandstones in three areas; i.e., Arvaikheer, Bayankhongor, and the upper reach of the Orkhon River, along the southern margin of the Khangai Mountains. Cherts are for microfossil (radiolarians + conoodnts) dating, whereas sandstones are for U-Pb dating of detrital zircons. We collected 30 samples of chert, and 3 samples of sandstone. This presentation reports the first results of microfossil dating and U-Pb zircon geochronology for these three areas.

Tectono-depositional evolution of the Mio-Pleistocene forearc basin on the Boso Peninsula, central Japan

*Nana Kamiya[1], Yuzuru Yamamoto[2], Masayuki Utsunomiya[3], Feng Zhang[4], Weiren Lin[1]

1. Graduate School of Engineering, Kyoto University, 2. Kobe University, 3. AIST, 4. Nagoya Institute of Technology

The Boso Peninsula, central Japan is located near a plate boundary between North America Plate, Philippine Sea Plate and Pacific Plate. The peninsula consists of accretionary prisms and a forearc basin fills, which indicates it developed with subduction of Sagami Trough. The forearc basin in the Boso Peninsula has developed with plate subduction and has a large-scale geological structure, the Kurotaki Unconformity. Variations of geological structure and lithology involved in the Kurotaki Unconformity has been confirmed, however detail of evolution such as paleotemperature and maximum burial depth are unclear. In this study, geological and engineering analyses were performed to investigate an evolution history of the Mio–Pleistocene forearc basin correlated to the plate subduction in the Boso Peninsula, central Japan.

Integrating the results of the geological, paleo-thermal and consolidation analyses, an evolution history of the Boso forearc basin were suggested. In the western part, major differences above and below the Kurotaki Unconformity were identified in the distributions of geologic bodies and their structures, paleotemperatures, and consolidation characteristics. These variations probably relate to a change in the convergence direction of the Philippine Sea Plate at ~3 Ma. Uplift and erosion of the Miura Group during the formation of the unconformity, and compression parallel to the direction of plate-subduction apparently caused the variations in the attitudes of geologic bodies. In the eastern part, the distribution of the consolidation yield stress appears to indicate that the burial process of the forearc basin occurred regardless of the development of the Kurotaki Unconformity, as ascertained from the patterns of consolidation yield stress for the Kazusa and Miura groups above and below the unconformity, respectively. Vitrinite reflectance corresponding to paleotemperature also shows no break in trend or values across the Kurotaki Unconformity. Because this feature is similar to the characteristics of the consolidation yield stress trend, any difference in vitrinite reflectance across the unconformity is thought to have disappeared because of the burial process. The uninterrupted trends in vitrinite reflectance and consolidation trend in the eastern part between the Miura and the Kazusa groups can be explained by the greater subsidence of the eastern part of the Boso forearc basin compared with the western part since ~2.3 Ma. Considering a possibility that a subsidence and uplift rate around the Boso Peninsula had been dependent on the way of subduction, the investigated variation of evolution between the western and eastern part of the Boso forearc basin contribute to determining the way of subduction.

Preliminary Study on the Crustal Deformation along Sagaing Fault in Myanmar by using GNSS data

*Tha Zin Htet Tin[1,2], Takuya NISHIMURA[3], Manabu Hashimoto[3], Eric Lindsey[4], Myo Thant[2,5]

1. Graduate School of Science, Kyoto University, 2. Department of Geology, University of Yangon, Myanmar, 3. Disaster Prevention Research Institute, Kyoto University, 4. Earth Observatory of Singapore, Nanyang Technological University, Singapore, 5. Myanmar Earthquake Committee

Background

The plate tectonic motion between India, Eurasia, Sunda and Burma plates is responsible for the major geological processes in Myanmar. Among them, earthquakes are important mechanism responsible for geohazards in Myanmar. Currently, relative motion between the India and Sunda plates is about 35 mm/yr (Socquet et al,2006) and the rate of subduction of Indian plate beneath the Burma plate is about 12 - 24 mm/yr (Mallick et al.,2019). Due to this subduction and convergence between the India-Eurasia and Burma plates, fold and thrust belts are developed in the western part of Myanmar. Another major active geological structure in Myanmar is the 1200km long Sagaing Fault, a right-lateral strike slip fault, north-south trending along central Myanmar with slip rate of 18 –20 mm/yr. Most of the major cities in Myanmar, including Yangon, Mandalay, Nay Pyi Taw, Bago, Sagaing, Taungoo, Meiktila, etc., lie near-by and along the Sagaing Fault. Many large earthquakes have struck along this fault, resulting in many hundreds of casualties and significant damages in Myanmar over the past century.

GPS Measurement and Data Processing

A GPS network was constructed under the collaboration between Earth Observatory of Singapore (EOS), Myanmar Earthquake Committee (MEC) and Department of Meteorology and Hydrology, Myanmar (DMH) in Myanmar since 2012. 17 continuous GPS stations were instslled along 3 transect perpendicular to the Sagaing Fault from upper to lower Myanmar. To improve coverage in the Indo- Myanmar (Burma) Ranges in the west and Eastern Highland in the east, additional campaign measurements have been conducted since 2016. We possessed more than 113 campaign stations and 17 continuous stations to enable an estimate of crustal deformation across Myanmar. We estimated site velocities for the 17 permanent stations since 2012 and 41 campaign stations since 2016. We included RINEX data from nearby permanent IGS network stations in our processing to improve the accuracy of site positions and define a consistent reference frame in our research area. Daily coordinate positions for permanent and campaign stations in the International Terrestrial Reference Frame 2014 (ITRF2014) were computed using GIPSY-OASIS ver 6.4 software from Jet Propulsion Laboratory (JPL). Ocean tide loading was calculated using FES2014b model by the Onsala Space Observatory (http://holt.oso.chalmers.se/loading/) with respect to the joint mass center of solid Earth and ocean combined.

Result

We confirmed that the present-day relative motion and the direction of movement between the GNSS stations are consistent with the dextral strike slip of this fault system. The stations on the eastern side of the Sagaing Fault show smaller velocities with respect to the Sunda plate than those on the western side of the Sagaing Fault. The western stations still have significant motion with respect to the India plate. This result implies that the eastern part of Myanmar is generally experiencing less internal deformation than

©2020. Japan Geoscience Union. All Right Reserved.

the western side. The velocities in the Mandalay area show an additional WSW-ward movement due to the effect of clockwise rotation of the Eastern Himalayan Syntaxis from the north.

Evidence for Late Mesozoic intraoceanic subduction offshore NE Asia from mantle convection and geoid models

*Lorenzo Colli[1], Jonny Wu[1], Yi-An Lin[1]

1. University of Houston

The existence of the Izanagi plate is well established both from magnetic lineations and fracture zones in the western Pacific and from tomographic imaging of the deep mantle underneath East Asia. But its spatial extent, position and motion through time remain poorly known.

A common scenario envisages the Izanagi as a large and long-lived plate extending from central Panthalassa to the eastern margin of Eurasia. In this scenario the Izanagi plate is conjugate to the Farallon and Phoenix plates before the inception of the Pacific plate and it subducts continuously beneath East Asia during the Mesozoic (e.g. Müller et al., 2016). But more complex scenarios, entailing the existence of additional plates and subduction zones, have been proposed based on both geologic evidence from the East Asian margin and tomographic images of mantle seismic structure.

Here we explore four kinematic plate motion models of increasing complexity, starting with a maximum-size Izanagi plate and introducing in steps a number of additional plates and intraoceanic subduction zones in accordance with geologic evidence along the East Asian margin. We assimilate these kinematic plate motion models in geodynamic models of global mantle convection in the form of a time-dependent velocity boundary condition at the Earth’ s surface. Their implications for the evolution of mantle structure in East Asia during Mesozoic time up to present-day are presented and discussed, focusing in particular on how well the modeled present-day state can match tomographic images of the mantle and the geoid.

Brittle-Plastic Structures Provide Constraints on the Rapid Exhumation of the Central Range: Taiwan

*Lauren Donati[1], Lindsey Aman[1], Susan Adams[1], Jonathan C Lewis[1]

1. Indiana University of Pennsylvania

Taiwan records some of the highest late Cenozoic exhumation rates in the world as the result of the collision between the Luzon volcanic arc and the passive margin of Eurasia. To understand how such rapid exhumation is accommodated, we focus on late-stage plastic and early brittle structures in river outcrop exposures along the eastern Central Range. We specifically focus on the youngest metamorphic fabric in these outcrops documented as S3, syn-kinematic veins, and crosscutting well developed joint sets. We suggest that veins document the bridge between the plastic and brittle regime, as mm-scale veins are locally cut by S3, while others cross-cut the outcrop. The geometry of these structures shows relative consistency. S3 is a shallow-dipping fabric that is locally well developed in cm- and mm-scale folds of older metamorphic fabrics. The veins and joints mostly strike NW-SE and dip nearly vertically. We focus on the details of these geometries over >100 km along strike, and in strike-normal transects along the Chingsui, Hongye, and Xinwulu/Dalun rivers. We see slight variation in the sub-horizontal orientation of S3 from N to S, with the biggest deviation occurring along the Chingsui River near where high-pressure rocks have been discovered. Joints show small changes in dip angle, however consistency in strike, with again, the greatest change in dip along the Chingsui River. Overall the veins are sub-parallel to the joints and show similar along-strike variations, with one exception in the area of the Chingsui River where the veins show more variation in strike. In the strike-perpendicular transects, S3 shows some variation in orientation, while veins and joints seem to change mostly in dip steepness. The patterns we see in the S3, veins, and joints provide constraints in the plastic-to-brittle transition in 3 dimensions. We suggest that S3, as the oldest structure, records the greatest variation in geometry and this reflects post-S3 processes. Similarly, the younger veins and joints show consistent strike and slight dip variation along strike. We suggest that the veins and joints formed in a uniform stress field and were differentially rotated passively in response to gradients in uplift rate and/or magnitude.

Where are the proto-South China Sea slabs? SE Asian plate tectonics and mantle flow history from global mantle convection modeling

*Yi-An Lin[1], Lorenzo Colli[1], Jonny Wu[1]

1. University of Houston

In this study we explored the contrasted plate tectonic reconstructions proposed for the proto-South China Sea and SE Asia, including Philippine Sea plate tectonics near Japan. We implemented four different end-member plate models into global geodynamic models to test their predicted mantle structure against tomography. All models reproduced the Sunda slabs beneath Peninsular Malaysia, Sumatra and Java and the proto-South China Sea (PSCS) slabs beneath present Palawan, northern Borneo, and offshore Palawan; some models also predicted slabs under the southern South China Sea. PSCS slabs generated from double-sided PSCS subduction and earlier Borneo rotation generated a slightly better fit to tomography but pure southward PSCS subduction was also viable. A smaller Philippine Sea plate (PSP) with a short ~1000 km restored northern slab (i.e. Ryukyu slab) was clearly superior to a very long >3000 km slab. Our preferred model had a smaller PSP overriding a vanished ocean south of Japan; this model produced slab anomalies south of the Ryukyu trench at ~400-800 km depth that best match seismic tomography.

The following plate model variants were assimilated in the geodynamic models: (1) southward vs. double-sided PSCS subduction; (2) early Borneo counterclockwise rotations during the Oligocene to Early Miocene vs. later rotations (mid- to Late Eocene and Early Miocene); (3) a smaller Philippine Sea plate restored with a shorter ~1000 km northern slab vs. a longer >3000 km slab. This study assimilates four different plate models into the numerical model TERRA (Bunge et al., 1998). We digitally re-built in GPlates (Boyden et al., 2011) the implemented the plate models as a set of continuously closing plates in order to generate a global self-consistent velocity field to be assimilated into the convection models. The temperature fields were converted to seismic velocities assuming a Pyrolite composition and equilibrium mineralogy. We quantify the correlation between our geodynamic models and seismic tomography within SE Asia. For the tomography models S40RTS and LLNL-G3Dv-JPS we explicitly accounted for their finite resolution (Ritsema et al., 2011; Simmons et al. 2019).

[E] Poster | S (Solid Earth Sciences)：S-IT Science of the Earth's Interior & Techtonophysics

[S-IT30] Tectonic collision systems in continents and oceans

convener:Ling Bai(ITP Institute of Tibetan Plateau Research, Chinese Academy of Sciences), James Mori(Earthquake Hazards Division, Disaster Prevention Research Institute, Kyoto University), Xiaodong Song(University of Illinois at Urbana-Champaign), Yuzo Ishikawa(The National Institute of Advanced Industrial Science and Technology)

Collisions between continental plates and between continental and oceanic plates resulted in the formation of significant orogen and subduction systems worldwide, including the deepest trough and highest mountain in East Asia. The tectonic structures and seismic hazards associated with the collision processes have long been studied in order to understand fundamental features in these different tectonic environments. We invite contributions from scientists working across various temporal and spatial scales on problems related to lithosphere and mantle dynamics and surface processes for the collision zones. This session will provide a platform to encourage collaborations in all related disciplines, including geomorphology, paleoseismology, structural geology, tectonics, seismology, geodesy, and modeling.

Upper mantle deformation of the Terror Rift and northern Transantarctic Mountains in Antarctica: Insight from P-wave anisotropic tomography

*heng zhang[1]

1. Institute of Tibetan Plateau Research, Chinese Academy of Sciences

A large number of teleseismic travel-time data are used to determine the first P-wave radial anisotropy tomography beneath the Terror rift, the northern Transantarctic Mountains (NTAM) and the Wilkes Subglacial Basin (WSB) in Antarctica. Our results show that variations of radial anisotropy occur in both horizontal and vertical directions. In the NTAM, a high-velocity zone with positive radial anisotropy is revealed at shallower depths, which reflects the lithospheric deformation pattern formed during the Ross Orogeny. In contrast, negative radial anisotropy appears at depths > 200 km under the NTAM, which is caused by the characterization of olivine fabric rather than foundering lithosphere. Beneath the western WSB, a two-layer lithosphere exists that contains rift-induced cracks. To the east of the NTAM, asthenospheric upwelling occurs at shallow depths beneath the Terror rift. Then the upwelling asthenosphere flows northward to Mt. Melbourne and southward to Mt. Erebus.

An Ms6.3 earthquake occurred at Medog County, Nyingchi City, Tibet at Beijing time 04:15 on 24 April 24 2019. This earthquake is located in the northeast corner of the Himalaya orogenic belt where the Indian plate underthrusts beneath the Eurasian plate. Here the crustal shortening and the tectonically rotated deformation is the strongest with respect to other areas along the Himalayan orogenic belt.

Based on the waveforms recorded by the local broadband seismic stations we deployed at the eastern Himalaya syntaxis, and the waveform and traveltime data obtained from Chinese and international seismic networks, we determined the earthquake location, focal mechanism and rupture process.

The resulting epicenter of this earthquake is (94.56±0.01˚E, 28.41±0.01˚N) and the focal depth is 13.3± 1.6 km below the surface (or 11.5±1.6 km beneath the sea level). The focal mechanism solution strike/dip/slip is 202˚/17˚/20˚. The large rupture is mainly concentrated about 5 km to the NNE of the initial rupture area. Combined with other previous geophysical and geological studies, we infer that the earthquake occurred at the rapid turning area where the Main Himalayan thrust suddenly rotated nearly 90˚. The major tectonic feature for this area is the west-dipping subduction and northward thrust of the Sang syntaxis with respect to the Namche Barwa syntaxis.

Crustal and mantle velocity structures of the Sulawesi Island from multi-scale seismic tomography.

*Bagus Adi Wibowo[1,2], Ling Bai[2], Supriyanto Rohadi[1], Muzli -[1], Andry Syaly Sembiring[1], Rahmat Triyono[1], Muhamad Sadly[1], Suko Prayitno Adi[1]

1. Meteorological, Climatological, and Geophysical Agency, Indonesia, 2. ITP Insitute of Tibetan Plateau Research, Chinese Academy of Sciences, China

We did multi-scale seismic tomography in and around the Sulawesi Island, Indonesia, to acquire better seismic velocity structures and to discuss its tectonic implications of the area. We used a regional-scale double-difference tomography method to invert the body wave (P and S-wave) phases of earthquakes from InaTEWS' (Indonesia' s Tsunami Early Warning System) earthquake catalog from 2017 to 2018. The data included some important seismic events occurred in this time period, such as The Palu Earthquake, the West Sulawesi (Mamasa) swarm earthquake and other seismic activity related to tectonic setting among research area.

From Vp and Vs velocity anomalies, we found signs of magmatic activity below volcanoes along the Northern Arm of Sulawesi, the activity of the left-lateral strike-slip fault of Palu-Koro, and signs of upward tectonic activity between lower crust and upper mantle boundary that may have caused the West Sulawesi (Mamasa) earthquake swarm. These findings explained the implication to local tectonic conditions after these significant seismic events and added a more critical understanding of tectonic interaction in lithosphere beneath the Sulawesi Island.

Forearc basin development at the Northern Andes –southern boundary transform fault: Progreso basin, SW Ecuador

*Carlos Alberto Aizprua Luna[1,2,3], Cesar Witt[2]

1. Department of Geosciences and Petroleum, Norwegian University of science and Technology (NTNU), Trondheim, Norway , 2. Univ. Lille, CNRS, Univ. Littoral Côte d’ Opale, UMR 8187, LOG, Laboratoire d’ Océanologie et de Gé osciences, F 59000 Lille, France, 3. Facultad de Ingeniería en Ciencias de la Tierra, Escuela Superior Politécnica del Litoral, Campus Gustavo Galindo –km 30.5 vía perimetral, Guayaquil, Ecuador

It has been recognized that obliquity between convergent plates along active margins results in strain partitioning, both normal and parallel to the trench. Such active margins may develop large scale strike-slip faults that can be prolonged for hundreds of kilometers, commonly located along the volcanic arc, and bounding different forearc crustal slivers. The mechanisms proposed for the development of such large-scale faults have been discussed and well documented in regions such as the western North America, where the accretion of allochthonous terranes may have played a great role in the observed deformation styles. However, less is known along the area linking the large strike-slip faults and the actual trench, and how this may have controlled the forearc tectonic-stratigraphic evolution along the area. Few studies, like the Eocene Tyee forearc basin in Oregon, discuss the formation of sedimentary basins along a plate boundary transform fault, in connection to a system developed along the suture of an allochthonous oceanic terrane accreted to the continental margin. In the Northern Andes, a Late Cretaceous oceanic plateau sliver underlies the forearc region of SW Ecuador, with its southern limit interacting with the continental basement of South America. The great Progreso Basin is located along and across the inferred suture zone, and its study has provided us with an insight on the fault termination styles of large-scaled strike-slip faults, their associated tectonic elements, their link to the trench, and their influence on the stratigraphic record. Based on multi-channel seismic profiles, industrial borehole data, surface exposures, and recent radiometric age results, we attempt to make a paleogeographic reconstruction of the early stages of forearc basin evolution at the southern boundary of the Northern Andes sliver. The geological record of rapid shallowing of the forearc from deep marine deposits into fluvio-deltaic successions by Oligocene time, and restricted conditions of the forearc region through the development of perched extensional sub-basins, suggest a more complex systems than a simple transtensional strike-slip regime at the fault termination area. We suggest that the inherited configuration following the collision and accretion of an oceanic crustal sliver accompanied by the development of a local and thick accretionary wedge by Paleocene time, and the post-Oligocene transtensional regime along the southern boundary transform fault of the North Andean Sliver better explain the observed basin configuration at this region.

Seismic anisotropy in the deep continental upper mantle beneath Tibetan Plateau

*Cheng-Chien Peng[1,2], Ban-Yuan Kuo[2], Eric Debayle[3], Ling-Yun Chiao[1]

1. IONTU Institute of Oceanography National Taiwan University, 2. Institute of Earth Sciences Academia Sinica, 3. Laboratoire de Géologie de Lyon, Université Claude Bernard Lyon 1

Multimode Rayleigh wave tomography (Pandey et al., 2015) shows a depth-dependent azimuthal anisotropy in the Tibetan Plateau which may involve different stress field orientations in the lithosphere and the underlying mantle. The azimuthal anisotropy model could explain some characteristics of SKS splitting, but fails to predict the large delay time in central Tibet, probably owing to the lack of sensitivity of Rayleigh waves in the deep upper mantle. To reconcile the discrepancy in delay time between the model prediction and the SKS data, we search for new anisotropy parameters of the upper mantle layer (200~250 km) of the model to fit the SKS observations. In this process, we fix the upper layers of the Rayleigh model assuming they were well constrained. The best fit result shows that changing orientation slightly (<30˚) and increasing anisotropy intensity to ~10% in the upper mantle layer can improve the SKS data fitting remarkably. Because 10% anisotropy intensity is unlikely within the 50 km thickness layer, we suggest that this anisotropy layer extends to deep upper mantle (>250 km) beneath the Tibetan plateau. This modified region is roughly beneath the north of the Bangong-Nujiang suture zone that coincides with the northern front of the underthrusted Indian lithosphere. The mechanisms that may cause this thick anisotropy layer in the mantle is under investigation.

Shear velocity structure of the crust and lithospheric mantle beneath Taiwan from teleseismic Rayleigh-wave tomography

*Ayush Goyal[1], Shu-Huei Hung[1]

1. Department of Geosciences, National Taiwan University

The interaction of two opposite-verging subduction systems of the Eurasian Plate (EP) and Philippine Sea Plate (PSP) and consequent collision between the Luzon arc of the PSP and Eurasian continental margin resulted in a lithotectonically complex orogen in Taiwan. To reveal its structural complexity associated with the plausible orogenic process and dynamic mechanism, numerous tomographic studies of crustal structures beneath Taiwan and the surrounding region have been conducted extensively. However, the crust-mantle boundary (Moho) and lithospheric mantle structure which potentially provide clues to unravel the tectonic model responsible for the Taiwan orogeny remains less explored. In this study, we analyze vertical-component Rayleigh wave data from teleseismic earthquakes recorded by a totally ~160 broadband on-land and ocean-bottom seismometer stations distributed across Taiwan and offshore islands and at seafloor offshore eastern Taiwan during the years of 2007-2017. A wavelet-based, two-station method that properly characterizes the time-varying spectral properties of earthquake signals is employed to measure dispersive phase velocities or travel times of fundamental-mode Rayleigh waves propagating between station pairs in the periods of 13-81 s. The obtained frequency-dependent traveltimes are then used to invert for a 3-D shear-wave velocity model. The preliminary resulting model indicates that the crust is thickest beneath the mid-western flank of the Western Central Range or Backbone Range Slate Belt and shallowest beneath the Huatung basin (HB) under the oceanic PSP. More detailed and robust features of shear velocity heterogeneities will be explored through the advanced probability inversion technique.

[S-IT31] Planetary cores: Structure, formation, and evolution

convener:Hidenori Terasaki(Faculty of Science, Okayama University), Eiji Ohtani(Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University), Gerd Steinle-Neumann(Bayerisches Geoinstitut, Universitaet Bayreuth), William F McDonough(Department of Earth Science and Research Center for Neutrino Science, Tohoku University, Sendai, Miyagi 980-8578, Japan)

There are fundamental links between the formation and evolution of planets and their satellites to that of their cores both in terms of magnetic field generation and chemical and physical structure. Defining physical and chemical properties of the cores and core materials of these terrestrial bodies are therefore fundamental for understanding their internal structures and thermal profile. Recent advances in experimental and theoretical studies provide new insights into the Earth's cores and other terrestrial bodies, including the role of light elements in the early history of planets and at current times. Recent, current and future space missions have and will continue to obtain data on the internal structure of terrestrial planets (e.g., Mars and Mercury) and planet-satellite systems. We anticipate presentations on recent advances on the physical and chemical properties of cores and discussions regarding the latest views of their formation and evolution. We welcome contributions from mineral/rock physics, geophysics, geochemistry, geodynamics, and planetary science.

The Earth's core has supposed to be constituted by iron-nickel alloys containing about 10% nickel as the main constituent and some light elements. The candidates of light element are sulfur, oxygen, carbon, hydrogen, and silicon. Among them, silicon is one of the most convincing light elements. The structure, physical properties and its chemical compositions of the Earth's core has been discussed with the seismic structure model of the Earth such as preliminary reference Earth model (PREM) based on seismic wave velocity observations. Constraints on the chemical composition of the Earth's core have been discussed by comparing the model with the physical properties of the Fe-Ni-X alloys that are candidates for the composition of the Earth's core. For the physical properties, a sound velocity and a density of materials are directly related to the knowledge obtained from seismic wave velocity observations. Therefore, the information of sound velocity and density for Fe-Ni-X system are important to understand the properties of the Earth's core and to restrict its chemical compositions. However, for the Fi-Ni-Si system, which is considered to be a promising candidate for the constituents of the Earth's core, were not well studied especially high pressure and high temperature conditions.
In this study, we measured the sound velocity and density of the Fi-Ni-Si system under high pressure and high temperature conditions, and discuss the composition of the Earth's core through comparison with the results and PREM.

Surface on Mercury is found to contain 1–4 wt% of sulfur from X-ray spectroscopy of the MESSENGER spacecraft (Nittler et al. 2011). The S content on the surface suggests that certain amounts of S and Si are likely to be contained in the Mercury core based on partitioning of S and Si between metal and silicate melts (Chabot et al. 2014).

In this study, we measured the V_P of liquid Fe–Ni–S–Si up to 17 GPa and investigated the effect of pressure and alloying of S+Si on the V_P to constrain the radius of Mercury core. High pressure experiments were performed using 1500 ton Kawai-type multianvil press at BL04B1 beamline, SPring-8 synchrotron facility. The P-wave velocity was measured using the pulse-echo overlap method.

The V_P of Fe-Ni-S-Si liquids of this study locate in between reported V_P of Fe-Ni-S and Fe-Ni-Si. Thus, there is an offset between S and Si effects on the V_P. Based on the obtained elastic properties of liquid Fe-Ni-S-Si, we estimated the Mercury core radius which satisfies the observed total mass and moment of inertia of Mercury and discuss possible core composition.

Metal-silicate partitioning of carbon at the core formation

*Yutaro Tsutsumi[1], Naoya Sakamoto[2], Kei Hirose[3], Shunpei Yokoo[1], Shoh Tagawa[4], Hisayoshi Yurimoto[5]

1. The University of Tokyo, 2. Creative Research Institution, Hokkaido University, 3. Earth-Life Science Institute, Tokyo Institute of Technology, 4. Department of Earth and Planetary Science, The University of Tokyo, 5. Department of Natural History Sciences, Hokkaido University

Carbon has been considered to be one of the possible major light elements in the Earth’s core. While carbon is known to be strongly siderophile (iron-loving) at relatively low pressures, its metal-silicate partitioning under high pressure and temperature (*P*-*T*) conditions, typical for those of core segregation from silicate (~50 GPa, 3500 K), has been least examined yet. Here we performed melting experiments on Fe metal + MORB glass at such high *P*-*T* conditions in a laser-heated diamond-anvil cell (DAC). The metal-silicate partitioning of carbon was examined by using two different sets of starting materials; carbon was included in Fe in one set of experiments, and it was contained as CO_2 in silicate glass in another set. After melting at high *P*, samples were recovered from a DAC, and their cross sections were prepared with a focused ion beam (FIB). Textural and compositional characterizations were made by electron microprobes. Subsequently carbon concentrations in coexisting molten iron and silicate melt were obtained by using a high-resolution imaging technique with secondary ion mass spectrometry (SIMS). These experimental results and the possible concentration of carbon in the core will be discussed at the meeting.

Thermodynamic analysis of density of Fe-Ni-S melts at high pressure

*Satoru Urakawa[1], Hidenori Terasaki[2], Akihiko Machida[3]

1. Department of Earth Sciences, Okayama University, 2. Department of Earth and Space Science, Osaka University, 3. QST

Density of liquid Fe-alloy is one of the important physical properties to understand dynamics of planetary liquid core. However, we have only limited information on the pressure, temperature and composition dependency of density of liquid Fe-alloy. We have focused on Fe-Ni-S alloy, which are thought to be universally present as core constituents of planets and satellites, and measured their densities at high-temperatures and pressures by X-ray absorption technique. Here we report the results of thermodynamic analysis of the density of liquid Fe-Ni-S alloy. Density (molar volume) of liquid Fe-Ni-S alloy measured at 3 GPa was analyzed by associated solution model assuming the associated compounds, Fe, FeS, NiS and Ni. We evaluated the molar volume and the thermal expansivity of each associated compound as well as the interaction parameters between associated compounds. As a result, we can express the temperature and composition dependence of the density of liquid Fe-Ni-S alloy at 3 GPa. We found a negative excess volume between Fe-FeS and FeS-NiS and a positive excess volume between Ni-NiS. We will also discuss the pressure evolution of the phase relationships of the Fe-FeS.

Possibility of percolation of Fe-S melts in asteroids

*Takumi Miura[1], Hidenori Terasaki[1], Tadashi Kondo[1]

1. Department of Earth and Space Science, Graduate School of Science, Osaka University

Many asteroids and planetesimals have been reported to compose of metallic cores surrounded by silicate mantles (Barrat et al., 2015). Due to negligible accretional heating in asteroids, percolation of liquid iron alloy through solid silicates is likely to be one of the plausible core formation process in asteroids. It is important for understanding asteroid core formation process to clarify whether or not liquid iron alloy percolates through solid silicate matrix. In previous percolation experiments, the dihedral angle between olivine and Fe-S melts is reported to be less than 60˚ below 2-3 GPa depending on olivine composition at oxidized conditions, indicating that the Fe-S melt can percolate through crystalline olivine (Terasaki et al., 2008). To understand core formation process in asteroids, it is important to measure the dihedral angel between Fe-S melts and orthopyroxene (opx) which is one of the major mantle mineral of asteroid as with olivine.

In this study, percolation experiments were performed at 2.5 GPa and 1863 K using cubic multi-anvil devices. Annealing durations range from 15 to 60 min at target temperatures. Starting material was natural opx powder (Fe#=0.29) and Fe-S (S=40, 50 at%). Fe-S layer was set between orthopyroxene layers. Textures of recovered samples were observed using scanning electron microscope. We observed that FeS did not percolate in solid opx, while $Fe_{60}S_{40}$ percolated in opx. In the percolated region, opx was turned into olivine by chemical reaction during experiment. Based on these results (texture, measured dihedral angle, and chemical compositions), we will discuss a possible process of percolation of Fe-S melt in opx solid.

Effect of Isostatic Rebound on Lithosphere in the Discrete Element Method Simulation

*Soojung An[1]

1. Kangwon National University

Mass redistribution of the lithosphere due to imposed or removed loads, so-called isostatic rebound, makes the surface to rise or sink. Loads may consist of continental shelves, ice, large lakes, thrust sheets, sediment, and volcanoes. Until the isostatic equilibrium is reached, the rising or sinking of the lithosphere will continue. When surface settings are being unloaded (i.e., melting of ice, sediment erosion), the new stress would be given continuously at existing fractures, inducing extension of the length of the microfracture. Also, it would trigger an earthquake arisen from stress releases which can induce rock failures suppressed by loads. A lot of numerical analysis method is being used to modeling this problem. Finite element method which considers the model a continuum-based has been widely used to analyze various phenomena of the earth’ s tectonic systems. However, since the finite element method considers the model a continuum-based, when it comes to observing surface extensional fractures on rifting regions along the basins being expanded, it is not suitable enough to study the rock failure mechanism. In this study, we simulated a time-dependent isostatic rebound with brittle failure of surface bedrock due to the removal of loads using DEM (discrete element method). The discrete element method is introduced by Cundall and Strack (1979), which can deal with the complex behavior of the material as a result of interactions between discrete particles. We used the open-source discrete element analysis software package YADE which holds good maintainability and expandability due to command scripting system using python.

[S-IT32] Do plumes exist?

convener:Hidehisa Mashima(Center for Obsidian and Lithic Studies, Meiji University), Gillian R Foulger(Durham University), Dapeng Zhao(Department of Geophysics, Tohoku University)

The debate regarding whether anomalous volcanic areas on Earth's surface are fed by deep-mantle plumes is widely considered to be the most significant debate currently ongoing in Earth science. Not only does the debate touch on a fundamental aspect of how Earth works dynamically, but the subject is extraordinarily cross-disciplinary to an extent that probably few scientists fully realize. Sub-disciplines that can contribute to efforts to resolve the debate include sedimentology, palaeontology, tectonophysics, geochronology, volcanology, petrology, geochemistry, geothermal research, seismology, geodesy, electromagnetics and many others.
In addition to the disciplines of Earth science, the plume debate provides a remarkable and thought-provoking subject for scientific philosophy and reflections on correct scientific methodology: (1) What exactly is a plume? People often change their definition of a plume a posteriori in order to fit their observations. (2) How can the plume- or the plate hypothesis be falsified? (3) Do Earth scientists tend to present only one possible interpretation of their data, or do papers reflect all possible interpretations? Unfortunately, the former is often the case. (4) Are published interpretations consistent with other data from the subject field area? Often they are not, and the inconsistencies are not sufficiently highlighted nor discussed. These issues are particularly useful for inducting students into correct scientific working. In summary, the debate provides enormously fertile ground for new, fundamental questions and cross-disciplinary research.
This session welcomes studies of melting anomalies on Earth from the point of view of any sub-discipline. We also welcome studies of geological phenomena which are attributed to mantle plumes, such as back-arc extension, plate motion, sedimentary basin formation and lithospheric uplift, and any other work that bears on this fascinating and challenging geological debate.

Origin of the Caroline Plateau/Seamount Chain from a short lived mantle plume

*Guoliang Zhang[1,3], Ji Zhang[1,2], Shuai Wang[1,2]

1. Institute of Oceanology, Chinese Academy of Sciences, 2. University of Chinese Academy of Sciences, 3. Center for Ocean Mega-Science, Chinese Academy of Sciences

The genesis of an oceanic plateau bears important information on the mantle dynamics and mantle compositions. The Caroline Rise (or Caroline ridges) has played an important role in the tectonic frame of the western Pacific, however, the nature and origin of the Caroline Rise has long been unclear. In this study we first confirmed that it represents an oceanic plateau formed as a large igneous province based on seafloor sampling program. The Caroline Plateau is connected to the east with the Caroline Seamount Chain that is considered to have been formed by a deep-rooted hotspot. To investigate the mantle source nature of the Caroline Plateau and its genetic relationship with the Caroline Seamount Chain, we age-dated and analyzed the geochemistry (major and trace elements and Sr-Nd-Pb-Hf isotopes) of the basalt samples from the Caroline Plateau. The basalt samples are classified into two groups, the alkali and the tholeiite groups. The results of age-dating indicate older ages for the tholeiite group than the alkali group. Thus, the tholeiite group basalts are apparently older than the Caroline Islands and are close to the basalts of Ontong Java Plateau in trace element patterns. We suggest that the tholeiite group basalts represent the main stage volcanism and the alkali group basalts represent the late stage volcanism of the Caroline Plateau. The alkali group basalts show trace element and isotope compositions similar to those of the Caroline Islands to the east. The tholeiitie group basalts can be formed by mixing between the alkali group basalts and the depleted Caroline plate basalts based on Sr-Nd-Pb-Hf isotope compositions, suggesting involvement of depleted upper mantle components in the mantle source. The MORB-like depleted geochemical nature of the tholeiite group basalts indicates formation of the Caroline Plateau under the thin Caroline plate lithosphere. The Caroline Plateau/Seamount volcanic chain could be explained by the Caroline hotspot based on their formation ages of and tectonic reconstruction. The Caroline Plateau/Islands volcanic system shows increasing alkalinity and Sm/Yb ratio of basalts with time, which implies for decreasing activities of a short-lived mantle plume. This work was financially supported by the National Natural Science Foundation of China (91858206, 41876040).

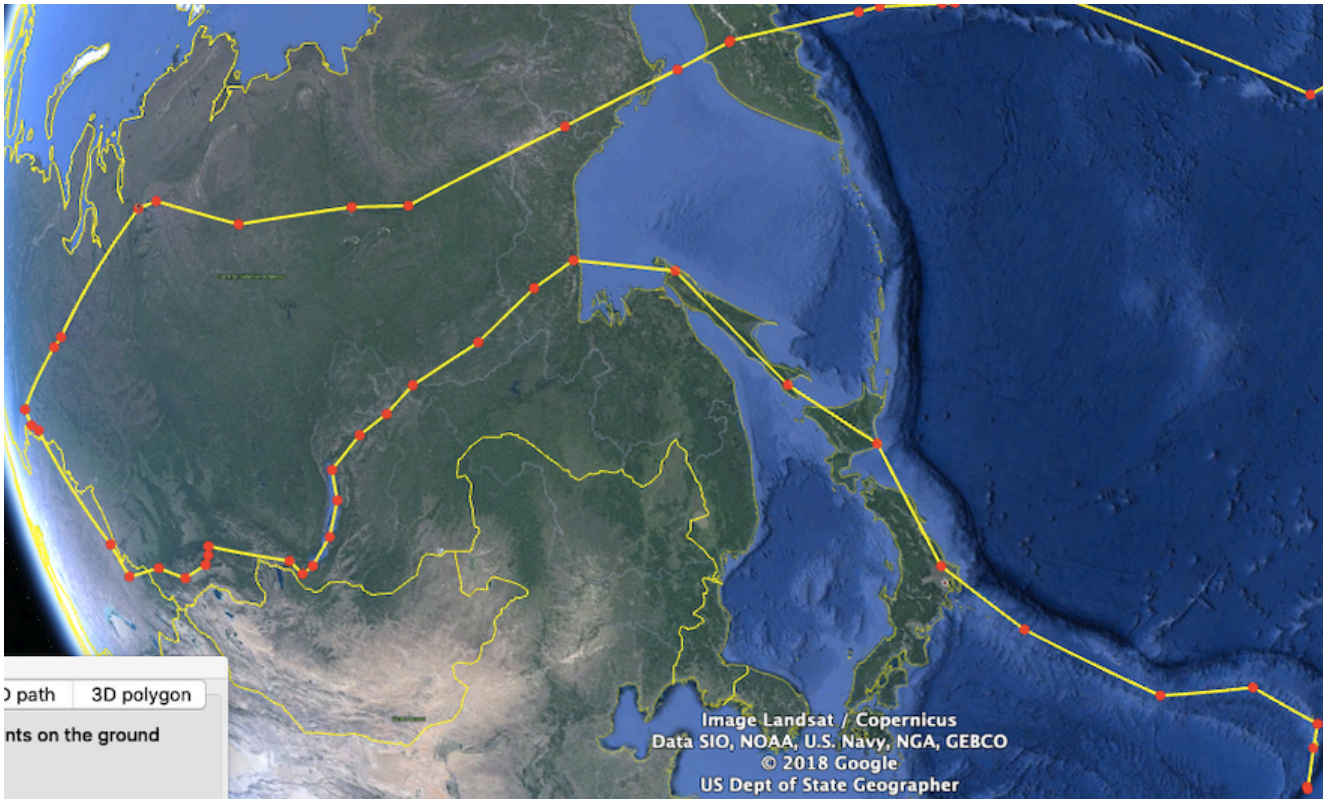
Meteorite Impact Origin of ***Mantle Plumes*** Growing Downward by ***Mantle Depletion of Volatiles*** Not Convection From CMB



*Hermann G. W. Burchard[1]

1. Oklahoma State University

The origin of ***Mantle Plumes*** has remained uncertain until now. Here, we present evidence of ***meteorite impact*** origin, based upon our prime example, the Yellowstone ***hotspot*** and Columbia River Basalt ***large igneous province*** LIP. The hotspot is shallow, only 200 km deep, invalidating a theory of mantle plume origin. The hotspot track runs from the Yellowstone National Park in NW Wyoming, back in time, to the volcanic Modoc Plateau in NE California. We present evidence of apparent remnants of an impact crater existing in the Modoc, a large multi-ring structure at least 160 km diameter. Much of this complex crater has become obliterated by later Cascadia and Sierra orogenies. The crater has a tall 4,100 foot non-igneous central uplift cone, locally known as Chalk Mountain, consisting of diatomaceous earth, presumably the rebound cone of a thin-crust meteorite impact at the Miocene cratonic margin. This falsifies a theoretical prohibition of cosmic impact volcanism. Based on recent insights into explosive volcanism a ***plausible mechanism based upon mantle depletion of dissolved volatiles*** is proposed for how meteorite impacts can lead to resurgent calderas of the Yellowstone type and apparent LIP origin from ***thin crust ET impacts***, invalidating theoretical constructs of mantle plumes. Another example of cardinal importance for planet Earth biosphere endurance and survival is a pair end-Permiian comet impacts in the South Kara Sea and the West Siberian basin, apparently fragments of the same giant comet or Edgeworth–Kuiper belt object. Very possibly other fragments of the same body have impacted at times near the Permo-Triassic transition, as the Emeishan LIP in Sichuan, China. The reason is that comets have a fragile nature, being weakly consolidated by gravitational accretion around metal cores, as seen in the Norilsk nickel mine, exploiting the metal core of the S Kara Sea impactor, analogous to the Sudbury, Ontario astrobleme. A hotspot track results from the initial magma chamber, excavated by teraton or even petaton TNT equivalent impact explosions, with deep mantle pentration by tens of km in thin oceanic crust. Here, the S Kara Sea impact initiated the continental extension of the Emperor-Hawaii sea mount chain, Mt Kilauea atop the remnant hotspot. The analogous W Siberian plane hotspot track exits mainland Asia at Sachalin Island, and continues on through Japan to the Marianas ending at the Challenger Deep, Fig. 1. In this case, unlike the S Kara Sea-Hawaii hotspot track, where the metal core remained in the crust at or near the impact site, the core penetrated the crust completely and sank into the mantle. The great depth of the Challenger Deep is due to the large weight of the metal core mass, still sinking deeper now, as can be seen from the GPS continental drift directions world-wide converging upon the Pacific region near Guam. For a continental impact such as Chicxulub on the Yukatan peninsula, the impact may excavate only to the Moho, with a plutonic ***warmspot*** as the result instead of a volcanic hotspot. The Greater Antilles mark the warmspot track by their granitic basements beneath Tertiary limestones, except in terminal Virgin Gorda, where granite rocks famously form the popular "Baths" at the surface, the warmspot having joined the volcanic arc of the Lesser Antilles.

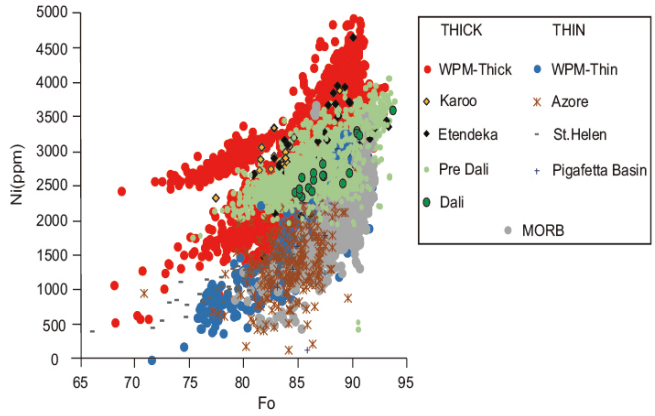
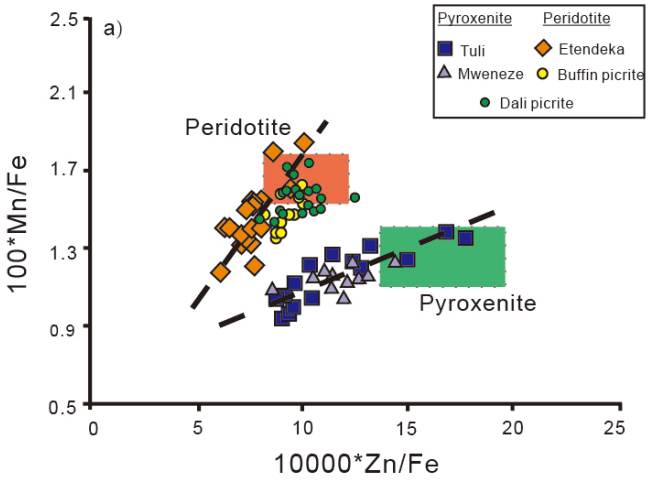
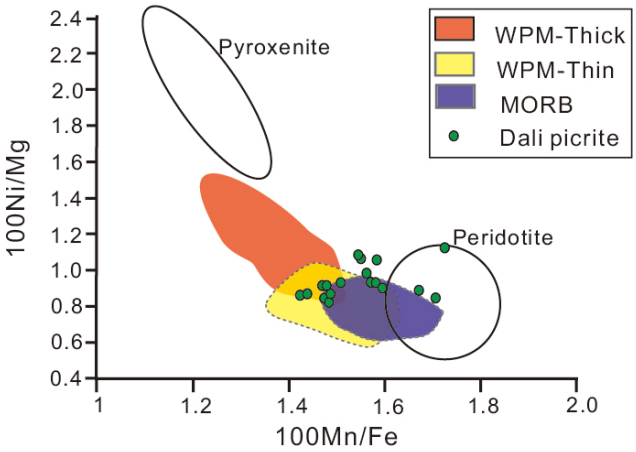
Genesis of high-Ni olivine phenocrysts of the Dali picrites in the Central Emeishan large igneous province



*Wenchang Cai[1], Zhaochong Zhang[1], Jiang Zhu[2], M. Santosh[1,3], Ronghao Pan[1]



1. China University of Geosciences, Beijing, China, 2. Yunnan Institute of Geological Sciences, Kunming,, China, 3. Department of Earth Sciences, University of Adelaide, Australia



The Emeishan Large Igneous Province (ELIP) is considered as one of the typical mantle plume-derived LIPs. The picrites formed at relatively high temperatures in this ELIP provide one of the important lines of argument for the role of mantle plume. Here we report trace element data on olivine phenocrysts in the Dali picrites from the ELIP. The olivines are Ni-rich, and characterized by high (>1.4) 100*Mn/Fe value and low (<13) 10000*Zn/Fe value, indicating a peridotite dominated source. Since olivine-melt Ni partition coefficient ($K_D Ni^{ol/melt}$) will decrease at high temperature and pressure, the picrites derived from peridotite melting at high pressure and which crystallized olivines at lower pressure can generate high concentrations of Ni in olivine phenocrysts, excluding the necessity of a metasomatic pyroxenite contribution. Based on the Al-in-olvine thermometer, olivine crystallization temperature and mantle potential temperature (T_P) were calculated at ~1491℃ and ~1559℃ respectively. Our results are ~200℃ higher than that of the normal asthenospheric mantle, and are consistent with the role of mantle thermal plume for the ELIP.

Continental crust in the ocean

*Gillian R Foulger[1]

1. Durham University

Conventional plate tectonics envisages simple continental breakup with clean splitting of supercontinents and subsequent orderly widening of oceans by seafloor spreading about a central ridge. No sooner was this paradigm proposed when the clear, first-order misfit of intraplate and large-volume volcanism was highlighted. That was quickly accommodated by adding an additional degree of freedom into the theory of Earth dynamics, i.e., ad hoc mantle plumes. Although this simple picture was adequate in the early years of plate tectonics, the subsequent rapid accumulation of vast datasets of ever-more-precise observations has rendered a theory of such simplicity no longer tenable. Simple plate tectonics can now serve only as a basic canvas on which the complexities of the real world must be painted. There is no better region for illustrating this than the Northeast Atlantic Realm which illustrates the full range of complexities. After a history of tectonic unrest spanning several 100 Myr true continental breakup, involving fracture of the entire lithosphere and ocean widening via sea-floor spreading, finally proceeded. However, geological complications are on at least an equal level to features arguably amenable to description by simple plate tectonics. Spreading ridges developed by propagation through continental lithosphere comprising a collage of cratons separated by orogenic belts. Where these propagators met insurmountable barriers the extension demanded by local kinematics could only be accommodated by diffuse continental extension. Continual changes occurred in the direction of regional extension and these resulted in local tectonic instabilities manifest in lateral ridge migrations, jumps, and parallel-ridge-pair extension. Extreme, magma-assisted continental extension, together with intense volcanism, formed lava-capped transitional crust. As a consequence the true extent of continental crust under the oceans is unclear. The geophysical characteristics of transitional crust are ambiguous in terms of physical properties. This presents a challenge to mapping continental material in the oceans, a problem that can be mitigated by joint interpretation with gravity, heatflow and geochemical data. Known continental blocks in the ocean include the array of blocks west of the British continental shelf (the Hatton-, George Bligh-, Lousy-, Bill Bailey’ s- and Faroe Bank Highs, and Wyville-Thompson- and Fugløy Ridges), the Jan Mayen Microplate Complex, the Greenland-Iceland-Faroe Ridge and likely others that remain to be found. All of the above complexities in the solid Earth have profoundly affected the natural environment in the region, especially the oceans and the biosphere, and must be taken into account in predictions of future evolution of the natural environment.

The magma system beneath Changbaishan Volcano, China: an insight from magnetotellurics imaging

*Wule Lin[1], Xiangyun Hu[1], Bo Yang[1]

1. Hubei subsurface Multi-Scale Imaging Key Laboratory, Institute of Geophysics and Geomatics, China University of Geosciences

The largest intraplate volcanic system in northeast Asia is the Changbaishan Volcanic Field in the Western Pacific Volcanic Belt approximately 1400 km from the Japan Trench, where the Pacific plate subducts beneath the Eurasian plate. The Changbaishan Volcanic Field is located on the northern edge of the Sino-Korean Craton, above a big mantle wedge. This stratovolcano is composed of an old basaltic shield, a young trachytic-to-rhyolitic cone, and a summit caldera. One of the two most violent eruptions in recorded human history occurred here between 920 and 960 AD and is known as the ‘Millennium Eruption’. The volcanic field experienced its most recent eruption in 1903 AD, followed by periods of unrest between 2002 and 2005. Concerns about increased activity made Changbaishan the focus of study for potential geologic hazards. Using magnetotelluric data collected from 2012 to 2014, we created a nearly linear N-S directional profile of the region across the Tianchi caldera in order to investigate the subsurface structure. A resistive crustal body is visible in the south part of the Changbaishan area in our three-dimensional model. Two successive magmatic conductors are beneath the Tianchi caldera less than 20 km from the surface. Petrologic analysis of comendite-trachyte from the Millennium Eruption indicates a formation from two different magmas and the double magmatic conductors are consistent with the geochemical model. Assuming the outermost resistivity of the magma body nearest to the surface is 25 Ω·m then it is located at a depth of 2 to 6 km and maybe responsible for recent volcanic earthquake events and ground deformation. Beneath the near surface magma chamber is a larger conductive magma body centered at an approximate depth of 15 km. This larger magma body maybe the main supply for the shallow magma system.

Evidence for the strike-slip opening of the Japan Sea

*Hidehisa Mashima[1]

1. Center for Obsidian and Lithic Studies, Meiji University

The opening tectonics of the Japan Sea is important for our understanding of the evolution and dynamics of East Asia. An appropriate model of the opening tectonics of the Japan Sea is the double door opening model based on paleomagnetic declinations observed in the Japan Arcs. The model assumes that SW Japan arc would have 40-60° clockwise rotated and NE Japan would have 40° anticlockwise rotated during the Japan Sea opening. Structural features of the Japan Arcs, the Japan Sea and their vicinities indicate that the Japan Sea would have opened south-southwestward as a strike-slip matter using the Tsushima-Goto Fault, Sakhalin-Central Hokkaido and the Japan Trench as master faults.

Faults oriented to an NNE-SSW direction formed in the Cretaceous are developed both in north Kyushu and SE Korea. Faults oriented to NNW-SSE to NW-SE directions are developed in the Paleogene north Kyushu sedimentary basin and the Paleogene East China Sea Shelf Basin. Pre-Paleogene strata continues with same direction from north Kyushu to the western Chugoku district. The Tsushima-Goto Fault striking between the Japan Sea and the East China Sea disconnects the north Kyushu sedimentary basin and the East China Sea Shelf basin. These structural features indicate that north Kyushu-the western Chugoku district would have migrated along the Tsushima-Goto Fault during the Japan Sea opening.

Echelon faults oriented to an NNW-SSE direction are developed in NE Japan. Rapid subsidence was occurred during the Japan Sea opening at the bending points of the NNW-SSE faults where the faults turn anticlockwise their directions from north to south. The eccentrically-subsidence indicates that the NE Japan would have carried out sinistral deformation using the Japan Trench as the master fault. Along Sakhalin-central Hokkaido, the boundary between the JS and the Okhotsk Sea, the Cretaceous Yezo Supergroup characterizing flysch is distributed as a narrow band. Dextral structures developed there in early Miocene, which would have been caused by the extending of the Kuril Basin. The Japan Sea is composed of basins and continental fragments bounded by faults oriented to NNE-SSW to N-S directions and faults oriented to an E-W direction.
These lines of evidence indicate that the Japan Sea would have opened as a strike-slip matter rather than the double-door matter. Paleomagnetic declinations observed in Japan would be the results of rotations of small faulted-blocks rather than those of coherent arcs. The brittle/ ductile transition zone in the crust beneath Japan would have been shallow under the high geothermal condition, which are represented by the submarine green tuff volcanism during the Japan Sea opening. The shallow brittle/ ductile transition would have made block rotation easy.

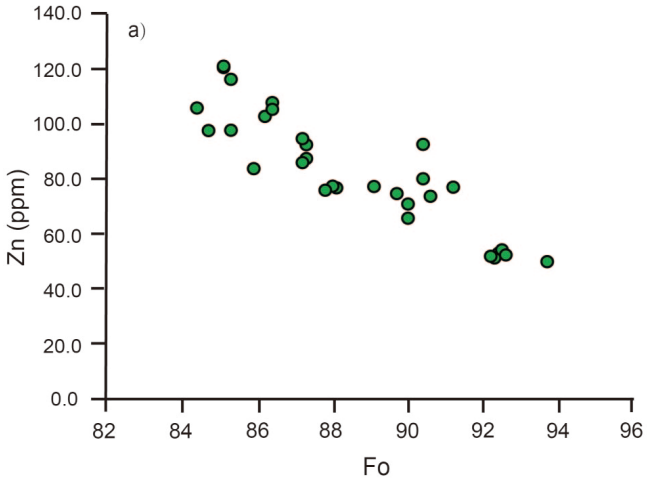
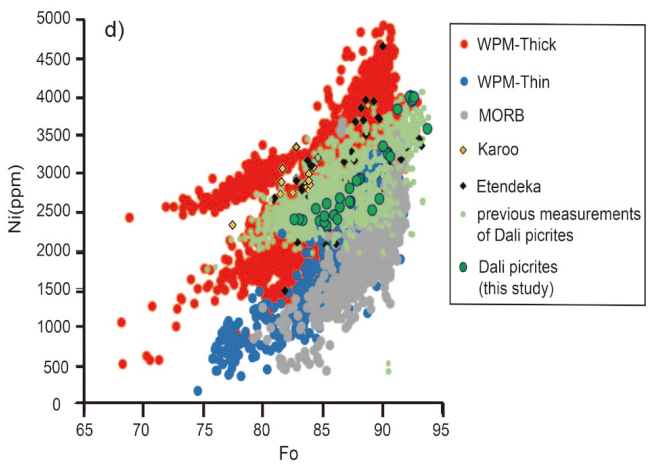
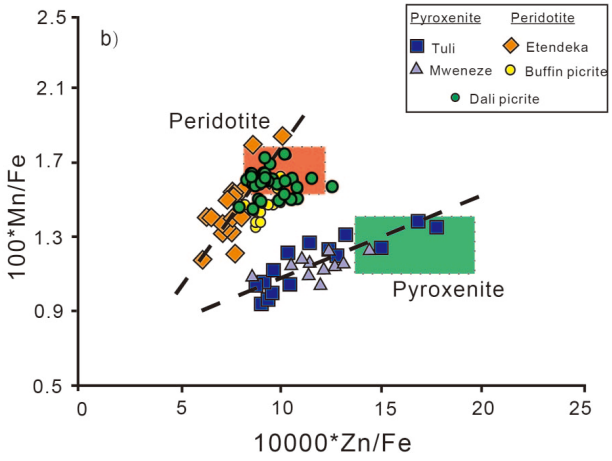
Genesis of high-Ni olivine phenocrysts of the Dali picrites in the Emeishan large igneous province, SW China.



*Wenchang Cai[1], Zhaochong Zhang[1], Jiang Zhu[1,2], M. Santosh[1,3], Ronghao Pan[1]



1. China University of Geosciences, Beijing, China, 2. Yunnan Institute of Geological Sciences, Kunming, China, 3. Department of Earth Sciences, University of Adelaide, Australia



The Emeishan Large Igneous Province (ELIP) in SW China is considered as one of the typical mantle plume-derived LIPs. The picrites formed at relatively high temperatures in the ELIP provide one of the important lines of argument for the role of mantle plume. Here we report trace element data on olivine phenocrysts in the Dali picrites from the ELIP. The olivines are Ni-rich, and characterized by high (>1.4) 100*Mn/Fe value and low (<13) 10000*Zn/Fe value, indicating a peridotite dominated source. Since olivine-melt Ni partition coefficient ($K_D Ni^{ol/melt}$) will decrease at high temperature and pressure, the picrites derived from peridotite melting at high pressure and which crystallized olivines at lower pressure can generate high concentrations of Ni in olivine phenocrysts, excluding the necessity of a metasomatic pyroxenite contribution. Based on the Al-in-olvine thermometer, olivine crystallization temperature and mantle potential temperature (T_P) were calculated at ~1491 ℃ and ~1559 ℃ respectively. Our results are ~200 ℃ higher than that of the normal asthenospheric mantle, and are consistent with the role of mantle thermal plume for the ELIP.

[S-GL33] Geologic structure and tectonic history of East Asia and Japanese Islands

convener:Jun Hosoi(Geological Survey of Japan, Institute of Geology and Geoinformation, AIST), Makoto Otsubo(Geological Survey of Japan, Research Institute of Earthquake and Volcano Geology)

The main aim of this session is to discuss geologic structure and tectonic history of East Asia, especially of Japanese Islands, on the basis of the recent results of geology and other earth sciences.

Different mechanisms have been proposed about how the subduction-related high-pressure terrane exhumates to the Earth’ s surface that might come from different tectonic settings. Taiwan orogeny results from arc-continental collision since 6-7Ma and recent studies show that high-pressure Yuli belt is associated with this process. The high-pressure terrane has been buried to ca. 50 km in-depth, and the surrounding terrane is ca. 12-20 km in depth. How the different terrane exhumed to the surface and what kind of structures are developed during the subduction to exhumation process? Here we collect the samples from low to high metamorphic and pressure terrane around the southern Central Range and use the RSCM methods, structural analysis, and zircon fission-track dating to reveal the possible exhumation process.

Three-stage foliations have been observed in eastern Central Range. The S1 is parallel to S0 associated with well-growth mica which is related to the highest metamorphism. The S2 is high-angle dipping foliation with fine-grain mica growth associated with tight to isoclinal folding. The S3 is shallow dipping foliation associated with small to mesoscale recumbent folding. The S3 results from the vertical force, which is strongly related to the recent exhumation process.

The RSCM results show the metamorphic temperature increases from ca. 340°C (low-grade slate) to ca. 500°C (high-pressure belt) in short distances that might infer a high shear zone; however, the zircon fission-track ages are similar in 0.7-1Ma and the eastern Central Range accelerate exhumation since ca. 2Ma simultaneously indicating the different metamorphic terranes have been merged before 2Ma. We suggest that the later stage foliation S2-S3 is related to this rapid exhumation process and the S1 is associated with the highest metamorphism suggesting it could be related to the subduction process.

Zircon U-Pb Ages from sandstones of the Muro Accretionary sequence in the Shimanto Superbelt, Kii Peninsula, Southwestern Japan

*Takanori Bessho[1], Hiroyuki Suzuki[2], Toshiya Yamamoto[3], Tohru Danhara[4], Hideki Iwano[4], Takafumi Hirata[5]

1. Department of Geosciences Osaka City University, 2. Nanki Kumano Jeopark Center, 3. Tanabe Highschool, 4. Kyoto Fissin-Track Co., Ltd., 5. Tokyo University

The depositional ages of Shimanto Accretionary Prism in the Kii Peninsula, Southwestern Japan, have been mainly determined by radiolarian fossils. But recently, the fission track and U-Pb ages of detrital zircon in the sandstone have been reported (Ohira et al, 2016; Tokiwa et al 2016, 2017). However, these reports are confined to Cretaceous and early Paleogene System. Zircon U-Pb dating of three specimens of sandstone from the later Paleogene Muro Accretionary Sequence (AC) was carried out by using LA-ICP-MS. The consideration on the difference of radiolarian ages and U-Pb ages of detrital zircon has been done. Moreover, the cause of increasing supply from East Asia Precambrian detritus after Middle Eocene were examined. Muro AC is subdivided into three tectonostratigraphic units (TU) by thrusts, i.e., the Notake, the Ohkamidawasan, the Ichikano and the Susami TU from north to south. The Radiolarian fossil age of Notake TU shows Middle Eocene. The one of the Ichikano TU are assigned to range from later Middle Eocene to Late Eocene and the one of the Susami TU range from later Middle Eocene to Early Oligocene.As for the zircon U-Pb age, the Notake TU dated at 72.0±0.2 Ma, the Ichikano TU at 36.1±1.9 Ma and Susami TU at 59.6±1.0 Ma respectively deduced from the weighted mean of the youngest cluster.The value of the zircon U-Pb age from Notake and Susami TU are clearly older than the radiolarian fossil age. These gaps are presumed to be due to influence of Magmatic hiatus. The zircon U-Pb age from Ichikano TU is concordant with the radiolarian fossil age. The part of the zircon being included in Ichikano TU is thought to be derived from contemporaneous igneous rocks. Paleo-Proterozoic zircons (1600-2500 Ma) have been slightly found in all samples and Almost of these zircons are rounded. Therefore, these zircons are thought to be recycled grains. As it becomes more abundant in the younger TU, i.e., Susami TU, the supply from the Precambrian clastics of East-Asia continent is presumed to be increased. These Precambrian clastics are well exemplified by containing rounded zircon, purple zircon, Ig2-type garnet (Teraoka et al., 1998; Bessho,2012) and Orthoquartzite (Tokuoka,1970; Tokuoka and Bessho, 1980). Furthermore, the increasing of Precambrian zircon will support this hypothesis. As for the cause of increasing of East Asia Precambrian detritus, three assumptions will be suggested. In the first place, igneous activity was poor in the deposition time of Muro AS. In the second place, subaerial erosion became intense because of the fall of sea level by glacial eustacy (Bickert and Heinrich, 2011). Furthermore, large submarine fan composing Muro AS grew up in the trench basin.This study was supported by a grant from the Nanki Kumano Geopark Promotion Council.

Geochemical characteristics of metamorphic and igneous rocks from the Hida belt: whole-rock major and trace elements, and multiple S isotope compositions

*Raiki Yamada[1], Shinnosuke Aoyama[2], Ouchi Wataru[1], Toshiro Takahashi[1], Satish Kumar M.[1]

1. Niigata University, 2. Yokohama National University

The Hida belt is one of the Japanese basement units, indicating relationships with the North China block [1] and/or the South China block [2]. Some studies consider that these metamorphic rocks were formed during the collision between the North and South China blocks [3]. Accordingly, the formation history and the origin of the Hida belt will be of great significance to understand establishment of the eastern Asia continent and processes of continental growth. We collected samples of metamorphic rocks and granitoids from the Hida belt for geochronological and geochemical analyses. In this abstract, we present some geochemical data of the Hida granites including multiple S isotope compositions.

The Hida belt consists of the Hida metamorphic rocks, the Unazuki metamorphic rocks and the Hida granites [4]. The Hida metamorphic rocks, composed mainly of orthogneisses, paragneisses, amphibolite and marble, were formed by several times of metamorphism, and the last regional metamorphism occurred in the eastern margin of the Eurasian continent during Early to Middle Triassic period (250–235 Ma; [5]). The Metamorphic grade reached from amphibolite to granulite facies, with eclogitic rocks [6]. Protolith of the Unazuki metamorphic rocks derived from late Paleozoic sediments, limestone and acidic volcanic rocks was also metamorphosed around 250 Ma at medium P/T conditions [7, 8]. The Hida granites consists of the Triassic Hida older granites and the Jurassic Hida younger granites [4]. We already reported 240 Ma and 190–180 Ma of ^{238}U–^{206}Pb weighted mean ages from the older and younger Hida granites, respectively [9].

SiO_2 content of the Hida granites ranges from 52.7 wt.% to 75.1 wt.%. Both of the older and younger Hida granites show I-type granitic trends in $_2$–ASI diagram and have intermediate composition between sub-alkaline and alkaline series [10]. All samples are plotted in volcanic arc field of tectonic discrimination diagrams for granitoids (Nb+Y–Rb [11] and Rb/30–Hf–Ta*3 diagrams [12]). Additionally, many samples of the Hida granites have adakitic composition (high Sr/Y ratio) and show depleted patterns toward HREE in REE pattern diagram. Negative anomalies of Nb and Ta in trace element patterns suggest that their origins are related to subduction zone magmatism. The Hida granites exhibit small variations in $\delta^{34}S$ ranging from −2.1‰ to +5.2‰ and $\Delta^{33}S$ from −0.02‰ to +0.00‰, suggesting sulfur was mainly derived from the mantle and subsequent high temperature mass-dependent processes. Our results of whole-rock geochemistry are consistent with the idea that the Hida granites were generated by melting of the mafic lower continental crust under high pressure environment where garnet coexists [13, 14]. It is considered that non-adakitic granites resulted from crustal melting under relatively low-pressure. Moreover, geochemical characteristics of the Hida granites suggest that the continental crust had grown in subduction zone of the margin of the eastern Eurasian continent.

Identification of the source caldera for the Pliocene pyroclastic flow deposit in NE Japan based on apatite trace-element compositions

*Reishi Takashima[1], Haruka Kusakawa[2], Yuji Orihashi[3], Hiroshi Nishi[1]

1. Tohoku University, 2. Chichibu Taiheiyo Cement Co. Ltd. , 3. Hirosaki University

It is known that a lot of calderas were formed on the Northeast Japan during Pliocene period. Such dense caldera-forming volcanic activity resulted in frequent intercalations of volcaniclastic deposit in the Pliocene sedimentary strata and deep-sea cores around Northeast Japan. However, most of these Pliocene volcaniclastic deposits have not been identified their source volcanoes. The Hirosegawa Tuff Member, consisting of a pair of Pliocene pyroclastic fall and flow deposits, is known as the widely traceable volcaniclastic deposits in the eastern part of central Northeast Japan. The source volcano of the member remains being not identified because of the poorly preservation of volcanic glass of the member in some locations as well as sporadic distributions of the member attributed to the tectonic uplift and erosion since Pliocene. Trace-element compositions of apatite phenocrysts are useful in tephrochronology because they change in response to various conditions of magma when they crystalize. In addition, apatite is highly tolerant to burial diagenesis and welding processes, its trace-element compositions are powerful tool for correlation of pre-Quaternary tephra, although this method has not become widely used so far. Here we analyzed trace-element compositions of apatite and U-Pb ages of zircon for the Hirosegawa Tuff Member and pyroclastic flow deposits of the Pliocene Calderas around Sendai, and demonstrate that the Hirosegawa Tuff Member mapped in previous studies is different volcanic ejecta depending on areas. Furthermore, these analyses identify the source volcano of the Hirosegawa Tuff Member at the type section to be the Shiroishi Caldera located 50km south of the type section.

New age constraints and tectonic significance of the early Miocene sediments in the Hidaka Belt around Tomuraushi area, central Hokkaido, Japan

*Futoshi Nanayama[1,2], Mahito Watanabe[1], Toru Yamasaki[1], Hideki Iwano[3], Tohru Danhara[3], Takafumi Hirata[4]

1. Geological Survey of Japan, AIST, 2. CWMD, Kumamoto University, 3. Kyoto Fission-Track Co. Ltd, 4. The University of Tokyo

In the Hidaka Supergroup of the Tomuraushi region, there was known alternated beds of sandstone and mudstone named the Chikapupetsu Formation, which has a slightly unconsolidation from the surrounding strata. In this study, the depositional age of the Chikapupetsu Formation was constrained by two methods. Two zircon U-Pb ages of 22.5 ±0.7 Ma and 19.5 ±0.1 Ma were obtained for the maximum depositional age of the formation based on the minimum age of detrital zircon grains from turbiditic sandstone and acidic tuff by the LA-ICP-MS method. In addition, presence of diatom fossils in the formation indicates an early Miocene age for the depositional age of the formation. Because the depositional age of the Hidaka Supergroup has been considered as the Paleocene to early Eocene, the Chikapupetsu Formation should be excluded from the Hidaka Supergroup. Instead it can be correlated with the upper members of the Tsubetsu and Kawakami groups on the basis of their depositional age. We already reported late Oligocene Tatsuushi and Erimo formations in the Hidaka Belt, which has been active as a right-lateral strike-slip fault since the late Oligocene. The Chikapupetsu Formation is considered to be a marine deposit formed between the Kamishiyubetsu Formation on middle Miocene and the Tatsuushi and Erimo formations on late Oligocene along with the activity of the Kamishiyubetsu tectonic zone.

This work was supported by JSPS KAKENHI Grant Number JP19K04025.

Provenance of the Yezo forearc basin in Northeast Japan from detrital zircon U–Pb age spectra

*Koh Kubomi[1], Shin-ichi Sano[2], Minami Murakami[3], Hiroto Ota[1], Mitsuhiro Nagata[1], Koshi Yamamoto[4], Shigeru Otoh[2]

1. Graduate School of Science and Engineering, University of Toyama, 2. Academic Assembly, Faculty of Sustainable Design, University of Toyama, 3. OYO Corporation, 4. Graduate School of Environmental Studies, Nagoya University

Introduction

In Hokkaido, the Cretaceous to Paleogene Yezo Group narrowly extends in the north direction, and the Upper Cretaceous Futaba and Nakaminato groups sporadically occur in the Pacific side of Northeast Japan[1)]. They are thought to have been deposited in the forearc basin along the East Asian active continental margin, called the "Yezo forearc basin" [1)]. The modal composition of sandstones[2),3)] of the Yezo Group, and the detrital zircon age spectra[4)] suggested that its provenance is the East Asian continental margin. However, we have not been able to identify the specific provenance of each formation of the Yezo Group and its equivalents. In this presentation, we discuss the provenance of the Yezo forearc basin from the detrital zircon age spectra of sandstone samples and the database of the age and distribution of igneous rocks in East Asia.

Geological Setting

The Yezo Group consists mainly of black mudstone and sandstone. It is subdivided into the Shuparogawa (Srs), Hikagenosawa (Hgs), Mikasa (Mks), Haborogawa (Hbs), and Hakobuchi formations (Hks1, Hks2), in ascending order[5)]. The Futaba Group, consisting mainly of sandstone and mudstone, unconformably covers the granites of the Abukuma Belt. The group comprises the Ashizawa (Aos), Kasamatsu, and Tamayama formations (Tys), in ascending order[6)]. The Nakaminato Group consists mainly of turbidite and is subdivided into the Hiraiso and Isoai formations (Is8), in ascending order[7)]. The codes for the nine sandstone samples analyzed in this study are in the parentheses.

Analytical Method

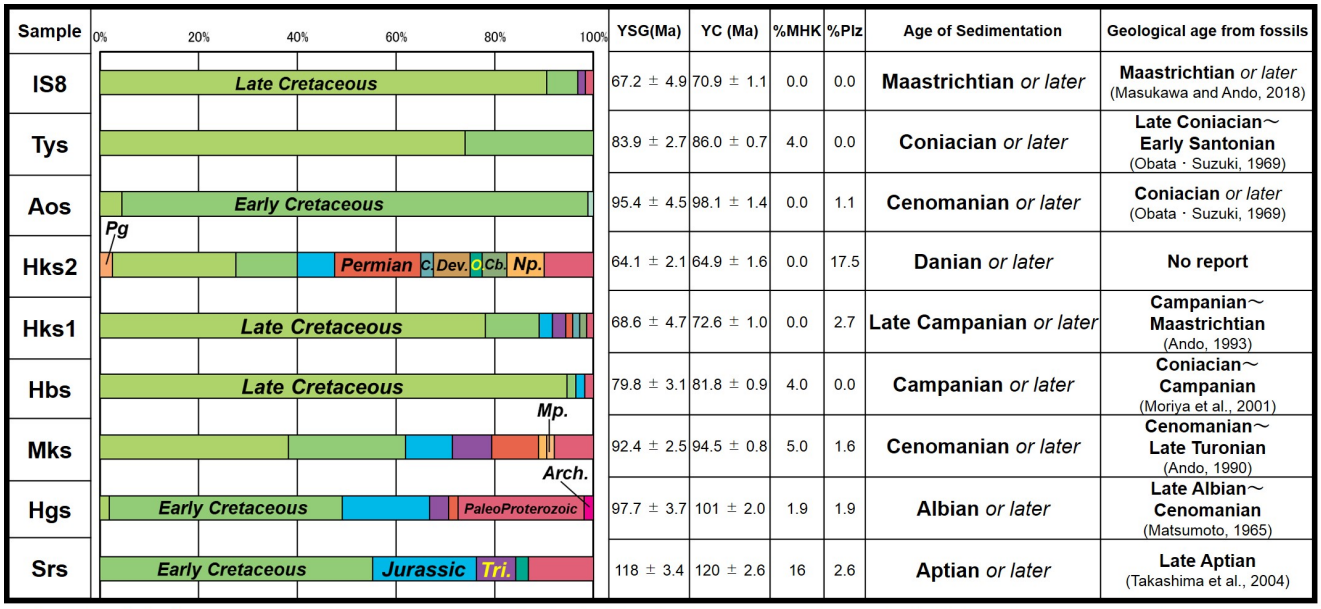
We separated detrital zircons from each sandstone sample, measured their U/Pb isotopic ratios with LA-ICPMS, and calculated the U–Pb ages. YC is the weighted mean of the youngest zircon $^{206}Pb/^{238}U$ age and the other ages with the error bar ($\pm 2\sigma$) overlapping with the youngest age.

Result

Figure 1 summarizes the result of our measurements of the Yezo, Futaba, and Nakaminato groups.

Discussion

Samples Srs, Hgs, and Mks have zircons crystallized during the magmatic hiatus in Korea[8)] (158–138 Ma), 230–210 Ma, and 2400–1800 Ma zircons. The database indicates that igneous rocks of these ages are widely exposed in South China[9)]. In addition, paleomagnetic studies[10)] suggested that the Hikagenosawa and Takinosawa formations of the Yezo Group was deposited at 10°N and moved to the north during the Cretaceous. Thus, the provenance of the Yezo Group was probably South China during the Aptian to Cenomanian.



The detrital zircons from sample Aos are mostly 120–100 Ma in age and likely originated from the 120–100 Ma granites in the Abukuma Belt[11)]. 96–83 Ma zircons occupy more than 70% of the detrital zircons from sample Tys and likely originated from the ca. 90–80 Ma igneous rock bodies in the Inner

©2020. Japan Geoscience Union. All Right Reserved.

Zone of Southwest Japan[12].
About 95% of the detrital zircons from sample Hbs are 100–80 Ma. Thus, coeval, 100–80 Ma igneous rocks of an active igneous belt must have occupied the hinterland of sample Hbs.
From the Hakobuchi Formation of the Yezo Group, sample Hks1 has 250–203 Ma, 310 Ma, and 490 Ma detrital zircons, and about 18% of the detrital zircons from sample Hks2 are Paleozoic (excluding Permian) ones (Fig. 1). Sample Is8 has 210 Ma and 1800 Ma zircons. 500–400 Ma and 300 Ma igneous rock bodies widely crop out in Far East Russia[13]. The provenance of the Yezo and Nakaminato groups in the latest Cretaceous was probably Far East Russia. These lines of evidence strongly suggest that the provenance of the Yezo forearc basin continuously changed from south to north.

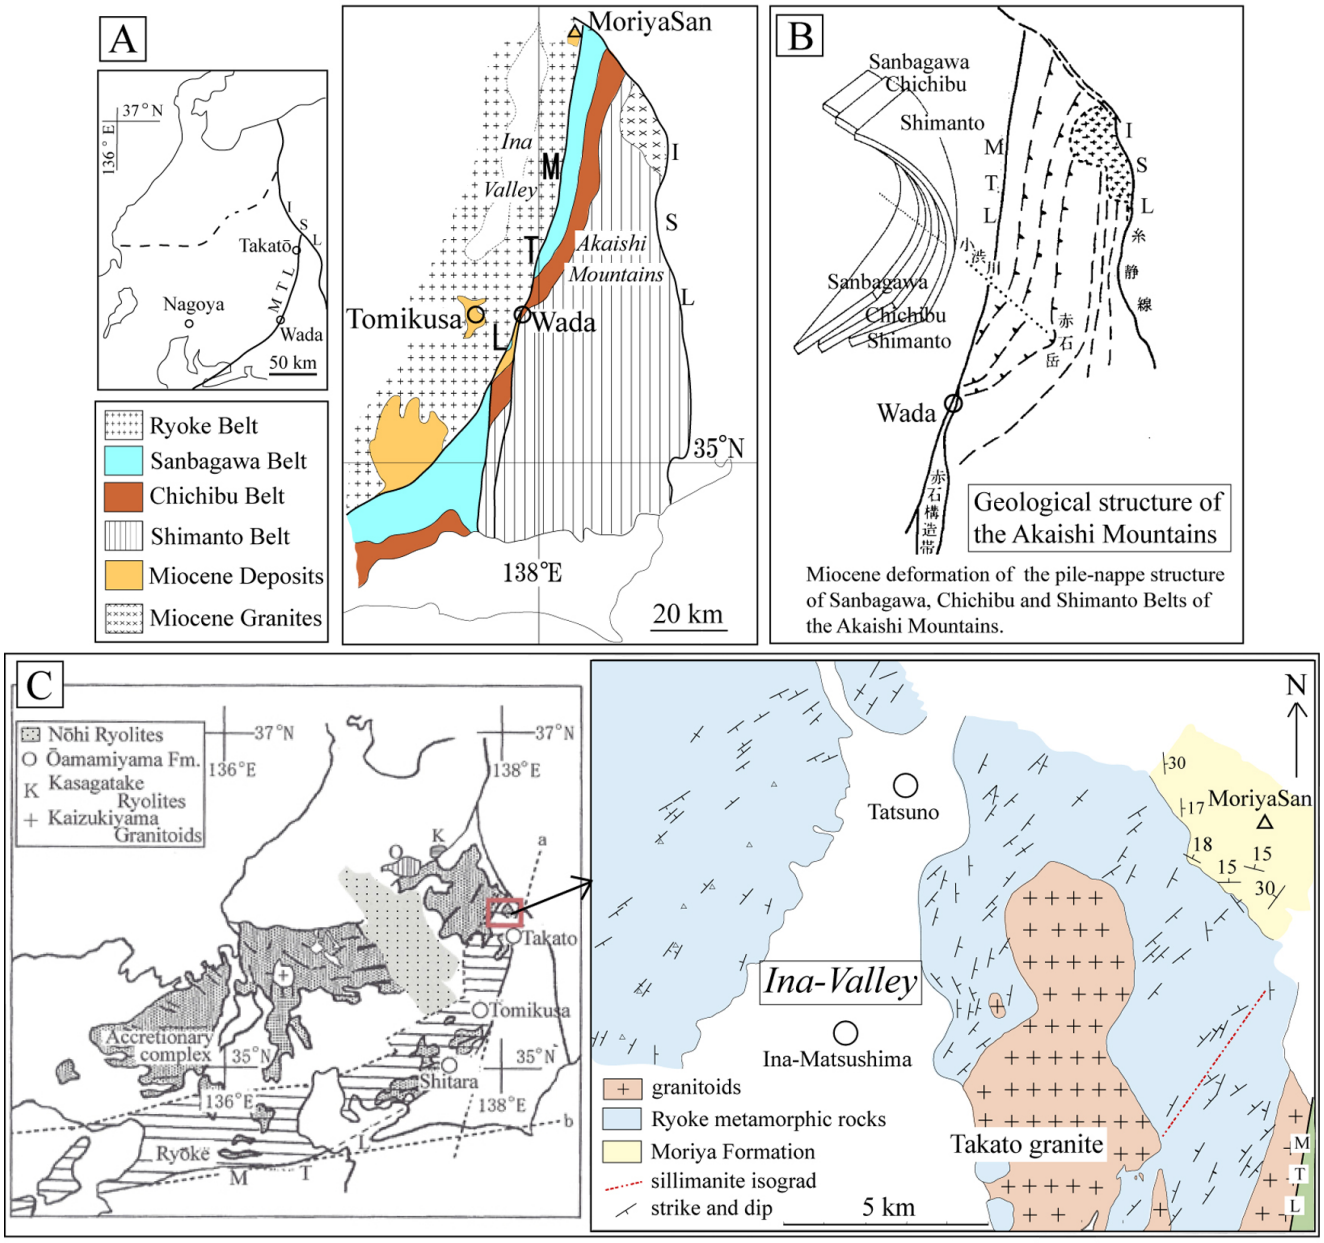
Tectonics of the Miocene Median Tectonic Line in the west of Ina-Valley, central Japan



*Akira Ono[1]

1. None

Consider the tectonics of geological bodies A and B which are in contact with a fault in a shallow crust. Rotation of the geological body B occurs with respect to A. The rotation axis is assumed to be vertical or horizontal, but in either case, overlap and void of the geological bodies occur at the boundary between the geological bodies A and B. This virtual overlap and void are actually eliminated by the tectonic movement and deformation of geological bodies around the boundary fault. A tectonic zone is formed between the geological bodies A and B after the rotation.
It is reasonable to assume that geological body A is the inner zone of the Ina-Valley area and geological body B is the Akaishi Mountains of the outer zone in view of the geology and tectonics of these areas. Figure A is a schematic geological map of the area in question. Bedding planes of the Miocene Moriya and the Tomikusa basins are dipping gently below 20˚. On the other hand, the Miocene Wada Formation of the Akaishi Mountains is highly deformed and bedding planes are steeply tilted. The marked tilting of the bedding planes can be regarded as a rotating motion with the almost horizontal rotation axis.
The geological structure of the Akaishi Mountains is not a layered structure of gently inclined geological bodies that is found in the Kanto and Kii Mountains. Various geological bodies of the Akaishi Mountains are complexly deformed as shown in Figure B, and many geological units are partially missing. This complex geological structure was formed during the expansion period of the Sea of Japan. Moreover the Akaishi Mountains greatly rotated counterclockwise with respect to the inner zone of the Kinki region. The rotation axis was vertical and lateral movements in the N-S direction were also very intense.
In the western edge of the Mino belt and the northwestern edge of the Ryoke belt, i.e. the Ina-Valley area, the strikes of bedding planes are about N45˚E (Figure C). In these areas, the rotational motion around the vertical axis is estimated to be almost the same everywhere. According to the paleomagnetic study of the Miocene andesite dike swarm in the eastern part of Takayama City, Gifu Prefecture, located at the west end of the problem area, the paleomagnetic data are almost the same as those of the inner zone of the Kinki district. In the opening period of the Sea of Japan, the Takayama and the Ina-Valley areas suffered no counterclockwise rotational movement relative to the inner zone of the Kinki region.
Considering the large differences in the Miocene tectonics mentioned above, a tectonic zone may be formed between the Ina-Valley area and the Akaishi Mountains during the opening period of the Japan Sea. It is reasonable to consider large-scale horizontal and vertical movements of geological bodies in the tectonic zone. However, this kind of tectonic zone has hardly been confirmed. This contradiction can be resolved by assuming that most of the geological bodies in the tectonic zone were transported toward the earth surface. The missing geological bodies may be found as clastic materials in Miocene subduction zone. The current eastern border of the Ryoke belt near the Akaishi Mountains may have suffered similar tectonics during the formation of the Miocene Median Tectonic Line. In this area, narrow geological units elongated in N-S directions are found, and this is evidence for the missing tectonics.

On the paleocurrent of the Miocene Goto Group in Fukue Island, Nagasaki Prefecture

*Yuta Ikebata[1], Shoichi Kiyokawa[1]

1. Department of Earth and Planetary Sciences, Graduate School of Science, Kyushu University

The Goto Islands are located about 60 km west of Kyushu and consist of five major islands and more than 200 islands around them. This region is located at the western edge at the Sea of Japan expansion period (around 15Ma) and occupies an important position to record tectonics that shift from land arcs to island arcs at the edge of the continental edge of East Asia. In the Goto Islands, The Goto Group (Ueda, 1961) consisting of Miocene sedimentary rocks is distributed throughout. Rhyolites (Matsui and Kawata, 1986) and granites (Kawata et al., 1994) are intruding into it. In addition, the entire structure and detailed stratigraphy of the Goto Group has been clarified (Yamamoto, 2006MS; Hasegawa 2008MS; Yasunaga et al., 2005MS). In particular, the Goto Group exposed to Fukue Island consists of the Tachiya layer consisting of tuff breccia, the Okuura formation (Kawada, 1994) consisting of alternation of sandstone and mudstone, the toraku formation consisting of alternation of sandstone and mudstone, and hotokezaki formation consisting of sandstone, which is rich in charcoal products and develops a large cross bedding from the bottom. The Okuura Formation is further divided into three parts: lower, middle and upper. The lower part consists of alternation of fine to medium sandstone and dark gray shale to siltstone. The middle part consists of alternation of about 20 m thick medium-grained sandstone and 1-2 m thick mudstone. The upper part coarsens from the lower part into alternation of fine-grained white sandstone and black sandstone, alternation of medium-grained sandstone and mudstone, and medium-grained sandstone. In this study, we focused on the thick sandstone layer in the Goto Group, determined the paleocurrent mainly in the cross bedding and investigated the changes in each stratigraphy and regional flow from the time of the formation of the Goto group.
In this study, a total of 158 paleocurrent data were obtained in Fukue Island, including the Okuura formation (60 pieces), the Toraku formation (94 pieces), and the Hotokezaki formation (4 pieces). It was found that the paleocurrent obtained for each stratigraphy changed from the lower, northeast to south, and then again to the north, and changed to indicate various flows at the top level. In addition, it was found that paleocurrent showed the different direction flow even in the same layer level as by region, and it was remarkable especially in the upper part of the Okuura formation and the toraku formation. In the future, I will collect data at the bottom and middle part of the Goto Group, which has a small number of data. In addition, I conduct surveys on islands other than FukueIsland and collect data from a wide area.

Keywords: Miocene rocks, paleocurrent

North-South extension and compression juring the Japan Sea opening in the Amakusa, western Kyushu, Japan

*Kentaro Ushimaru[1], Atsushi Yamaji[1]

1. Division of Earth and Planetary Sciences, Graduate School of Science, Kyoto University

The opening of theJapan Sea in the early to middle Miocene was believed to be accompanied by compressional tectonics at its southwestern margin, i.e., northern and western Kyushu, Japan; and the compression resulted in the folds in Tsushima Island between Korea and Kyushu and in Amakusa Islands, western Kyushu (Ishikawa and Tagami, 1991; Sakai, 1993). Eocene formations are folded with NNE-trending axes in Amakusa. In the present work, we collected orientation data from planar intrusive bodies in Amakusa-Shimoshima Island to test their hypothesis.

We observed altered andesite intrusions, i.e., 50 dikes and 18 sills. Their ages are loosely constrained to be 14–20 Ma by the radiometric ages of intrusive bodies in Amakusa (Nagao et al., 1992; Hamasaki, 1996) The method of Yamaji and Sato (2011), which fits a mixed Bingham distribution to the orientations of planar intrusions, was applied to the 68 data. As a result, we obtained normal-faulting and reverse-faulting stress regimes, indicating N-S extensiona and N-S compression. The latter is oblique to the fold axes, so that the previous researchers' hypothesis about the folding accompanied by the Japan Sea opening is improbable. A few NNE-trending rhyolitic dikes in the island led Yamamoto (1991) to suggest horizontal maximam stress in the trend. The rhyolitic dikes may have been accompanied by the first phase rifting in the Okinawa Trough to the southwest of the island.

Visualization of a high-strain shear zone based on a field survey for minor faults: A case study of southern Kyushu, Japan

*Akira Goto[1], Koji Shimada[1], Masakazu Niwa[1], Shuji Terusawa[2]

1. Japan Atomic Energy Agency, 2. OYO Corporation

Owing to a nationwide GNSS network installed since mid-1990s, several high-strain shear zones defined as concentrated regions of strain rates have been recognized in Japanese Islands (Sagiya et al., 2000, PAGEOPH). The high-strain shear zone with a sinistral strike-slip was identified also in southern Kyushu (Nishimura and Hashimoto, 2006, Tectonophysics; Wallace et al., 2009, Geology). There have had large earthquakes in this area such as the 1997 Northwestern Kagoshima Earthquake (Faculty of Science, Kagoshima Univ., 1997, Report of CCEP), however, any seismogenic faults associated with these earthquakes or active faults with strike-slip tectonic landforms had not been previously recognized at the surface.

In this study, we focused on existing minor faults to clarify a geological evidence of the shear zone suggested by geodetic studies. Basement rocks in the study area are mostly composed of sandstone and mudstone of the Shimanto accretionary complex, and are with a minor exposure of the Miocene Shibi-san Granodiorite (Yoneda and Iwamatsu, 1987, J. Geol. Soc. Japan). Mesoscale fault zones with clayey gouge and cataclasite are rare in the study area. Instead, minor faults cutting bedding planes and deformation structures subparallel to the bedding (such as mélange fabric), suggesting the formation clearly after the accretion of the Shimanto accretionary complex, are commonly observed. Slip directions can be examined from striations along the minor faults. Striations are also often identified along joints in the massive sandstone. Based on orientation data of these striations, we applied stress tensor inversion techniques (Yamaji, 2000, J. Struct. Geol.; Yamaji and Sato, 2012, Comp. Geosci.) to elucidate stress states. Our field survey in northwestern Kagoshima (22 ×16 km) revealed an occurrence of the E-W trending zone of ~2 km wide showing a stress state consistent with the sinistral high-strain shear zone (NE-SW compression and NW-SE extension). This zone largely overlaps the aftershock distribution of the 1997 Northwestern Kagoshima Earthquake. This study can contribute to one of helpful approaches to examine potential future activities of faults (or shear zones) without clear tectonic landforms.

This study was funded by METI, Japan as part of its R&D program supporting development of technology for geological disposal of HLW.

Keywords: high-strain shear zone, stress tensor inversion, minor faults, southern Kyushu

Structural position of the Akiyoshi Limestone in the Permian accretionary complex of the Akiyoshi Belt, Southwest Japan

*Koji Wakita[1], Hokuto Obara[2], Takanori Nakagawa

1. Yamaguchi University Community Future Center, 2. Mine Akiyoshidai Karst Plateau Geopark Promotion Council

Akiyoshi Limestone of the Akiyoshi Belt yields well preserved fusulinids, and its detailed stratigraphy and geological structure have been studied nearly for 100 years. The characteristic feature is the overturned structure of the limestone beds. The mechanism of the overturned structure has been discussed as the Akiyoshi Orogeny, but recently the limestone collapse model has been widely accepted. However, the limestone collapse model in the Japan Trench has some problems. Daiichi Kashima Seamount on the Pacific Plate has collapsed in the trench. However, the collapsed materials are never accreted into the continental margin along the Japan Trench, where the tectonic erosion occur. On the other hand, in the Nankai Trough, which is the accretionary boundary along the Southwest Japan, seamounts never collapse at the trench. As the hard seamount advances by pushing away the soft accretionary prism, and the accretionary wedge is deformed instead.
The most probable case is the limestone part on the seamount offscraping in the deep part of the accretionary wedge. After the offscraping, the limestone fragment moved upward, and appeared at the outer forearc high. The limestone fragment collapses and accumulates into forearc basin and/or trench slope basin. The purpose of this study is to reveal the accretionary process of the Akiyoshi limestone, which was offscraped from the top of the seamount and incorporated into the accretionary prism in the Permian period. Present analog of the Permian accretionary complex of the Akiyoshi Belt is the accretionary prism formed along the Java Trench near the Sulawesi Island, western Indonesia. In the presentation, new tectonic model of Akiyoshi limestone is proposed using analog of the Java accretionary wedge.

Deformation characteristics and metamorphic temperature of the high-pressure terrace of the Taiwan orogeny

*Han Chun Lin[1], Yuan Hsi Lee[1], Lucas Mesalles[1], Jian Cheng Lee[2]

1. Department of Earth and Environmental Sciences, National Chung-Cheng University, 2. Institute of Earth Sciences, Academia Sinica, Taiwan

Different mechanisms have been proposed about how the subduction-related high-pressure terrane exhumates to the Earth’ s surface that might come from different tectonic settings. Taiwan orogeny results from arc-continental collision since 6-7Ma and recent studies show that high-pressure Yuli belt is associated with this process. The high-pressure terrane has been buried to ca. 50 km in-depth, and the surrounding terrane is ca. 12-20 km in depth. How the different terrane exhumed to the surface and what kind of structures are developed during the subduction to exhumation process? Here we collect the samples from low to high metamorphic and pressure terrane around the southern Central Range and use the RSCM methods, structural analysis, and zircon fission-track dating to reveal the possible exhumation process.

Three-stage foliations have been observed in eastern Central Range. The S1 is parallel to S0 associated with well-growth mica which is related to the highest metamorphism. The S2 is high-angle dipping foliation with fine-grain mica growth associated with tight to isoclinal folding. The S3 is shallow dipping foliation associated with small to mesoscale recumbent folding. The S3 results from the vertical force, which is strongly related to the recent exhumation process.

The RSCM results show the metamorphic temperature increases from ca. 340°C (low-grade slate) to ca. 500°C (high-pressure belt) in short distances that might infer a high shear zone; however, the zircon fission-track ages are similar in 0.7-1Ma and the eastern Central Range accelerate exhumation since ca. 2Ma simultaneously indicating the different metamorphic terranes have been merged before 2Ma. We suggest that the later stage foliation S2-S3 is related to this rapid exhumation process and the S1 is associated with the highest metamorphism suggesting it could be related to the subduction process.

[S-RD35] Mineral Resources for Society: Ore deposit formation and exploration

convener:Yasushi Watanabe(Faculty of International Resource Sciences, Akita University), Kotaro Yonezu(Deaprtment of Earth Resources Engineering, Faculty of Engineering, Kyushu University)

Mineral resources are fundamental to Society, particularly for a modern way of life, as they are used in every facet of life, from housing and transport to low-C energy sources to mobile phones. Metals and non-metals are mined from surface or underground ore deposits. The largest production - aside from industrial minerals - is iron ore from iron formations, 2,400 million tonnes (Mt) yearly (USGS), and P2O5 (263 Mt). This is followed by Al (60 Mt), Cr (30 Mt), Cu (20 Mt), Zn + Pb (19 Mt) and Ni (2 Mt); Mo and Sn (each 290 kilotonnes, kt), REEs (130 kt), Co (111 kt), Li (43 kt) and Ag (25 kt). Smaller amounts of essential metals include In (720 t), Ga (300 t) and Ge (126 t). Reserves (i.e., amounts proven by drilling to be economically feasible to mine) for many elements are 2-3+ decades, with known Resources typically up to 100 years or more (e.g., Fe, P), at present consumption rates.

Future global mineral resources depend on the consumption rate minus the recycling rate for given elements; shortfalls need to be made up over time by discovery of new resources. Discovery occurs by exploration; although technology assists this task, geologists must still work in the field and map, assess alteration and geochemical anomalies, and test these plus geophysical anomalies by drilling. Few anomalies ever reach a feasibility study, and many deposits with a feasibility study eventually are not mined for economic, social, environmental, political or other reasons. In order to be geologically successful at exploration, geologists must understand the characteristics of the ore deposit style sought, and appreciate the variations that occur within the deposit style they are seeking. This requires understanding how ore deposits form, and how characteristics may vary depending on different geologic settings. This session invites presentations on ore deposits and features that assist their discovery.

Heavy mineral sands ore deposits in Somaliland (Southern Gulf of Aden) coastal areas

*Awul Mohamud Ibrahm[1], Mohammed Ali[2]

1. Burao University, 2. Khalifa University of Science and Technology

Heavy mineral enriched samples along the Somaliland coast were analysed using X-ray Fluorescence, X-ray Diffraction and SEM-EDS techniques. This study reveals that a considerable amount of heavy minerals is present along the Somaliland coast and confirms the presence of high concentration titanium and iron bearing minerals. The titanium detected in geochemical analysis occurs in the form of ilmenite, rutile, titanite and taniferous magnetite. Also, present in minor or trace amounts, are garnet, zircon and monazite.

Heavy mineral accumulations in the east and west of Somaliland have different mineralogical assemblages. The east of Somaliland is dominated by quartz with moderate concentration of plagioclase, K-feldspar, magnetite, hematite and titanium bearing minerals, whereas in the west of Somaliland, the dominant minerals are quartz, K-feldspar and plagioclase with variable proportions of ilmenite, rutile, mica, amphibole and pyroxene. These variations in mineral assemblages suggest different composition of the catchment areas that supply sediment to these deposits. The catchment area in the east of Somaliland consists mainly of Proterozoic crystalline basement of the Qabri Bahar complex, Gabbro-Synenite belt and granitic intrusions that outcrop in Hudiso, Tulo Dibijo and surrounding areas. The primary sources of heavy minerals in the west of Somaliland comprise of high-grade metamorphic rocks of the Mora and Qabri Bahar complexes as well as the Miocene volcanics that outcrop in Laferug and Hagabo areas.

The heavy mineral sand deposits observed along the Somaliland coast have the potential to provide commercially important heavy minerals, in particular ilmenite.

Keywords: Heavy mineral sands deposits, Ilmenite, Rutile, Titanium Oxide

Economic potential of red earth deposits in the north and northwestern coastal belt of Sri Lanka

*W.L.A.C.I. Weedagama [1,2], N.W.B. Balasooriya[2], Atula Senaratne[2], Bhathiya Athurupana[2], Rohana Chandrajith[2], Nadeesha H. Koralegedara[2]

1. Post Graduate Institute of Science, University of Peradeniya, Peradeniya, Sri lanka, 2. Department of Geology, University of Perdeniya, Peradeniya, Sri Lanka

Massive layers of red earth formations that belong to the Quaternary age is found along the northwestern coastal belt of Sri Lanka. The deposit is overlaying the Miocene limestone beds, covering approximately 40 sq. km with an average thickness of 20 m. At present the material is wasted and used only as a land filling material. Therefore, the present study aims to evaluate the economic importance and also assess the spatial distribution of economically important minerals in the red-earth deposit. Red earth samples were collected from 2 to 3 m depths from selected locations along the deposit. Sieve analyses, isodynamic separation followed by XRD analyses and ICP-MS techniques were used to determine the particle size distribution, mineralogy and geochemical composition of collected samples. The main constituents of red earth were quartz, clay- and iron oxide minerals such as magnetite and hematite. Zircon and monazite are also present in minor quantities. The granulometric data showed that southern part of the deposit is well sorted (CC<4) sand compared to the northern part (CC>4). The content of Rare Earth Elements (REEs) were significantly higher in the southern part compared to the northern part. Among the REEs, cerium (499 mg/kg), lanthanum (255 mg/kg), and neodymium (205 mg/kg) were dominated. Even though the REEs concentrations were proportionally increased with the depth, some intermediate layers were found with a lower content of REEs. The lateral distribution of opaque minerals such as magnetite and ilmenite showed a similar trend where 2 to 3% of such minerals were recorded. Kaolinite was the most abundant clay mineral in the deposits. The clay content significantly decreased towards the northern part of the deposit. The red earth also showed a potential of removing toxic elements such as Pb, As and Cr from industrial waste water.

Keywords: Red earth, rare earth elements (REE), water treatment potential, Miocene limestone

Mineralogy and sulfur isotopic compositions of the Mowana vein-type copper deposit, Northeastern, Botswana

*AMOGELANG KOOGANNE[1], Akira Imai[2], Ryohei Takahashi[1], Andrea Agangi[1]

1. Akita University, 2. Kyushu University

The Mowana deposit is located in the southern part of the Zimbabwe Craton which extends into the north of Botswana. It contains approximately 72.000 kt of measured and indicated mineral resources at 0.8% average copper grade and 0.25 % cut off grade. The deposit has since discovery received little study and documentation. Therefore, this study presents the preliminary documentation of the mineralization and associated alteration characteristics on the basis of petrography and sulfur isotopic analyses.

The Mowana copper deposit is hosted within the north-northeast striking and nearly vertical dipping sliver known as the Bushman Lineament of carbonaceous and argillaceous metasediments of the Paleoproterozoic Matsitama Metasedimentary Group formed in a large sedimentary basin in the Southern African Shield. The Matsitama Metasedimentary Group is enclosed within foliated granitoids of the Mosetse Complex. The contact between the granite-gneiss and the overlying sediments is tectonic. These units are overlain by the Phanerozoic Karoo Supergroup sequence of conglomerates and siltstones.

The Cu mineralization occurs in quartz ±calcite ±alkali feldspar vein and breccias which are near or in contact with the silicified limestone and argillite host rocks. Moreover, appreciable amounts of galena and sphalerite are hosted in the quartz ±calcite ±fluorite veins. The granitic gneisses occur as country rocks. The graphitic schists occur as irregularly distributed lenses or patches between the mineralized breccia and carbonate rocks as well as the mineralized breccia and the argillite. The host rocks are characterized by silicification, chloritization, epidotization, sericitization, and carbonate alterations. The principal metallic minerals are chalcopyrite, pyrite, galena, and sphalerite. Supergene mineralization is categorized by the significant presence of chalcocite, native copper and bornite. The upper part of the deposit is oxidized as indicated by the presence of supergene malachite and chrysocolla. Gangue minerals are mainly quartz, calcite, sericite, epidote, and chlorite.

Sulfur isotopic ratios were determined on the sulfides; chalcopyrite and pyrite from the mineralized quartz veins. The $d^{34}S$ of five chalcopyrite samples from the mineralized veins range from -0.8 to +3.3‰ while the $d^{34}S$ of two pyrite samples are higher, +15.4 and +18.0 ‰. The contrasting sulfur isotopic ratios from the chalcopyrite and pyrite suggest different sulfur sources for the two minerals. The high $d^{34}S$ of pyrite can be attributed to closed system reduction of seawater sulfate of the Paleoproterozoic era.

Potential for Iron Oxide-Apatite Deposit and Iron Oxide-Copper-Gold Deposit in Japan: A new paradigm beyond current metallogeny

*Hiroyasu Murakami[1], Atsushi MIYASHITA[2]

1. Waseda University, 2. Seikei University

The Naka-Osaka Mine in Shimonita, Gunma Prefecture, Japan, is the geosite of the Shimonita Geopark. This mine is also an industrial heritage site where iron manufacturing was carried out in the early Meiji era in Japan. It was produced high-grade magnetite ore. In the Naka-Osaka deposite, fine-grained euhedral apatite is commonly observed as inclusions of magnetite ore. The apatite containing chlorine has similar chemical property as the altered minerals associated with magnetite, which suggests that apatite has the same origin to magnetite. Magnetite with apatite in a neutral to alkaline alteration zone at high temperatures above 500˚C in close to the large-scale tectonic line. These features of the Naka-Osaka mine strongly suggests that the magnetite ore deposit belongs to the iron oxide-apatite (IOA or Kiruna) type.

In addition to current results from the Naka Osaka deposit showing the probability of IOA (Iron-Oxide Apatite or Kiruna) type deposits in Japan, based on that iron oxide type (IOA and IOCG) deposits were discovered around the world from the Precambrian to the Mesozoic ages, therefore, we will reconsider a potential iron oxide type deposits (IOA and IOCG) among magnetite -bearing hydrothermal deposits in Japan. In the vicinity of the Naka-Osaka Mine, there are magnetite ores with gold-containing skarn at the Nakatsu deposit in the Chichibu Mine, and magnetite ores with gold-containing skarn and loellingite at the Kobushi Mine. The origin of these ore deposits needs to reconsider whether an iron oxide-copper-gold type (IOCG).

Iron oxide (IOA and IOCG) deposits, which is occasionally attracting attention as rare earth resources, have recently been explained by a hydrothermal origin with high-temperature iron-chloride fluid penetrating tectonic zone, which is becoming more convincing than an igneous origin related to solidification of iron oxide melt (so-called magnetite lava). Adding to the result from Naka-Osaka deposit, we will propose a new metallogeny based on identifying the presence of apatite in the magnetite ore and their chemical compositions by expanding a scope of magnetite bearing hydrothermal deposits including Kamaishi and Ashio. We also explore a possibility of discovery for a giant copper deposit in Japan by reviewing the formation temperature, pressure (depth) as well as Cu / Au ratio of these deposits.

Chemical and optical evaluation of zircon synthesized by Li-Mo flux method

*Masahiro KAYAMA[1], Das Kaushik[2], Yuta Tsuchiya[3]

1. Department of General Systems Studies, Graduate School of Arts and Sciences, The University of Tokyo, 2. Department of Earth and Planetary Systems Science, Hiroshima University, 3. Department of Biosphere-Geosphere Science, Okayama University of Science

Zircon, $ZrSiO_4$ phase occurring in various types of terrestrial and extraterrestrial rocks, is an important mineral to interpret the geological history. Crystallization, metamorphic, and sedimentary ages of zircon in the rocks can be determined by the radioactive elements. The zoning textures and Ti content in zircon reflect the thermal history of the magmatic and metamorphic processes. Furthermore, the elementary and structural features of zircon easily change during hydrothermal alteration. Natural zircon shows a decrease of the crystallinity, finally leading to amorphization, as a process of metamictization by radiations from radioactive elements in geological time. Zircon in impactite and meteorites often records an impact event of the host body as the shock-induced microstructure and texture. Such useful information on igneous, metamorphic and sedimentary processes have been obtained from microanalyses (e.g., electron microscope, SHRIMP, LA-ICP-MS, and Raman spectroscopy) of zircon. Synthetic zircon has been available as a standard material for accurate microanalyses, e.g., highly-pure synthetic zircon for checking sample background and a starting material for high-pressure and -temperature experiments to reproduce the metamorphic process and hydrothermal alteration in the geological events. Therefore, in this study, zircon was synthesized by the Li-Mo flux method reported by (Hanchar et al. 2001) using a heating furnace under various conditions.

Synthetic ZrO_2 and SiO_2 powder samples and Li_2SiO_3, Li_2MoO_4 and, MoO_3 flux were put into an unwelded platinum crucible (100 cc) in the heating furnace at room temperature (RT) and ambient pressure. Temperature in the heating furnace rose initially from RT to 1250 ˚C for 18 h, then kept at 1250 ˚C for 10 h, decrease from 1250 to 1000 ˚C for 500, 125, 63, 32, and 12 h (cooling rate of 0.5, 2.0, 4.0, 7.8, and 20.8 ˚C/h, respectively), and finally dropped from 1000 ˚C to RT for 25 h. All the recovered samples were measured by the optical and scanning electron microscopes, cathodoluminescence (CL) microscopy, and Raman spectroscopy. WDS analysis by EPMA and LA-ICP-MS measurements were performed for only zircon synthesized at a cooling rate of 0.5 ˚C/h.

All of the zircon grains synthesized at each cooling rate show a large amount of euhedral single crystals with inherent crystal planes and a few to several hundreds of micrometer size under an optical microscope. The crystal grain size seems to decrease with the cooling rate from 4.0 to 20.8 ˚C/h and show almost no change below 4.0 ˚C/h, implying that all of the dissolved SiO_2 and ZrO_2 were separated completely from the flux above 4.0 ˚C/h to form $ZrSiO_4$ crystals. CL microscopy revealed that there are oscillatory and sector zoning textures in all of the synthetic zircon, of which the shapes are corresponding to crystal planes of the zircon (that is, outer rims) observed in an optical microscope. WDS analyses of the major chemical composition of the zircon at 0.5 ˚C/h show SiO_2, ZrO_2, HfO_2 contents of 33.02, 66.46, and 1.79 wt%, respectively. Chemical compositions of these elements are homogeneous within the single crystals. As a result of WDS analyses of the zircon, trace elements of Y_2O_3, Al_2O_3, ThO_2, P_2O_5, Yb_2O_3, CaO, Nb_2O_5, UO_2, and Sc_2O_3 are below 0.005 wt% in content or undetected. LA-ICP-MS analyses of the zircon indicate that Y and Nb contents reach 2.6 and 1.0 ppm, and La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu, Pb, Th, and U were below 1 ppm or detection limit. Raman spectroscopy of the synthetic zircon at

©2020. Japan Geoscience Union. All Right Reserved.

0.5 ˚C/h calibrated using a Kr bright line exhibits pronounced peaks at 974 and 1008 cm^{-1}, both of which the peak positions are corresponding to theoretical values of zircon unaffected by radiations, that is, metamictization. These facts imply that zircon crystals synthesized here are high quality and is expected to be used as a standard material for various microanalyses and experimental replication.

Geological study around Strontian mine considered from zeolite and galena.

*Yuki Inoue[1], Mana Yasui[2], Hiroshi Hagiya[1], Atsushi Yamazaki[3]

1. Tokyo City University , 2. Waseda Research Institute for Science and Engineering, 3. Department of Resources and Environmental Engineering, School of Creative Science and Engineering, Waseda University

The Strontian mine is located approximately 170 km northwest of Edinburgh in Scotland. The Strontian mine had been produces lead and zinc since the 18th century, and barium in the 20th century. Not only mineral ore but zeolites containing Sr and Ba have been reported(Green et, 2008).

Utada (1995) reports that there is no relationship between host rock and zeolite in the Izu Peninsula, but in recent years Fujita et al.(2016) have closely related host rocks and zeolite as their composition in the Ogasawara Islands. The purpose of this study is to compare the composition of zeolite from the Strontian mine with the host rock and another rocks and to examine the formation and neighboring geologic relationships of zeolite.

This study investigated ore formation centered on zeolite. Zeolite was found at the Strontian mine. They were analyzed using SEM-EDS and XRF, XRD. The zeolite and rocks produced at The Strontian mine were analyzed using SEM-EDS and XRF and XRD. Three types of zeolite produced at the Strontian mine, harmotome, brewsterite, and heulandite-Sr, were confirmed by XRD and SEM-EDS. From the symbiotic relationship of these minerals, the temperature during zeolite formation was estimated at 65-85 ℃. Zeolite from the Strontian mine is rich in bivalent cations. Also, they contain a lot of Sr and Ba. The granodiorite around the mine is rich in Sr and Ba. Sr and Ba were the most abundant in plagioclase. Observation of granodiorite with a polarizing microscope and SEM-EDS revealed that Ca and K of plagioclase were replaced and became sericite.

The age of formation of the lead mine was estimated using galena isotopes. The Strontian mine was estimated at 430 Ma, considering a two-stage evolution from 2670 Ma Lewis gneiss. This age was consistent with the age of titanium and zircon granodiorite.

From the analysis results of these zeolite and galena, Pb, Sr and Ba derived from granodiorite formed the Strontian deposit at the Strontian mine by hydrothermal circulation accompanying the intrusion of the 430 Ma Strongian granodiorite. Finally, it is considered that the hydrothermal activity contained in the veins formed zeolite as the temperature of the series of hydrothermal activity circulation decreased.

The influence of OH content on elastic constants of single-crystal topaz studied via sphere-resonance method

*Kako Aradachi[1], Tohru Watanabe[1], Morihisa Hamada[2]

1. University of Toyama, 2. Japan Agency for Marine-Earth Science and Technology

Transport of ocean floor sediments by plate motions might play an important role in the circulation of materials within the Earth. Imaging subducted sediments through seismological observations requires a thorough understanding of elastic properties of sediment origin hydrous minerals. Topaz is a hydrous mineral with ideal chemical formula $Al_2SiO_4(F_{2-x},OH_x)$, which can be formed from subducted sediment at high pressures. Although elastic constants of topaz have been reported, experimentally determined values show no systematic relationship between elastic constants and OH molar content. Moreover, there are significant differences between experimental and theoretical values. To understand the influence of OH content on elastic constants, we have studied elastic constants of three single crystals of topaz with different OH contents (x=0.28, 0.45, 0.66) by the sphere-resonance method.
Sphere samples (D=2.6~6.5 mm) were made from single crystals of natural topaz by the two-pipe method. Lattice parameters were determined and orthorhombic symmetry was confirmed by XRD. Resonant frequencies were measured with different specimen-holding forces. Extrapolating to the specimen-holding force of zero, we obtained frequencies of "free" oscillation. Elastic constants were determined by comparing measured and calculated resonant frequencies. The xyz algorithm (Visscher et al., 1991) was employed to calculate resonant frequencies of the sphere samples. At an ambient temperature, Our determined elastic constants C_{11}, C_{22}, C_{44}, C_{66}, C_{12}, C_{23} and C_{31} increase with increasing OH molar content, while C_{33} and C_{55} decrease. These changes are similar to those seen in theoretical values (Ulian and Valdre, 2017) except for C_{11}, though there are significant differences between experimental and theoretical values.

Structural changes of diatomaceous earth by heat treatment

*Naoya Sasaki[1,2], Akane Arasuna[1], Masayuki Okuno[1]

1. Kanazawa University, 2. Industrial Research Institute of Ishikawa

In this study, the structural changes in the diatomaceous earth from U.S.A (Grade D110, Celite Co.) by heat treatment up to 1200˚C were investigated using XRF, XRD, ATR-IR and Raman spectroscopy. These results provide important information to elucidate the structure of fossilized diatom shell that has been rarely reported and the characteristic of structural change by heat treatment comparing the previous result for diatom.
The results of chemical analysis show this sample included of 93.1 mass% SiO_2 due to diatom shells and also containing a small amount of Al_2O_3, Fe_2O_3, MgO and CaO from clay minerals. Observed TG curve of this sample shows it contains about 12 mass% of H_2O molecules and OH. The diatomaceous earth samples were heat-treated at 200, 400, 600, 800, 900, 1000, 1100 and 1200˚C.
The XRD patterns for samples up to 800˚C show broad amorphous phase peaks at around 2θ=22˚ and weak diffraction peaks at around 2θ=19˚ due to clay minerals. The XRD patterns for heat-treated samples at 900 and 1000˚C showed amorphous phases. This means clay minerals amorphized at 900˚C due to dehydration. At 1100˚C and 1200˚C, cristobalite phase were observed. The positions of broad peaks for amorphous phase show the samples have 6-membered rings of SiO_4 tetrahedra as the basic structural unit. On the other hand, previous results for thermal change of diatom show crystallization above 800˚C.
ATR-IR spectrum for non-treated sample is similar with that of diatom except sharp O-H band at around ν=3620cm^{-1}, this band could be attributed to OH of clay minerals. On the other hand, the broad band ν=2800-3700cm^{-1} could be attributed H_2O molecules in amorphous SiO_2 phase. se bands disappeared by heating at 900˚C. This result is consistent with that of XRD measurement. bands at ν=800 and 1020cm^{-1}, which are attributed to the Si-O-Si bending vibration and the Si-O stretching mode show not large thermal change up to 1000˚C. Over 1000˚C, these bands shift their position and become sharp by crystallization of cristobalite.
Raman spectrum at ν=200-800cm^{-1} of non-treated sample is also similar with that for diatom of the previous work. This mean the basic structure of diatomaceous earth composed 6-membered rings of SiO_4 tetrahedra. Because, the intensity around ν=450cm^{-1} is strong, which band could be attributed symmetric stretching band of Si-O-Si. By increasing treated temperature up to 1000˚C, the intensities around at ν=450, 490 and 600cm^{-1} increase. This means 6-membered rings of SiO_4 tetrahedra are largely increased and 4- and 3-membered rings appear and the nanostructure becomes similar to the spectrum SiO_2 glass by heat treatment. This Raman spectrum change is not similar with that of diatom. Furthermore, the structural changes of diatomaceous earth by heat treatment show a different tendency from the diatom that have been reported so far. Now, we can guess that the difference of temperature change in XRD between diatom and diatomaceous earth can be probably due to the small quantity of clay minerals and fossilization process diatom to diatomaceous earth.

Density and elastic properties of liquid gallium using externally heated diamond anvil cell

*Ryo Tsuruoka[1], Hidenori Terasaki[1], Seiji Kamada[2,3], Fumiya Maeda[3], Tadashi Kondo[1], Iori Yamada[1], Satoru Urakawa[4], Akira Yoneda[5], Naohisa Hirao[6], Saori I. Kawaguchi[6], Akihiko Machida[7]

1. Department of Earth and Space Science, Graduate School of Science, Osaka University, 2. Frontier Research Institute for Interdisciplinary Sciences, Tohoku University, 3. Department of Earth and Planetary Materials Science, Graduate School of Science, Tohoku University, 4. Department of Earth Sciences, Okayama University, 5. Institute for Planetary Materials, Okayama University, 6. JASRI, 7. QST

It is important to measure density of liquid metals at high pressure and high temperature for understanding compression behavior and elastic properties of liquid metals. Since gallium (Ga) has a low melting temperature, Ga can become liquid state easily under high pressure. The densities of liquid Ga have been reported by X-ray tomography (Li et al. 2014), by sound velocity (Ayrinhac et al. 2015), by reverse Monte Carlo simulations combined with X-ray scattering data (Yu et al. 2012). However these densities were not consistent with each other. X-ray absorption method is effective to measure liquid density directly. In this study, the densities of liquid gallium were measured using X-ray absorption method combined with an externally heated diamond anvil cell (DAC).

In X-ray absorption method, density of liquid Ga was obtained from measured incident and transmitted X-ray intensities of the samples using Lambert-Beer law (Takubo et al. 2019). Ga sample and two reference materials (RbBr, KBr, or Fe) were loaded into each hole drilled on a pre-indented Re gasket. The Re gasket was coated with Al_2O_3 to avoid a reaction between the Ga sample and the gasket. High pressure was generated using a symmetric DAC with a lever-arm frame. High temperature was generated using external heaters composed of Pt-Rh wires with a ZrO_2 insulator. X-ray absorption measurements were conducted with monochromatic X-ray of 30 keV at BL10XU and BL22XU beamlines in SPring-8.

The density of liquid Ga were measured up to 10 GPa and 533 K. The elastic properties (bulk modulus (K_{T0}), its pressure derivative (K')) of liquid Ga were calculated by fitting the density data with equations of state (EOSs) and obtained 45.8(4) GPa, 6.1(2) from third-order Birch-Murnaghan EOS at 500 K, respectively. In lower pressure region, the compression curve is consistent with the density calculated from sound velocity data reported by Ayrinhac et al. (2015). However, our results show that density variation is smaller than Ayrinhac et al. (2015) in higher pressure (e.g. 1% smaller at 10 GPa).

Nano-polycrystalline diamond synthesized through the decomposition of stearic acid under high pressure and high temperature condition

*Hideaki Kawamura[1], Hiroaki Ohfuji[1]

1. Geodynamics Research Center, Ehime University

Nano-polycrystalline diamond (NPD) synthesized by the direct conversion of graphite under high pressure and high temperature conditions (15-25 GPa, 2000-2500℃) has an ultra-high hardness and superior mechanical properties and is therefore widely used for various industrial and scientific applications. In the present study, we found a novel route for synthesizing NPD using stearic acid ($C_{18}H_{36}O_2$) as a starting material. The temperature condition required for the synthesis of transparent NPD from stearic acid is as low as 1000℃ at 13 and 17 GPa, which is surprisingly lower (by ~1000℃) than those for the conventional NPD synthesis using graphite and related carbon sources such as glassy carbon. We also characterized the microtexture and crystallographic feature of the products recovered from a wide range of temperature and pressure conditions using TEM and discussed the formation mechanism from stearic acid at significantly lower temperatures. The samples recovered from 13 and 17 GPa are transparent NPD composed of extremely fine diamond crystals with grain sizes smaller than 20 nm. In contrast, those synthesized at 10 GPa are composed exclusively of graphite, whose crystallinity and grain size clearly change from almost amorphous like to platy crystals up to 100 nm with heating temperature.

Our study suggests that the amorphous-like, extremely poorly crystalline carbon produced by the thermal decomposition of stearic acid provides preferential nucleation sites for diamond and significantly lower the activation energy for diamond formation. The removal of volatile components such as H_2O generated through the stearic acid decomposition from the system is also important to obtain pore-free transparent NPD. Our finding would open up new possibilities for further sizing-up of NPD samples (at present 1 cm both in diameter and height at maximum) at moderate temperature and pressure, which will be essential for new and advanced applications of NPD in both scientific and industrial fields.

The magnetite-maghemite-hematite transformation

*Ibuki Kinebuchi[1], Atsushi Kyono[1], Yoshinari Sano[1]

1. University of Tsukuba

Magnetite (Fe_3O_4), which is ubiquitous in the crust, is transformed into hematite (α-Fe_2O_3) by the oxidation of Fe^{2+} to Fe^{3+}. In this oxidation process, maghemite (γ-Fe_2O_3) is formed as an intermediate phase, which is isomorphous as magnetite. Maghemite has a part of the octahedral site in magnetite that is vacancy. Elucidation of the oxidation mechanism of magnetite will lead to elucidation of magnetic susceptibility changes during weathering of igneous and sedimentary rocks, but continuous changes in local structure of magnetite are largely unknown. In this study, in order to elucidate the mechanism of the phase transition from magnetite to hematite via maghemite, X-ray absorption fine structure (XAFS) and X-ray diffraction (XRD) measurements were used to determine the area around Fe in the oxidation process of magnetite. We investigated the continuous local structural change of, and the change of long-range structure of the whole crystal.
XANES showed that the proportion of Fe^{3+} increased with increasing heating temperature and heating time, and finally all Fe became Fe^{3+}. From the radial structure function of EXAFS, it was found that the peak depending on the presence of Feoct in magnetite attenuated as the heating temperature increased, and then changed to a function indicating the structure of hematite. From the XRD, as the heating temperature increases and the heating time increases, first, octahedral vacancies have characteristic peaks in ordered maghemite, and then magnetite and maghemite peaks decrease, and hematite peaks appear and increase. From the above results, in the oxidation of magnetite, the Fe-O bond of some octahedral site is broken first, and Fe diffuses to become maghemite. Then, the rearrangement of Fe and O in the octahedral site with a vacancy at the center and the Fe-O4 tetrahedral site is thought to cause a phase transition to a hematite consisting entirely of octahedra.

Effect of pressure on the band gap and the Seebeck coefficient of silicon

*Hitoshi Gomi[1], Ran Wang[2], Takashi Yoshino[2]

1. Tokyo Institute of Technology, 2. Okayama University

Many physical properties of semiconductors and insulators are characterized by their band gap energy, which is the energy difference between the valence band minimum (VBM) and the conduction band maximum (CBM). The pressure dependence of the band gap energy of Si is unique among the group 14 elements, which form the diamond-type crystal structure. The other three semiconductors (C, Ge and Sn) have positive pressure coefficient of the band gap energy, i.e. the band gap energy increases with increasing pressure whereas Si has negative pressure coefficient (Wei & Zunger, 1999; Angilella et al., 2008). The Seebeck coefficient is one of the important physical properties that closely related with the band gap energy (Goldsmid & Sharp, 1999; Ricci et al., 2017). However, measurements of the Seebeck coefficient under high pressure are very limited for both metallic (e.g. Getting & Kennedy 1970; Nishihara et al., 2019) and non-metallic (Yoshino et al., submitted) samples. Therefore, we conducted first-principles calculations of Si-I (diamond structure) by using the Quantum ESPRESSO package. The structure relaxation was performed at 0, 5 and 10 GPa pressures with PBE-PAW potential. To calibrate the bandgap, we also computed the quasi-particle self-consistent GW (QSGW) calculation with the ecalj package. The calculated bandgap values are $E_{g,PBE}$ = 0.609 and $E_{g,GW}$ = 1.465 eV for PBE-PAW and QSGW, respectively at 0 GPa, whereas the literature value is 1.11 eV. The bandgap energy decreases with increasing pressure. Note that most of the exchange correlation functionals such as PBE underestimate the bandgap energy, whereas the GW approximation tends to overestimate it. Because the Seebeck coefficient critically depends on the bandgap energy, we empirically corrected it as $E_g = 0.4*E_{g,PBE} + 0.6 * E_{g,GW}$. The Seebeck coefficient was calculated by using the BoltzTraP package. The effect of impurity is represented within the rigid band model. The absolute value of the Seebeck coefficient decreases with carrier (impurity) concentration. Our calculation at 0 GPa and 300 K underestimated the literature values with the impurity concentration lower than ~10^{19} (cm^3). This is due to the phonon drag effect (Weber and Gmelin, 1991). Our calculation considered the diffusion term only, but the actual Seebeck coefficient should be sum of the diffusion term and phonon drag term. Note that the phonon drag becomes negligible at high temperature and/or high carrier concentration. The absolute value of the Seebeck coefficient decreases with increasing pressure, because the bandgap decreases with pressure. Similarly, it decreases with decreasing carrier concentration at high temperature. Therefore, pressure (and hence the bandgap energy) and impurity concentration have competing effects on the Seebeck coefficient of Si.

Density measurement of magmas under high pressure by the sink/float method

*Akio Suzuki[1]

1. Department of Earth Science, Graduate School of Science, Tohoku University

Density of magmas (silicate melts) is an important property, which controls its transportation in the Earth’ s interior. Therefore, various studies have been carried out under high pressure. We have engaged in the density measurement under the static compression. By the measurement of the X-ray absorbance, we can determine the density. However, the synchrotron X-ray beam is essential for high pressure experiments. The density of melt under high pressure can be restricted by observing the sinking and the flotation of the buoyancy markers in the melt. This sink/float experiments can be conducted without the synchrotron beam. Using the sink/float method we have measured various compositions of magmas (silicate melts). The buoyancy marker is selected with considering the following requirements. (1) The marker crystal does not react with the melt. (2) Its equation of state is accurately determined under high pressures and high temperatures to calculated the density of the marker. In the experiments, initially the marker crystal is loaded at the center of the sample container, and it is surrounded by the sample powder. At high pressure the sample was heated to be molten. If the heating duration is sufficient, the marker crystal sinks or floats depending on the density difference between the surrounding melt and the marker. The sample is quenched under high pressure to hold the position of the marker crystal. The recovered sample is cut to confirm the position of the marker. In the presentation, we demonstrate the recent development of the density measurement of magmas (silicate melts) by the sink/float method.

Twinning in wadsleyite

Nobuyoshi Miyajima[1], Johannes Buchen[1,2], *Takaaki Kawazoe[1,3]

1. Bayerisches Geoinstitut, University of Bayreuth, 2. Division of Geological and Planetary Sciences, California Institute of Technology, 3. Department of Earth and Planetary Systems Science, Hiroshima University

Twinning was discovered in wadsleyite, which is the most abundant mineral at the upper part of the mantle transition zone. Wadsleyite crystals were synthesized from a powder of San Carlos olivine with distilled water at a pressure of 15 GPa and a temperature of 1670 K for 3 h using a multi-anvil apparatus. The wadsleyite twin was found based on change in color at a twin boundary due to strong pleochroism of wadsleyite by observing a thin section of the twin by optical microscopy. A thin foil perpendicular to the twin boundary was cut by focused iron beam (FIB) and was observed by transmission electron microscopy (TEM). The TEM observation revealed that twin domains make a 180˚ rotation about an axis perpendicular to the {101} plane in the pseudo-cubic system (cf. ringwoodite). Moreover, the composition plane of the twin domains is the {101} plane in the pseudo-cubic system. The wadsleyite twinning may be important in phase transformation, growth and deformation.

Melting experiments in the system $MgSiO_3$-SiO_2 at 13 GPa

*Takuya Moriguti[1], Akira Yoneda[1], Eiji Ito[1]

1. Institute for Planetary Materials, Okayama University

Melting behavior of silicates is essentially important to assess the chemical differentiation in a deep magma ocean in an early stage of the Earth. Therefore, melting relations of the system MgO-SiO_2 have been extensively studied since a pioneer work by Bowen and Anderson [1]. Furthermore, many scenarios of chemical differentiation in the deep magma ocean has been proposed based on the results of high pressure melting experiments (e.g. [2]). However, almost all of these works have been carried out on limited range of compositions from MgO to $MgSiO_3$, assuming that the bulk mantle composition is peridotitic or close to that derived from CI chondrite. Recently, enstatite chondrite (E-chondrite) has been favored as the source material of bulk earth [3], because the isotope systematics of the Earth and Moon are nearly identical to those of E-chondrite over O, N, Mo, Re, Os, and Cr. In E-chondrite, the silicate composition is characterized by $SiO_2/(SiO_2+MgO)$ = 0.53 ~ 0.58 (molar ratio: SiO_2[M]) [4], which is substantially higher than that of the peridotitic mantle (~0.43).

In order to understand the mantle differentiation in the E-chondrite earth model, it is indispensable to clarify the melting relations in the system $MgSiO_3$-SiO_2 at high pressures. Moreover, it also enables us to constrain the chemical composition of the crust formed in the early Earth. Nevertheless, there have been only limited works on the melting behavior of the system $MgSiO_3$–SiO_2 under high pressures. Information regarding phase relations in the system has been so far limited to 5 GPa based on the experiments using the multi anvil apparatus (MAA) [5], Using a diamond anvil cell (DAC), on the other hand, melting experiments on the system MgO-SiO_2 were carried out at pressures from 24 to 139 GPa in phase equilibrium studies in order to determine eutectic melting curves and examine eutectic compositions [6, 7]. Compared with DAC, MAA has remarkable advantages of larger sample volume under stable and homogenous temperature conditions (e.g. [8]). In this study, therefore, we are precisely determining the melting relations in the system $MgSiO_3$–SiO_2 at pressures between 5 and 25 GPa using the Kawai-type multi anvil apparatus; we would present the results obtained at 13 GPa in the presentation.

In the system $MgSiO_3$–SiO_2, SiO_2[M] values of eutectic point were 0.56 (1620 ºC) [9] and 0.60 (1920 ºC) [5] at 1 and 5 GPa, respectively, showing increase of SiO_2[M] with increasing temperature and pressure. In this study at 13 GPa, eutectic composition was 0.60 of SiO_2[M] at 2300 ºC, which is same as that at 5 GPa and showing systematic increase in eutectic temperature with increase of pressure. If source material of Earth is enstatite chondrite, therefore, composition of melts formed at magma ocean (up to ~3000 ºC and ~30GPa) in the early Earth show chemical homogeneity to ~400 km depth from the surface.

In this study, we also examined temperature effect on the experimental pressure up to 2500 ºC based on the phase boundary between stishovite–coesite (SiO_2), showing that the pressure at 2500 ºC was almost 3 GPa higher than that at room temperature. We conclude that this difference is caused by thermal expansion of specimens in the cell during heating.

[S-MP37] Supercontinents and crustal evolution

convener:Madhusoodhan Satish-Kumar(Department of Geology, Faculty of Science, Niigata University), Krishnan Sajeev(Centre for Earth Sciences, Indian Institute of Science), Tomokazu Hokada(National Institute of Polar Research), Yasuhito Osanai(Division of Evolution of Earth Environments, Faculty of Social and Cultural Studies, Kyushu University)

Supercontinent formation and dispersion has been enigmatic in the Earth's history. Eurasia is one such current supercontinent and incredible progress in the understanding of its geological evolution has been achieved in the past decades. Earlier supercontinents in
the Earth's history such as Gondwana (0.5 Ga), Rodinia (1.0 Ga), Columbia/Nuna (2.0 Ga), Kenorland (2.5 Ga) and Vaalbara (3.1 Ga), have been the focus of several studies, however limited information on older supercontinents has restricted in understanding their tectonic evolution. Several important unsolved issues remain, such as how, when and where these supercontinents formed and how long they remained as such before breaking apart. Additional questions arise on the processes that triggered the fragmentation and unification of continents. In this session, we invite authors around the world to present original new
data as well as review results on the continental scale crustal processes and tectonic evolution that are associated with supercontinent formation events in Earth's history. The well-studied Eurasia and Gondwana supercontinents are of particular focus. Topics of interest include, but not restricted to, extremes in metamorphism, P-T-d-t evolution, magmatism, and the role of fluids. We hope to provide a platform for scientific discussions that will enlighten our understanding of the physical and chemical processes in the continental crust that records episodes of orogenesis that contributed to the formation and evolution of supercontinents.

Subdivision of the Lützow-Holm Complex in East Antarctica

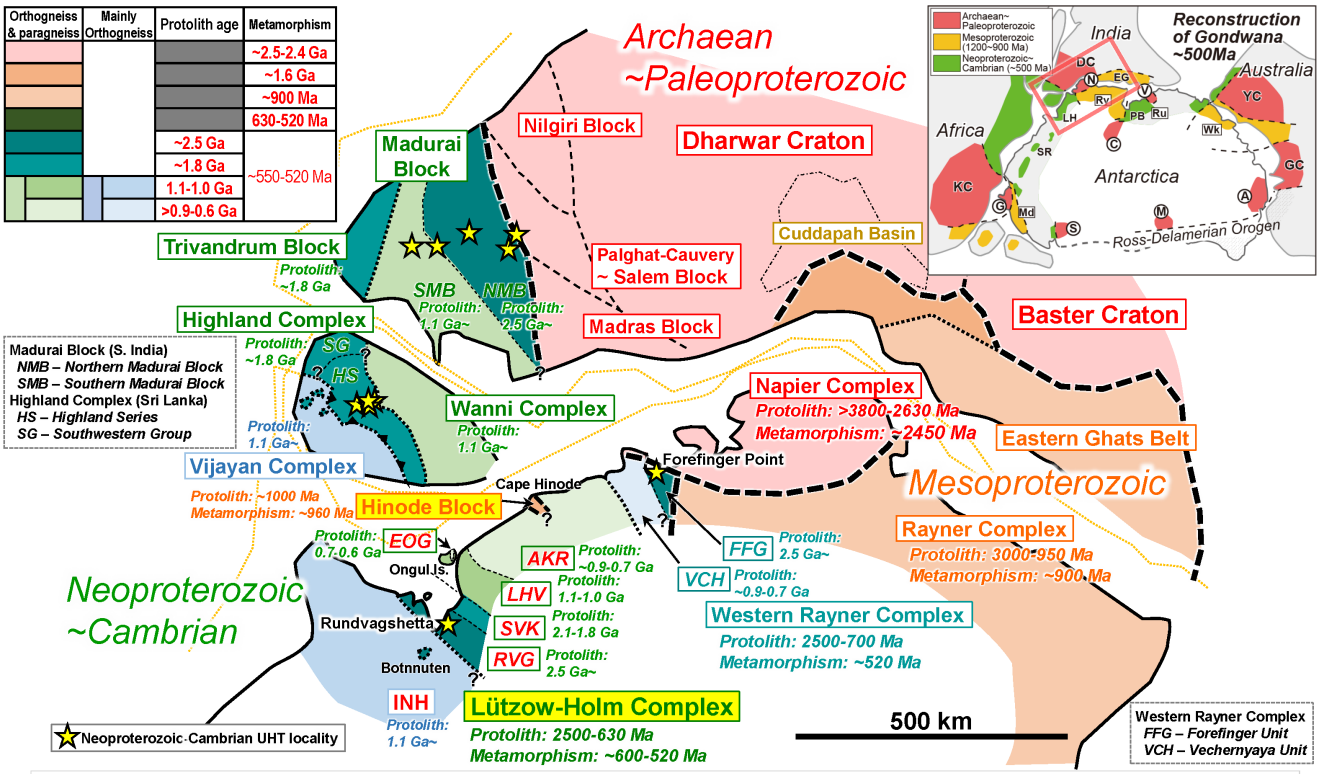
*Tomokazu Hokada[1,2], Daniel J. Dunkley[1], Kazuyuki Shiraishi[1,2], Yoshikuni Hiroi[3,1], Yoichi Motoyoshi[1,2]

1. National Institute of Polar Research, 2. The Graduate University for Advanced Studies, SOKENDAI, 3. Chiba University

Neoproterozoic to early Paleozoic geologic evolution of East Antarctica is key for understanding of the final amalgamation of Gondwana supercontinent. The Lützow-Holm Complex in eastern Dronning Maud Land of East Antarctica is located within the Neoproterozoic-Cambrian suture zones continuing from India through Sri Lanka. All these areas experienced high-grade metamorphism at ~600-520 Ma (e.g., Shiraishi et al., 2008).

In this presentation, we summarize the currently available U-Pb ages of this area (see Table and Figure attached in this abstract), and propose the subdivisions of the Lützow-Holm Complex based on the protolith ages as follows (from southwest to northeast);
- Inhovde Unit (INH; 1070-1040 Ma),
- Rundvag Unit (RVG; 2520-2470 Ma),
- Skallevik Unit (SKV; 1830-1790 Ma),
- Langhovde Unit (LHV; 1100-1050 Ma),
- East Ongul Unit (EOG; 630 Ma), and
- Akarui Unit (AKR; 970-750 Ma).

As discussed in Shiraishi et al. (2008), one important issue of this area is Cape Hinode that is geographically located within Akarui Unit of the Lützow-Holm Complex. The rocks in Cape Hinode experienced the high-grade metamorphism at ~960 Ma that is significantly older than the surrounding Lützow-Holm rocks (~600-520 Ma). Cape Hinode is, therefore, independent (exotic) to the surrounding Lützow-Holm Complex, and is defined as “Hinode Block”. The boundary between Hinode Block and the surrounding Akarui Unit of the Lützow-Holm Complex is not clear. Further study is required to interpret Kasumi Rock and Niban Iwa either belonging to Akarui Unit or Hinode Block.



Although this presentation does not intend to do the correlation between Antarctica and Sri Lanka-India, the earlier correlation proposed by Shiraishi et al. (1994) requires only minor modification. Lithological and geochronological similarities imply some broad picture on the correlation among each geologic units in Antarctica, Sri Lanka and India (see Figure). For example, Botnnuten located in the southernmost part of the Lützow-Holm Complex is one isolated mountain exposed in the ice sheet, and is possibly klippe belonging to Rundvag Unit as like several isolated klippes (Highland Complex) located within the Vijayan Complex, Sri Lanka.

Figure: Regional geology, and the subdivision of the Lützow-Holm Complex.

Table: Summary of the published U-Pb ages for the Lützow-Holm Complex. Pink: metamorphic rocks (igneous origin), blue: metamorphic rocks (sedimentary origin), gray: intrusive rocks (syn/post-tectonic).

Detrital zircon geochronology of the Limpopo Complex, southern Africa: Implications for Neoarchean to Paleoproterozoic collisional events

Taeko Uehara[1], *Toshiaki Tsunogae[1,2], Thembiso Otladisang Basupi[1], Yukiyasu Tsutsumi[3]

1. The University of Tsukuba, 2. University of Johannesburg, 3. National Museum of Nature and Science

We report new detrital zircon ages of quartzites from the Central Zone of the Limpopo Complex, which corresponds to the collisional suture within the Kalahari Craton. The Central Zone has been subdivided into several units: Beit Bridge Complex, Phikwe Complex, and Motloutse Complex. The Beit Bridge Complex occupies the dominant part of the Central Zone in Zimbabwe and South Africa, and is composed of supracrustal rocks including pelitic gneiss, meta-BIF, marble, quartzite, and metabasites that underwent high- to ultrahigh-temperature metamorphism (e.g., Tsunogae and van Reenen, 2011). Cores of detrital zircons from quartzites show magmatic ages of 3.6-3.0 Ga, suggesting that the zircons were probably derived from proximal sources such as the basement gneisses in the Zimbabwe Craton and the Kaapvaal Craton. The ages are also comparable with the inferred collision age of the Zimbabwe and Kaapvaal Cratons (ca. 2.7 Ga), suggesting that the quartzites deposited between 3.0 and 2.7 Ga.

In contrast, detrital zircon ages of the Phikwe and Motloutse Complexes in Botswana are significantly younger (2.9-2.4 Ga), suggesting that the quartzites from the complexes deposited after 2.4 Ga. Therefore, although Beit Bridge, Phikwe, and Motloutse Complexes are correlated based on the occurrence of similar supracrustal lithologies, the quartzites in the Botswanan side of the Central Zone might have formed after the Neoarchean “Limpopo Orogeny”. The timings of protolith formation and high-grade metamorphism in the Phikwe and Motloutse Complexes could be related to the Magondi Orogeny that affected the western part of the Zimbabwe Craton at ca. 2.0 Ga.

Multiple sulfur isotope geochemistry of the Precambrian mafic dyke swarms in the Dharwar craton, South India.

*Silpa Ammini Sasidharan[1], Madhusoodhan Satish-Kumar[1]

1. Department of Geology, Faculty of Science, Niigata University

Archean rock units are perfect tracers of various events occurred in the early Earth systems. The records of the anoxic atmosphere in the Archean and the interaction of the lithosphere-hydrosphere and atmosphere has been recorded in these units as Mass Independent Fractionation (MIF) of sulfur isotopes until about 2.4 Ga. The recycling of these Archean materials in the mantle leads to the occurrence of sulfur isotopic composition with Mass independent fractionation in the mantle-derived rocks. However, isotope fractionation can also occur in high-temperature high-pressure conditions, possibly associated with deep mantle dynamics. As per the cosmochemical records, a prime share of the Earth’s sulfur is present at the core [1]. This implies that the magma reservoirs in the deep mantle should also have fractionated sulfur isotopes although it has been considered to have chondritic sulfur isotopic ratio. In the mantle, sulfur is found predominantly in the form of sulfides [2]. Significant equilibrium isotopic fractionation occurs in the deep Earth under the higher pressure-temperature conditions, however, recently recycling of surface sulfur has been considered as well using multiple sulfur isotope signatures [3].
In the current study, the mafic dyke swarms in the Dharwar craton are considered. A detailed geochemical characterization of the dykes were carried out, including Sr and Nd isotopic composition. The results indicate a prominent enriched mantle component in younger paleoproterozoic dykes, whereas older Archean dykes preserve primitive mantle signatures [4]. Reconnaissance analysis of representative dyke of various ages have been carried out for the multiple sulfur ($\delta^{34}S$, $\Delta^{33}S$ and $\Delta^{36}S$) isotope composition. $\delta^{34}S$ for all the samples were negative, whereas $\Delta^{33}S$ and $\Delta^{36}S$ shows only nominal, but distinct variations. The samples are showing a scattered distribution in the variation diagrams of both $\delta^{34}S$ versus $\Delta^{33}S$ and $\Delta^{33}S$ versus $\Delta^{36}S$ and are suggesting a mantle signature in most cases. The distribution of the multiple sulfur isotope and their relative abundances in the form of $\Delta^{33}S$, $\delta^{34}S$, and $\Delta^{36}S$ leads to a better understanding of the Archean sulfur reservoirs and the possible isotopic fractionation in the deep earth. Further detailed studies are ongoing, and we present a comprehensive evaluation of recycling vs. mantle components in the Archean to Paleoproterozoic lithospheric mantle beneath the Dharwar craton.

Signatures of poly-phase deformation and an upper amphibolite metamorphism from garnet bearing schists of Askot Klippe, Kumaun Himalayas

*Prakash Chandra Arya[1], Krishnan Sajeev[1]

1. Indian Institute of Science

Askot klippe, a detached mass from the main crystallines of the Himalayas, lies in the lesser Himalayan sedimentary zone of the eastern Kumaun Himalayas, it is known for its occurrence of polymetallic mineralization within the schist and gneisses. The present work is focused on microtextural studies and computation of the thermal gradients of the garnet bearing schists of Askot klippe, these schists preserves signatures of poly phase deformation in their microstructure related to tectonic transportation and deformational histories of Himalayan orogeny. The micro-texture of these schists shows three distinct stages of deformation (D1, D2, and D3) with syn-tectonic garnet growth. The Thermal gradients have been computed by using Fe-Mg exchange between garnet and biotite. The X_{Mg} values for garnet and biotite are X_{Mg} (grt) ~ 0.06 and X_{Mg} (bt) ~ 0.85 respectively. The computed temperatures (~590 ^{o}C) suggests that the garnet bearing schists of Askot klippe has undergone a peak metamorphic conditions upto upper amphibolite facies.

Sr-Nd isotopic evidence for juvenile components and extensively reworked ancient crustal materials in the Vijayan Complex, Sri Lanka

*M A Sanjeewa P K Malaviarachchi[1], Madhusoodhan Satish-Kumar[2], Toshiro Takahashi[2]

1. Department of Geology, Faculty of Science, University of Peradeniya, Sri Lanka, 2. Department of Geology, Faculty of Science, Niigata University, Japan

The Vijayan Complex (VC) of Sri Lanka comprises a significantly large volume of calc-alkaline amphibolitic and granitic orthogneises (biotite gneiss, hornblende-biotite gneiss and granitoids) of ages known as ~1-1.1 Ga. A considerable volume of basic and felsic to intermediate magmatic intrusions also occur concordant with the main amphibolitic-granitic suite. In the present study, we present major and trace elements and Sr-Nd isotope systematics of a range of orthogneisses from the Vijayan Complex of Sri Lanka. Two groups of samples were recognized geochemically; (1) rocks having OIB-like trace and rare earth element composition with less-radiogenic 87Sr/86Sr isotope ratios (Depleted Group) and (2) rocks having MORB-like composition with extremely high-radiogenic 87Sr/86Sr ratios (Enriched Group). The majority of the samples in both groups show depleted mantle-model ages (TDM) in the range of 1.4-3.3 Ga, which is considerably older than the published magmatic crystallization age (~1 Ga) of the VC. High and variable Sr initials and negative epsilon Nd values of > +4 are compatible with their derivation by melting of older basement rocks with a long crustal residence history. The rest of the samples have model ages in the range of 0.9-1.1 Ga, nearly-coeval with the crystallization age of the VC, indicating their separation from the mantle as juvenile inputs. Therefore, protolith sources of the majority of these rocks could be mixtures of distinctive components formed much earlier than the time of predominant magmatism (~1 Ga) in the VC. Hence, we envisage that the VC constitutes a collage of juvenile components and extensively reworked ancient crustal materials in variable proportions within the main amphibolitic-granitic suite.

Geochemical characteristics of mafic and felsic igneous rocks (1.9-1.75 Ga) in the Lesser Himalaya: Regional variation and its implications for tectonic setting

*Ryuichi Shinjo[1], Tomoki Amuro[1], Kohei Oura[1], Kazuya Oshiro[1], Shiro Tahara[1], Harutaka Sakai[2]

1. Department of Physics and Earth Sciences, University of the Ryukyus, 2. Department of Geology and Mineralogy, Kyoto University

The major and trace element and Nd-Hf isotopic compositions of Proterozoic meta-igneous rocks from the lower part of Lesser Himalayan sequence provide insights into the nature of their source mantle and its tectonic setting. We observed bimodal (basaltic and rhyolitic) magmatic feature in these rocks; this type of volcanism generally occurs in areas of extensional tectonics, particularly rifts. Two types of mafic rocks are identified: within-plate-type (OIB or more specially E-MORB like) rocks and Nb-Ta-depleted, continental arc like rocks. Within-plate type mafic rocks are dominated in the eastern Nepal, but similar rocks are also found in the western Nepal. Although models for the tectonic setting of these igneous rocks remain controversial (e.g., passive margin, continental arc, continental rift with possible hotspot), our new geochemical data supports the rift model associated with mantle plume activity, which evolved to the passive margin. The Nb-Ta depleted, arc-like rocks have lower eNd (t) and eHf (t) than within-plate type rocks; we consider that this type of magmas formed by interaction of mantle-derived magmas with crustal components. The felsic rocks have similar or slightly lower eNd (t) and eHf (t) values relative to arc-like mafic rocks, suggesting relatively limited crustal interaction. They are derived from juvenile crust of underplated mafic magmas. Most of felsic rocks have remarkably low Nb/Ta ratios (<5), suggesting modification on their chemical composition by intensive sub-solidus magmatic-hydrothermal alteration.

A Tarim-North India connection in northern Gondwana related to final closure of the Proto-Tethys Ocean: Constraints from provenance of early Paleozoic sedimentary rocks in the Altyn Tagh orogen

*Qian Liu[1,2], Toshiaki Tsunogae[2,3], Guochun Zhao[4,5]

1. JSPS, 2. Tsukuba Univ. , 3. Johannesburg Univ. , 4. HKU, 5. Northwest Univ.

Evolution of the northern margin of Gondwana, especially to the north of India and Australia, remains enigmatic. The primary reason for this enigma is complex amalgamation of northern Gondwana involving a wealth of present-day East Asian blocks associated with consumption and closure of the Proto-Tethys Ocean during early Paleozoic time. Compared to considerable progress on configuration of some other Asian blocks in northern Gondwana (e.g., South China, North China, and Lhasa, etc.), much controversy still concerns when and where the Tarim craton was amalgamated with northern Gondwana due to final closure of the North and South Altyn Oceans (two branches of the Proto-Tethys Ocean between southeastern Tarim and northern Gondwana).

Provenance tracing of sedimentary rocks based on detrital zircon U-Pb-Hf isotopes has been widely applied to constrain paleotectonic relationships among major tectonic units. This forms the justification of this study, which focused on systematic field-based zircon U-Pb dating and Hf isotopic analyses for early Paleozoic sedimentary rocks in the Altyn Tagh orogen, southeastern Tarim. New dating results reveal depositional ages from ca. 494 to 426 Ma. Provenance tracing indicates the ca. 494-477 Ma samples dominantly sourced from local Altyn Tagh to the south of the North Altyn Ocean, whereas an augmented supply of detritus from Tarim to the north of the North Altyn Ocean characterizes the ca. 465-449 Ma samples based on remarkable increase of ca. 840-780 Ma, 2.0-1.7 Ga, and 2.7-2.4 Ga detrital zircons. This change indicates a major provenance shift from a single to multiple source regions between ca. 477 and 465 Ma, marking the timing of final closure of the North Altyn Ocean. Zircon U-Pb-Hf isotopic data from the ca. 444-426 Ma samples resemble those from the ca. 465-449 Ma samples, suggesting local sediment recycling related to a post-collisional regime. Together with ophiolitic, (ultra)high-pressure metamorphic, and magmatic records in the region, final closure of the North Altyn Ocean can be constrained to occur in the Middle Ordovician, slightly later than final closure of the South Altyn Ocean during latest Cambrian-Early Ordovician time. Considering the other branches of the Proto-Tethys Ocean, we infer that the entire Proto-Tethys Ocean might have been progressively closed at ca. 500-420 Ma, leading to amalgamation of most East Asian blocks with northern Gondwana. Detrital zircon U-Pb-Hf isotopic comparison indicates that Tarim shares a closer affinity to North India than to other tectonic units located further to the east of Australia or west of Arabia-Iran along the northern margin of Gondwana. This work would be a significant contribution towards understanding configuration of Gondwana associated with evolution of the Proto-Tethys Ocean.

This study was financially supported by a National Natural Science Foundation of China Project (grant 41730213), a Grant-in-Aid for Scientific Research from Japan Society for the Promotion of Science (JSPS) to Dr. Qian Liu (No. 19F19020), and a Hong Kong Research Grants Council General Research Fund (grant 17307918). Native iron and serpentinization of peridotite, Oshika Village, Nagano Prefecture, Japan

*Yuya Takeda[1], Seiichiro Uehara[2]

1. Department of Earth and Planetary Science, Graduate School of Science, Kyushu University, 2. Department of Earth and Planetary Science, Faculty of Science, Kyushu University

Serpentinization is a reaction to form serpentine from peridotite and hot water, and Fe^{2+} becomes Fe^{3+} since magnetite is formed from Fe^{2+} in forsterite. At that time, hydrogen is generated, and a more reducing environment is formed iron, awaruite (Ni_2Fe-Ni_3Fe) (Frost, 1985).
Peridotite in Oshika Village, Shimoina-gun Nagano Prefecture is located mainly in Irisawai and Ogawara, and iron formed by serpentinization is reported for the first time in Japan (Okamoto et al., 1981; Sakai & Kuroda, 1983). Serpentine veins have three stages. Iron is found in veins composed chrysotile-2M_{c1} and brucite in the 2nd stage of serpentine veins. In this study, the peculiar serpentine vein was reexamined for the purpose of the elucidation of the formation of iron and awaruite.
Obtained samples were analysed by powder X-ray diffraction (XRD) to determine the constituent serpentine species.The selected samples were analyzed by optical microscope, scanning electron microscope (SEM) with energy dispersive spectrometer (EDS), electron microprobe analyzer (EPMA) and transmission electron microscope (TEM). Experimental devices was Ultima IV and Rint Rapid II (XRD), JSM-7001 (SEM), JMS-8530FF (EPMA). TEM observation was carried out at 300kV using JEM 3200FSK at the Ultramicroscopy Research Center at Kyushu university.
The peridotite is composed of forsterite and chromite, linear serpentine veins ranging from a few cm to 10 of μm in width. There were up to 4 directions of the vein. Serpentinization was made to be 4 stages from the anteroposterior relation of the vein by the observation by the slice. The vein of these 4 stages was made to be serpentine veins I, II, III, IV from the early one. The serpentine veins consisted lizardite, chrysotile-2M_{c1}, brucite, magnetite, iron, and awaruite. The serpentine veins are characterized in Table 1. Serpentine vein IV have elliptical and striated areas rich in brucite. Iron has irregular shapes, and some change to magnetite. Awaruite is a minute crystal, and it is unevenly distributed in the vein. The chemical compositions of serpentine and brucite in the veins were measured by SEM-EDS, and #Mg=Mg/ (Mg + Fe) was obtained. The serpentine of veins I and II was #Mg=0.94, that of veins III and IV was #Mg=0.96, and that of brucite was #Mg=0.66~0.79 0.77~0.86.
Iron is in serpentine veins III and IV, ranging in size from 1 μm to 100 μm, and contains up to 3.2% Ni and 3.1% Co. Iron of serpentine vein III was arranged in the position in which the long axis of the ellipse was perpendicular to the serpentine vein, and the iron of serpentine vein IV was irregularly shaped. Native iron was also found in the serpentine veins, which were not linear. Awaruite is found in all serpentine veins and most of them are in the range of 50 nm to several 100 nm, and many of them are automorphic crystal. Awaruite consists of $Ni_{0.79}Fe$ to $Ni_{2.55}Fe$ and is rich in iron.

Metamorphism and geochronology of garnet amphibolite from the Beishan Orogen, southern Central Asian Orogenic Belt: Constraints from P-T path and zircon U-Pb dating

*Wenbin Kang[1], Wei Li[1]

1. State Key Laboratory of Continental Dynamics, Department of Geology, Northwest University, Xi'an 710069, China

Numerous lenses of garnet amphibolite occur in the garnet-bearing biotite-plagioclase gneiss belt in the Baishan area of the Beishan Orogen, which connects the Tianshan Orogen to the west and the Mongolia-Xing'an ling Orogen to the east. The study of metamorphism in Beishan area is of great significance to explain the tectonic evolution of Beishan orogen. According to the microstructures, mineral relationships, and geothermobarometry, we identifed four stages of mineral assemblages from the garnet amphibolite sample: (1) a pre-peak stage, which is recorded by the cores of garnet together with core-inclusions of plagioclase (Pl_1); (2) a peak stage, which is recorded by the mantles of garnet together with mantle-inclusions of plagioclase (Pl_2) + amphibole (Amp_1) + Ilmenite (Ilm_1) + biotite (Bt_1), developed at temperature-pressure (P-T) conditions of 818.9–836.5 ˚C and 7.3–9.2 kbar; (3) a retrograde stage, which is recorded by garnet rims + plagioclase (Pl_3) + amphibole (Amp_2) + orthopyroxene (Opx_1) + biotite (Bt_2) + Ilmenite (Ilm_2), developed at P-T conditions of 796.1–836.9 ˚C and 5.6–7.5 kbar; (4) a symplectitic stage, which is recorded by plagioclase (Pl_4) + orthopyroxene (Opx_2) + amphibole (Amp_3) + biotite (Bt_3) symplectites, developed at P-T conditions of 732 ±59.6 ˚C and 6.1 ±0.6 kbar. Moreover, the U-Pb dating of the Beishan garnet amphibolite indicates an age of 301.9 ±4.7 Ma for the protolith and 281.4 ±8.5 Ma for the peak metamorphic age. Therefore, the mineral assemblage, P-T conditions, and zircon U-Pb ages of the Beishan garnet amphibolite defne a near-isothermal decompression of a clockwise P-T-t (Pressure-temperature-time) path, indicating the presence of over thickened continental crust in the Huaniushan arc until the Early Permian, then the southern Beishan area underwent a process of thinning of the continental crust.

Field evidence and mineral assemblage of eclogite from the Khungui zone, Zavkhan terrane, Western Mongolia

*Manzshir Bayarbold[1], Atsushi Okamoto[1], OTGONBAYAR DANDAR[1], Masaoki Uno[1], Noriyoshi Tsuchiya[1]

1. Graduate School of Environmental Studies, Tohoku University

Eclogite and blueschist complexes are the most important indicators of the tectonic evolution of the folded system such as the Central Asian Orogenic belt (CAOB), the largest orogenic belt in the world. One of the most important features of the CAOB is a widespread occurrence of high pressure (HP) and ultrahigh pressure (UHP) eclogites and blueschist facies rocks in many tectonic belts. The UHP-HP rocks related to the mostly ophiolite sequences, show the suture zone between Paleo Asian-ocean and small cratons. These suture zones are represented by Muya in eastern Siberia, Gorni Altai in southern Siberia, Northern Mongolia, Kokechetav in Central Kazakhstan, Chandman in western Mongolia. However, relationship between these occurrences is still unclear. In addition, only one occurrence of the HP rocks has been reported in Mongolia (Chandman). Therefore, in order to constrain tectonic evolution of Paleo Asian-ocean (PAO), it is important to study UHP-HP rocks in CAOB. In this study, we investigated occurrences and petrology of eclogite, and amphibolite in the Khungui zone, Zavkhan terrane, western Mongolia, and discuss its metamorphic evolution and significance in the CAOB.

Zavkhan terrane in western Mongolia represents a northwest segment of CAOB. Zavkhan terrane is a Proterozoic cratonic fragment and divided into three subzones, which are the Urgamal, Hutul and Khungui zones from west to east. Khungui zone is dominated by gneiss, quartzite, and amphibolite of Paleoproterozoic Buduun metamorphic formation, the basement of Zavkhan cratonal terrane.

We focus on 5 garnet amphibolites collected from Buduun formation of Khungui zone, Zavkhan terrane. Bulk composition of amphibolites shows on average 50.7 % SiO_2, 9.3% CaO, 2.5% Na_2O and 0.84% K_2O, trace-elements patterns are similar to those of N-MORB, except for the element of Th. All amphibolites shows schistosity and have garnet (Grt), amphibole (Amp), quartz (q), clinopyroxene (Cpx), rutile, epidote (epi), plagioclase (Pl), muscovite (mus). It is noted that omphacite occurs as Grt inclusions in the most of samples.

Grts occur as two types: euhedral grain and aggregate. Compositionally, garnets can be divided into three types: garnet 1 (Grt1), garnet 2 (Grt2), and transitional garnet (TGrt). Grt1 is observed as cluster (400 μm) of garnet grains but its composition shows one garnet grain. Grt1 contains few inclusions (omphacite and q) and has composition zoning from core ($Alm_{60.8}Grs_{28.2}Prp_{9.6}Sps_{1.4}$) to rim ($Alm_{57.53}Grs_{32.75}Prp_{8.89}Sps_{0.82}$). Omphacite is observed in rim of Grt1. Grt2 (190 μm) contains numerous inclusions (core: q, amphibole, epi, and rarely mus, and rim: omphacite) and has composition zoning from core ($Alm_{51.3}Grs_{34.17}Sps_{8.62}$, $Prp_{5.84}$) to rim ($Alm_{57.0}Grs_{35.91}Prp_{5.69}Sps_{1.32}$). TGrt1 (40-210 μm) has very rare inclusions (q and rarely amp) and homogenous composition ($Alm_{59.26}Grs_{32.07}Prp_{7.43}Sps_{1.22}$). Cpx (omphacite) occurs in matrix (Xjd=0.32-0.38) and as inclusion (Xjd=0.34-0.44) of Grt rim (Grt1 and Grt 2). Cpx is replaced by Pl, amp, and q forming symplectite. Calcic to sub calcic amp occur in matrix and as inclusions of garnets. In matrix, amp has compositional zoning from barroisite at core to hornblende at rim whereas amp in grt has hornblendic composition.

The Grt amphibolites from Buduun formation, Khungui zone, Zavkhan terrane were suffered from eclogite

©2020. Japan Geoscience Union. All Right Reserved.

facies metamorphism. Based on minerology and mineral chemistry, 3 metamorphic stages can be determined: pre-Peak (M1), Peak (M2), and retrograde (M3). M1 is marked by inclusions (Amp (calcium), Epi, Mus, and q) in Grt2 core. M2 is represented by omphacite (in Grt1 and Grt2 rims) and composition of Grt1 (402-466 ˚C) and Grt2 (411-525 ˚C) rims. M3 (retrograde) is traced by transformation of omphacite into amp-Pl-q symplectite and hornblende. The new point of eclogite facies rocks is important to reconstruct tectonic evolution of PAO, especially from the Chandman area to northern Mongolia.

Eclogite-to-granulite transition in the Ufipa Complex (Tanzania): Pressure—Temperature—time paths of a Pan-African continental collision zone

*Morita Isamu[1], Tatsuki Tsujimori[1], Nelson Boniface[2], Kennet E Flores[3], Shogo Aoki[4], Kazumasa Aoki[4]

1. Tohoku University, 2. University of Dar es Salaam, 3. Brooklyn College of the City University of New York, 4. Okayama University of Science

Eclogites and eclogite-facies rocks in most high pressure–ultrahigh pressure (H*P*–UH*P*) metamorphic complexes have generally experienced retrograde metamorphism. In collision zones, deeply subducted continental crust rocks undergo recrystallization/overprinting throughout exhumation. During crustal stabilization of H*P*–UH*P* rocks after a collisional event, granulite- and/or upper amphibolite-facies often obliterates the records of prograde and/or metamorphic peak. Pressure-temperature-time paths often expressed these metamorphic histories in several complex such as the Western Gneiss Region, Eastern Himalaya, and North Qinling. We conducted petrological and geochronological research for partially granulitized eclogite and associated metamorphic rocks of the Neoproterozoic Ufipa Complex (Southwestern Tanzania). We distinguished at least three metamorphic stages, an eclogite stage (M1), a granulite stage (M2), and a retrograde amphibolite stage (M3). Mineral assemblages and geothermobarometry revealed *P*–*T* conditions of 2.4–2.6 GPa and 920–960℃ for the M1 eclogite stage, and 1.3–1.6 GPa and 900–940℃ for the M2 granulite stage. *In-situ* zircon LA-ICP-QMS U–Pb dating and REE geochemistry combined with inclusion mineralogy on polished thin-section yielded an eclogite-facies stage at 588 ±3 Ma. H*P* granulite-facies recrystallization zircons yielded 562 ±3 Ma. These new data suggest a time interval Δt between eclogite facies peak and retrograde H*P* granulite-facies recrystallization of ~26 Mry. Based on these estimations, a clockwise *P*–*T* path was constructed and exhumation rate was yields ~1.0–1.6 km/Mry. This data is consistent with the results of one-dimensional numerical modelling for double thickened crust that assumes that the *P*–*T* path was attributed to tectonic thermal perturbation and relaxation. This model also suggest a clockwise *P*–*T*–*t* path, followed by strong isothermal decompression, which similar to the thermobarometric calculations on the Ufipa eclogites. This model also support high exhumation rate of ~1.0-1.6 km/Mry.

Geochemistry, Pressure-Temperature conditions and tectonic setting of the amphibolite from the southern part of Motloutse Complex, eastern Botswana

*Thembiso Otladisang Basupi[1], Toshiaki Tsunogae

1. Graduate of Life and Environmental Sciences, University of Tsukuba

Amphibolites constitute prominent rock types in Archean high-grade terranes in eastern Botswana and these include the Motloutse and Phikwe Complex terranes (Aldiss, 1991; Carney et al., 1994). Phikwe Complex is considered part of the larger Limpopo Complex high-grade terrane between the Archean Kaapvaal and Zimbabwe cratons. Available studies indicate polymetamorphic amphibolite- to granulite-facies conditions from metasedimentary rocks of the Phikwe Complex (McCourt et al., 2004). Unlike the Phikwe Complex, no granulite-facies conditions or polymetamorphism has been reported so far from the Motloutse Complex, which occurs to the SW of the Zimbabwe Craton (Smith and Phofuetsile, 1985; Aldiss, 1991). In spite of this, there has been no study in modern literature on the amphibolite rocks belonging to Motloutse complex. This study is to focus on the geochemistry, pressure-temperature (*P-T)* condition and tectonic setting of mafic rocks (amphibolites) of the Motloutse Complex and amphibolites from Phikwe Complex are introduced for comparison.
The field survey conducted indicated amphibolites occupying prominent hills in the respective areas surrounded by granitoids. Available geochronological data indicate that the granitoids in both areas are Neoarchean (ca 2.65 Ga). Therefore, the mafic rocks must be older than ca 2.65 Ga. Overprint events (e.g., partial melting) were observed in amphibolites.
The field description shows that the amphibolites are made up of plagioclase, hornblende, biotite and quartz. Petrographic images of the amphibolites shows slight alteration of plagioclase to sericite and triple junction texture of the hornblende-plagioclase (plagioclase as an indication of deformation). Alignment of minerals is a common feature. Hornblende + plagioclase + quartz + sericite + ilmenite + magnetite dominates the composition.
Metamorphic temperature estimates for amphibolites from Maope area using hornblende-plagioclase geothermometry of Holland and Blundy (1994) ranges from 650 to 780 ˚C. The geothermobarometry *P-T* condition estimates using the hornblende-plagioclase of Schmidt (1992) and Anderson and Smith (1995) recorded 572 to 670˚C at 3.5 to 7 kbar and 450 to 670˚C at 3.7 to 7.3 kbar. These results estimate bracket the Maope amphibolites on the upper amphibolite to lower granulite facies metamorphic condition.
Whole-rock geochemical analysis indicates that the amphibolites are characterised by high SiO_2 (45.40–54.82 wt.%) and MgO (4.40–10.25 wt.%) contents, some are comparable with boninites. The TAS plot characterise the amphibolites of Maope area and Phikwe area as basaltic to basaltic andesite composition. The primitive mantle elements normalised and chondrite-normalised REE pattern indicate that they are likely to have been derived from the same parental magma. The positive Pb, Sr, and Eu anomalies reflect plagioclase accumulation on the magma during fractionation. The tectonic setting plots show volcanic arc basalts in an oceanic arc environment. The results also show hydrated magma of tholeiitic composition due to subduction that lead to boninites like mafic rocks. We therefore suggest that the protolith of the Maope amphibolites formed by subduction as boninites like mafic rocks in an oceanic arc environment. Based on field evidence and results of geothermobarometry, we suggest that the amphibolites were later exposed to peak metamorphism due to partial melting that is believed to have been the only Paleoprotezoic (2.06 Ga) overprint in Motloutse Complex (Zeh eta al., 2009). Crystal Preferred Orientation Development of Secondary Olivine Formed by Hydration of Orthopyroxene: Implication to Anisotropy of Shallow Mantle Wedge during Initiation Stage of Subduction

*OTGONBAYAR DANDAR[1], Atsushi Okamoto[1], Takayoshi Nagaya[2], Masaoki Uno[1], Noriyoshi Tsuchiya[1]

Crystal preferred orientation (CPO) of olivine (Ol) provides significant effects on physical properties of the upper mantle, and the comparison of the Ol CPO analyses and observations of seismic anisotropy make it possible to simulate the flow pattern of upper mantle. The CPO analyses on naturally or experimentally deformed Ol samples have shown the relationship between deformation conditions (stress, temperature and H_2O content) and CPO patterns produced by the plastic deformation [e.g. 1]. In contrast, some studies have suggested specific topotactic relationships between Ol and serpentine minerals [e.g. 2, 3]. Therefore, the metamorphic reactions provide crucial controls on the physical properties of mantle. However, our understanding on their effects for mantle wedge anisotropy is still limited. In this study, we show the characteristic features of CPO of secondary olivine (S-Ol) formed after orthopyroxene (Opx) in metaharzburgite from the Naran massif, the Khantaishir ophiolite, western Mongolia and discuss seismic anisotropy of S-Ol-bearing mantle wedge during initiation stage of subduction.
